EDITORIAL ADVISORY BOARD

FOREWORD

This is a most timely publication because of the vast amount of new information on forest sciences that has been produced over the last few years and because of the growing realization of the vital importance of forests to the world. Fortunately for our future, the world is beginning to realize that forests are both vital for our survival and that they offer many benefits. These benefits vary from the more obvious ones such as timber and fibers for paper pulp, to the environmental aspects such as the sequestration of carbon, the protection of watersheds and the prevention of flooding in many areas. Also there is a growing emphasis on the production of non-timber forest products because of their role in sustainable management of forests.

Since forests are so crucial to our future their sustainable management is essential and this requires a great amount of expertise and information. As I look at the list of the authors and the advisory board of this Encyclopedia, it reads like a who's who of forest science. These experts have put together a collection of information and up-to-date contributions that will be an invaluable resource for anyone involved with forests in any way. I am sure that students at all levels, their teachers and lecturers, professional researchers, policy makers, and even the interested layman or amateur forester will find these volumes of great use.

As I look through the coverage I find it most comprehensive and contemporary. It includes such important modern topics as the molecular biology of forest trees, the role of forests in the carbon cycle, computer modeling and the use of recently developed methods such as geographic information systems. More traditional aspects such as forest biology and ecology, the processing of forest resources into a wide range of products, forestry management and practice and the economic and social aspects of forestry are brought up-to-date here. Not only are the contributions themselves useful, but they also direct the serious investigator to more in-depth or advanced material on each topic. It is also most useful that this fine work will be available in an electronic version that will facilitate cross-referencing to related topics and references.

I know that I will find these volumes most useful and frequently used and I am sure that they will be a standard reference work on forest sciences for at least the next decade. How timely at a period of human history when there is a desperate need to stop deforestation, re-forest many destroyed areas and develop better methods for sustainable use of forests and to conserve the many species of plants and animals which they hold.

Prof. Sir Ghillean Prance FRS
School of Plant Sciences, University of Reading,
Reading, UK

INTRODUCTION

At the start of the Third Millennium the levels of public and political attention to forests, their benefits to mankind, and their management are at their highest. National and international institutions, governmental and non-governmental organizations, all forms of media and representatives of civil society are searching for socially equitable methods of managing forests to obtain all their multiple benefits. Underlying this search is the need for precise and relevant information about the forests, their uses and management together with the political and social institutions that can best effect sustainable management.

Our audience for this reference work includes libraries, governmental and non-governmental organizations, universities and individuals involved in research on forests, forest products and services, and relevant topics, local, national and international decision-making authorities and administrations, forest land-owners and other forest-dependent individuals.

The ranges of biophysical and socio-economic aspects of forests, forestry, forest products and forest services are extremely large; correspondingly, past and current research cover large numbers of scientific disciplines and policy issues. Systematic research has been undertaken for over a century in some forest sciences such as silviculture and forest management; in other topics newly emerging techniques, such as those of molecular genetics, are being developed to aid understanding of physiological and environmental characteristics of trees and forests or to assist selective breeding of trees for plantations. An Encyclopedia of Forest Science therefore has to encompass a broad spectrum of pure and applied sciences, ancient and modern technologies, and old and recent knowledge.

In this Encyclopedia we have obtained outstanding contributions of some 200 specialists covering 250 topics that have wide implications for forest conservation, management and use worldwide. Of course, it is not possible to cover every possible subject of relevance to forests but the ones selected are generally of global interest; and even if they are of local, national or regional character, they are important to all those concerned with forest management, research, education, training, policy-making or public information.

Because of the great breadth of expected readership we have asked a wide range of contributing experts to produce up to approximately 4000 words summarizing current views of their topic. The contributions are not written in the traditional form of a scientific journal article with detailed bibliographic references for all major statements. Rather each is a continuous, highly readable description based on an author's personal view of the state of knowledge in her/his area of expertise. Selected major references are given at the end of each contribution to facilitate and encourage further reading on the subject. Wherever possible photographs, other graphical illustrations and tables are used to make the material more concise and visualized. Cross-referencing between contributions and the provision of dummy entries in the table of contents facilitate a full coverage of material relevant to each topic.

Some contributions are short because it proved difficult to identify an author with the appropriate experience and willingness to write full articles. However, these may be enlarged in future editions of the Encyclopedia and in the web-based version of it. The availability of modern information technology facilitates not only the preparation of such a work but also the maintenance of its timeliness, the spreading of its availability and the ease of searching and downloading selected material.

As Editors we thank the authors for their contributions, the editorial advisors for their specialist support, and the staff of Elsevier for their prompt and effective actions that have allowed the four volumes of the Encyclopedia to be published within two years of the initial commissioning of this reference work. We hope that the Encyclopedia will prove to be a valuable tool and source of information for many years to come. In particular we hope it will encourage a growing public and a dedicated profession to understand the facts and institutions necessary for wise management, use and conservation of the world's forest resources for the equitable benefit of all mankind.

GUIDE TO USE OF THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the Encyclopedia is arranged as a series of entries in alphabetical order. Most entries consist of several articles that deal with various aspects of a topic and are arranged in a logical sequence within an entry. Some entries comprise a single article.

To help you realize the full potential of the material in the Encyclopedia we have provided three features to help you find the topic of your choice: a Contents List, Cross-References and an Index.

1. Contents List

Your first point of reference will probably be the contents list. The complete contents list will provide you with both the volume number and the page number of the entry. On the opening page of an entry a contents list is provided so that the full details of the articles within the entry are immediately available.

Alternatively you may choose to browse through a volume using the alphabetical order of the entries as your guide. To assist you in identifying your location within the Encyclopedia a running headline indicates the current entry and the current article within that entry.

You will find 'dummy entries' where obvious synonyms exist for entries or where we have grouped together related topics. Dummy entries appear in both the contents list and the body of the text.

Example
If you were attempting to locate material on yield tables and forecasting via the contents list:

YIELD TABLES *see* MENSURATION: Forest Measurements; Growth and Yield; Timber and Tree Measurements; Yield Tables, Forecasting, Modeling and Simulation.

The dummy entry directs you to the Yield Tables, Forecasting and Simulation article, in the MENSURATION entry. At the appropriate location in the contents list, the page numbers for articles under Mensuration are given.

If you were trying to locate the material by browsing through the text and you looked up Yield Tables then the following information would be provided in the dummy entry:

Yield Tables *see* **Mensuration**: Forest Measurements; Growth and Yield; Timber and Tree Measurements; Yield Tables, Forecasting, Modeling and Simulation.

Alternatively, if you were looking up Mensuration the following information could be provided:

MENSURATION

Contents

Forest Measurements
Timber and Tree Measurements
Growth and Yield
Yield Tables, Forecasting, Modeling and Simulation
Tree-Ring Analysis

2. Cross-References

All of the articles in the Encyclopedia have been extensively cross-referenced.

The cross-references, which appear at the end of an article, serve three different functions. For example, at the end of the PATHOLOGY/Diseases of Forest Trees article, cross-references are used:

i. To indicate if a topic is discussed in greater detail elsewhere.

> PATHOLOGY/Diseases of Forest Trees.
> *See also*: **Ecology**: Plant–Animal Interactions in Forest Ecosystems. **Pathology**: Diseases Affecting Exotic Plantation Species; Heart Rot and Wood Decay; Insect Associated Tree Diseases; Leaf and Needle Diseases; *Phytophthora* Root Rot of Forest Trees; Pine Wilt and the Pine Wood Nematode; Root and Butt Rot Diseases; Rust Diseases; Stem Canker Diseases; Vascular Wilt Diseases. **Soil Biology and Tree Growth**: Soil and its Relationship to Forest Productivity and Health. **Tree Breeding, Practices**: Breeding for Disease and Insect Resistance.

ii. To draw the reader's attention to parallel discussions in other articles.

> PATHOLOGY/Diseases of Forest Trees.
> *See also*: **Ecology**: Plant–Animal Interactions in Forest Ecosystems. **Pathology**: Diseases Affecting Exotic Plantation Species; Heart Rot and Wood Decay; Insect Associated Tree Diseases; Leaf and Needle Diseases; *Phytophthora* Root Rot of Forest Trees; Pine Wilt and the Pine Wood Nematode; Root and Butt Rot Diseases; Rust Diseases; Stem Canker Diseases; Vascular Wilt Diseases. **Soil Biology and Tree Growth**: Soil and its Relationship to Forest Productivity and Health. **Tree Breeding, Practices**: Breeding for Disease and Insect Resistance.

iii. To indicate material that broadens the discussion.

> PATHOLOGY/Diseases of Forest Trees.
> *See also*: **Ecology**: Plant–Animal Interactions in Forest Ecosystems. **Pathology**: Diseases Affecting Exotic Plantation Species; Heart Rot and Wood Decay; Insect Associated Tree Diseases; Leaf and Needle Diseases; *Phytophthora* Root Rot of Forest Trees; Pine Wilt and the Pine Wood Nematode; Root and Butt Rot Diseases; Rust Diseases; Stem Canker Diseases; Vascular Wilt Diseases. **Soil Biology and Tree Growth**: Soil and its Relationship to Forest Productivity and Health. **Tree Breeding, Practices**: Breeding for Disease and Insect Resistance.

3. Index

The index will provide you with the page number where the material is located, and the index entries differentiate between material that is a whole article, is part of an article or is data presented in a figure or table. Detailed notes are provided on the opening page of the index.

4. Glossary

A glossary of terms used within the Encyclopedia appears in Volume 4, before the index. This is organised alphabetically and features explanations of many of the specialist terms used throughout this publication.

5. Contributors

A full list of contributors appears at the begining of each volume.

Introduction

Species choice is not a new problem. In 1665 John Evelyn wrote in his book *Sylva*:

> First it will be requisite to agree upon the species: as what species are likely to be of greatest use, and the fittest to be cultivated and then to consider how planting may be best effected.

When the Food and Agriculture Organization produced a book on *Choice of Tree Species* in 1958, the importance of first identifying the purpose of tree planting was still recognized. Over 130 pages of the book deal with ecological principles to assist selecting trees for use in different parts of the world. This includes descriptions of various climate, soil, and vegetation classifications. These systems are now mainly of historical interest. But before the widespread availability of computers, information on environmental conditions was often represented as classes, and areas suitable for particular species were frequently shown as zones on maps.

In terms of introducing exotic species, the work of Golfari was some of the most practically important. Golfari and his colleagues produced maps dividing Brazil into 26 regions on the basis of altitude, vegetation types, mean annual temperature, rainfall and its distribution, water deficit, and frost occurrence. They indicated species, mainly eucalypts and pines, suitable for particular regions.

Information of this sort is developed on the basis of knowledge of conditions within a species natural distribution, as well as its success or failure when evaluated in trials outside its natural distribution. For example, two volumes written by Poynton, published in 1979, describe the introduction of eucalypts and pines to southern Africa. These books provide some of the most detailed descriptions of tree species trials ever prepared. The volume on eucalypts includes information on the introduction of 134 species. Details of natural occurrence, characteristics and uses, silviculture, utilization, and potential are presented for each species and results from trials are summarized. Details for specific trial sites are also tabulated for each species. Information is provided on country, plantation name and plot number, silvicultural zone, altitude, annual rainfall, aspect, soil depth and texture, age, stocking, mean diameter at breast height (dbh), mean height, mean volume, and mean annual increment as well as general comments on health and form. Information on the latitude, longitude, and elevation of 271 sites is provided in an appendix along with mean maximum temperature of the warmest month, mean minimum temperature of the coldest month, and mean annual rainfall of each site where available. Another appendix includes recommendations for species suitable for particular climatic zones and a map is included showing these zones.

A Guide to Species Selection for Tropical and Sub-Tropical Plantations, produced at the Commonwealth Forestry Institute in 1980, marked a significant step away from the use of classifications and maps, and towards the use of computer-based methods. The characteristics of 125 species were described in terms of 40 factors grouped within headings, including taxonomy, natural occurrence, climate, soils, silviculture, production, protection planting, timber, utilization, nursery, principal pests and diseases, and principal references. For those users with access to a computer a program was provided to search these data. But as personal computers were not widely available in 1980, instructions were also provided on how to use punched cards to sort through the data manually and select suitable species for particular uses and environments.

Unlike the books prepared by Poynton, the *Guide to Species Selection* only provided summary information for particular species and not site-specific results. In the late 1980s the Commonwealth Scientific and Industrial Research Organization (CSIRO) Division of Forestry and Forest Products developed a computerized tree crop database called TREDAT. This was designed for the storage and selective retrieval of results from trials. It currently contains information for 411 species, mainly of Australian origin, and for 303 sites, mainly in Australia. It includes information on a total of 90 factors relating to site characteristics, management history, tree performance, botanical identity, and project description. Though this information is useful for assisting species selection, the system contains only raw data for specific sites. It does not contain summary information on the characteristics and requirements of particular species.

Over the years many articles and books have been written to assist species selection for particular countries or regions. These usually contain summary information on factors such as uses, natural occurrence, plantations outside the natural distribution, and environmental requirements. Sometimes these descriptions are complemented by tabular information, which makes it easier to check the uses and environmental requirements of many species quickly. As personal computers became more widely available several programs were developed that enabled tabular data to be searched more efficiently. When selecting tree species for a particular site it is well worth checking to see if a relevant article, book, or computer program exists to assist species choice in a particular region of interest.

Previous reviews have identified some key questions to consider when selecting species for planting. These are:

- What are the environmental characteristics of the site?
- What product or service is the tree species to provide?
- Which species will grow on the sites available?

Site Characterization

It is usually desirable to collate some basic information on site conditions before considering which species are suitable for planting. The location of sample sites can be accurately recorded using global positioning systems (GPS). The location of sites may also be recorded in terms of slope, aspect, and position in the landscape (e.g., hilltop, midslope, or valley bottom).

Minimum climatic information includes mean monthly values for maximum temperature, minimum temperature, and precipitation. Key factors such as mean annual temperature, mean maximum temperature of the hottest month, mean minimum temperature of the coldest month, rainfall seasonality, and dry-season length can be simply calculated from these monthly values. In frost-prone areas, information on absolute (i.e., record) minimum temperature is also useful. Monthly mean temperature and rainfall data are generally readily available from standard sources, such as summaries published by national meteorological agencies and the Food and Agriculture Organization or from the web. In some cases interpolation relationships may be available that allow more reliable estimates to be made for sites which are some distance from meteorological stations. Monthly mean values for solar radiation and evaporation may also be useful to run models that can estimate potential growth rates. However, they are not generally required for species selection.

Samples for assessing soil conditions can be obtained by using soil augers or digging pits. If large areas are to be sampled, mechanical drilling equipment or backhoes can speed up the sampling process. For species selection purposes only simple information on soil texture as well as reaction (pH) and drainage are usually required. More detailed physical and chemical information may be taken to estimate potential productivity. For example, measurements of soil depth as well as texture allow water-holding capacity to be estimated. Samples for chemical analysis are often taken from the topsoil layer (i.e., *A* horizon) and at a lower depth. Analyses may be carried out for major nutrients, such as nitrogen, phosphorus, and potassium, as well as for exchangeable cations of minor nutrients. If appropriate, other analyses such as soil salinity may also be required.

Information on natural vegetation was widely used to assist species selection in the past. Both overstory and understory species respond to the climatic and soil conditions of the site and can provide an indication of its potential for other species. However, as potential sites for plantations have often been previously disturbed, the value of natural vegetation as an indicator of site potential has declined.

The CAB International Forestry Compendium

Having collected information on site conditions, the questions of which species are suitable for particular uses and which species will grow on particular sites can be considered.

The Forestry Compendium developed by CAB International (CABI) is probably the most impressive tool that has been developed to assist tree species choice. The Forestry Compendium aims to provide global coverage and was prepared using contributions from hundreds of experts around the world. It includes a taxonomic database for 22 000 species, with detailed descriptions for 1200 species. The first CD-ROM version of the global module was released in 2000 and a revised version was issued in 2003. It is planned to release improved CD-ROM versions every 2–3 years and a version including the latest amendments can also be accessed via the internet (www.cabicompendium.org/fc).

A particular advantage of the CABI system over other tree selection systems is that it allows access to the research literature by providing over 50 000 references with abstracts. For example, the reference browser in the 2003 CD-ROM version provides access to abstracts of 67 references mentioning species choice and 128 references referring to species selection.

Though the Forestry Compendium has many potential applications, tree species selection is one of its main purposes and it includes a detailed species selection module, which can be entered from the main menu. The user can select from scores of options listed under four main headings: uses, distribution, environment, and silviculture.

Uses

Determining the ultimate use of trees is a vitally important step in species selection. Modern forest processing facilities generally require raw materials of consistent quality. So, if the aim is to grow trees to supply an existing processing plant then the species selection process may be easy. The existing plantations or forests supplying a particular facility may already indicate the only acceptable species.

However, if opportunities to use different species are more open, the Forestry Compendium can assist selection within three main usage categories: land/environment, wood, and nonwood, that together include a total of more than 110 subcategories (**Figure 1**).

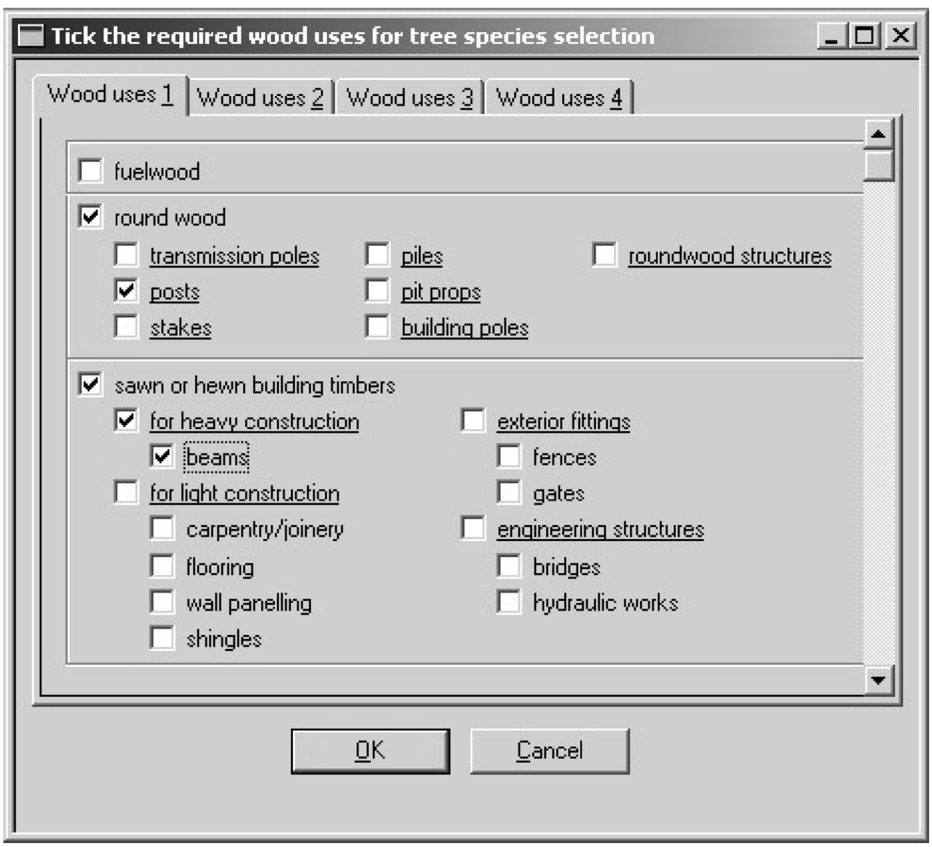

Figure 1 CABI *Forestry Compendium* – wood uses, menu 1 of 4. Reproduced with permission from CAB International (2003) *Forestry Compendium.* CAB International, Wallingford, UK. Available as CD-ROM or online at: www.cabicompendium.org/fc.

Distribution

The Forestry Compendium's Tree Species Selection Module provides the option to select a species on the basis of its country or region, or on latitudinal limits. It is possible to select species that are native or have been introduced to more than 650 countries or regions.

Environment

Altitude, rainfall, temperature, and soil properties are the main environmental categories used in the Tree Species Selection Module to determine which species can grow on particular sites. Altitude, rainfall, and temperature data can be entered as single numbers or ranges.

Soil properties can be selected under four main headings. Soil texture includes light (sands and sandy loams), medium (loams and sandy clay loams), and heavy (clays, clay loams, and sandy clays) options. Soil drainage includes free, impeded, and seasonally waterlogged. Soil reaction includes very acid (pH <4.0), acid (pH 4.0–6.0), neutral (pH 6.1–7.4), and alkaline (pH >7.4). Special soil tolerances include shallow, saline, sodic, and infertile.

Silviculture

Various silvicultural characteristics can be selected within the Tree Species Selection Module. For example, an ability to tolerate any or all of nine factors, including drought and termites, can be selected. Similarly, ability to coppice or fix nitrogen can be selected from six silvicultural characteristics. Options are also provided to select from three categories of seed storage, five categories of vegetative propagation, and five methods of stand establishment.

Species Selection

The user can select a wide variety of options within the four main headings of uses, distribution, environment, and silviculture. The database can then be searched for species that satisfy any or all of these characteristics. **Figure 2** shows the results of a simple search carried out using the Forestry Compendium.

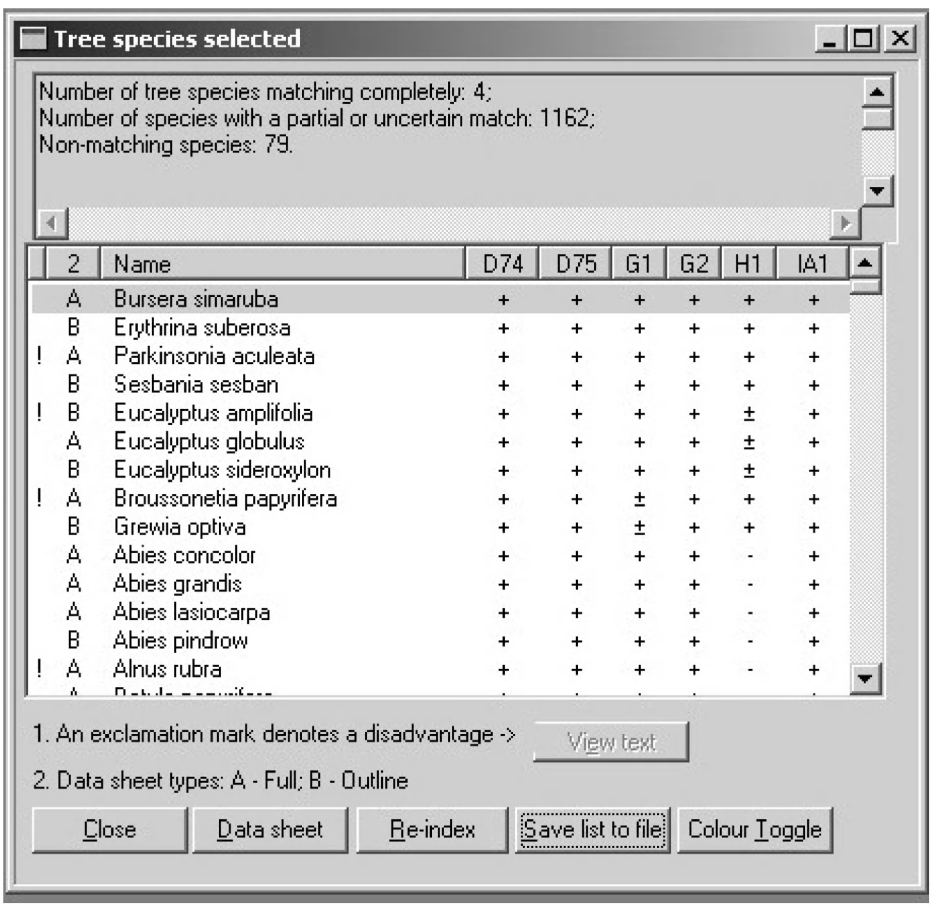

Figure 2 CABI *Forestry Compendium* – tree species selection output. Reproduced with permission from CAB International (2003) *Forestry Compendium*. CAB International, Wallingford, UK. Available as CD-ROM or online at: www.cabicompendium.org/fc.

The features requested were D74 wood pulp, D75 short fiber pulp, G1 mean annual rainfall 500–750 mm, G2 winter rainfall seasonality, H1 mean annual temperature 20–25°C, and IA1 light-texture soil (sands, sandy loams). The output indicates the number of species that completely satisfy the requirements, those that provide a partial match, and those that fail on all counts. Individual species are listed with those that satisfy most criteria at the top of the list.

Exclamation marks in the first column indicate potential problems, such as possible risk as weed species. There is increasing concern about species that can become established outside the areas where they are intended to grow. Particular care should be taken when introducing potentially invasive species, such as *Prosopis juliflora* and *Acacia* spp., into areas where they have not previously been grown.

The second column indicates if full (A) or outline (B) data sheets are available. Full data sheets include sections on name, importance, botanical features, geographic distribution, environmental amplitude, silviculture and management, protection, variation and breeding, uses, disadvantages, and references. The columns following the species name indicate whether it has fully satisfied (+), partially satisfied (+/−), or failed to satisfy (−) the particular criterion.

Checking the data sheets will indicate that some of the species shown in **Figure 2**, such as *Bursera simaruba* and *Erythrina suberosa*, have little current commercial use. Others, such as *Eucalyptus globulus*, have been successful in many countries. Information like this can help select species worth including in trials. However, if it is available, the most useful information may come from practical experience in local and nearby regions.

Pests and Diseases

The Forestry Compendium provides information on insect pests, diseases, and parasitic plants which may cause problems for particular trees within each species description. For example, *Lophodermium pinastri* causes needle cast problems for *Pinus sylvestris* (Scots pine) in nurseries and in young (2–5-year-old) high-density plantations. Highlighting the name of the disease and selecting a 'soft link' button brings information about the disease onto the screen. This often includes maps showing the countries where it has been observed. Where available, control methods for important pests and diseases are described within each tree species description.

Matching Species and Sites

The CABI *Forestry Compendium* can be very helpful in assisting the process of species choice, but there are other useful tools and critical considerations. For example, it may be important to know in more detail where a particular species will grow, how well it will grow, and whether there are any economic, social, or environmental problems with its use.

Climatic Mapping

Climatic factors are important in determining where particular species will grow. Great advances have been made since the mid-1980s in developing interpolation methods to assist estimating mean climatic conditions for any location around the world.

For example, CSIRO's Division of Forestry and Forest Products has used an interpolated climatic database prepared at the University of East Anglia's Climatic Research Unit to develop a world climatic mapping program. This can take in any of the 1200 descriptions of species climatic requirements included in the Forestry Compendium and map which of 67 477 locations in a half-degree grid satisfies the description. For example, **Figure 3** shows climatically suitable areas for *Tectona grandis* (teak) with the description of climatic requirements being used shown below the map.

Climatic mapping programs are very helpful in checking and improving descriptions of species climatic requirements. For example, the description shown in **Figure 3** should probably be slightly modified to include some wetter and warmer areas in India. It is very difficult to appreciate the implications of a written description of climatic requirements, but a map makes these immediately apparent.

Descriptions of species climatic profiles can be developed from analyses of their natural distributions as well as their performance in trials outside their natural distribution. Ideally, geocoded data (i.e., latitude, longitude, and elevation) are collated for both the natural distribution and successful trials and interpolation relationships are used to estimate mean climatic conditions for each location.

In addition to the world climatic mapping program, CSIRO has developed more detailed climatic mapping programs for a wide range of regions, including Africa, mainland South-East Asia, and Latin America, as well as for individual countries, including Australia, Cambodia, China, Indonesia, Laos, Thailand, Philippines, Vietnam, and Zimbabwe.

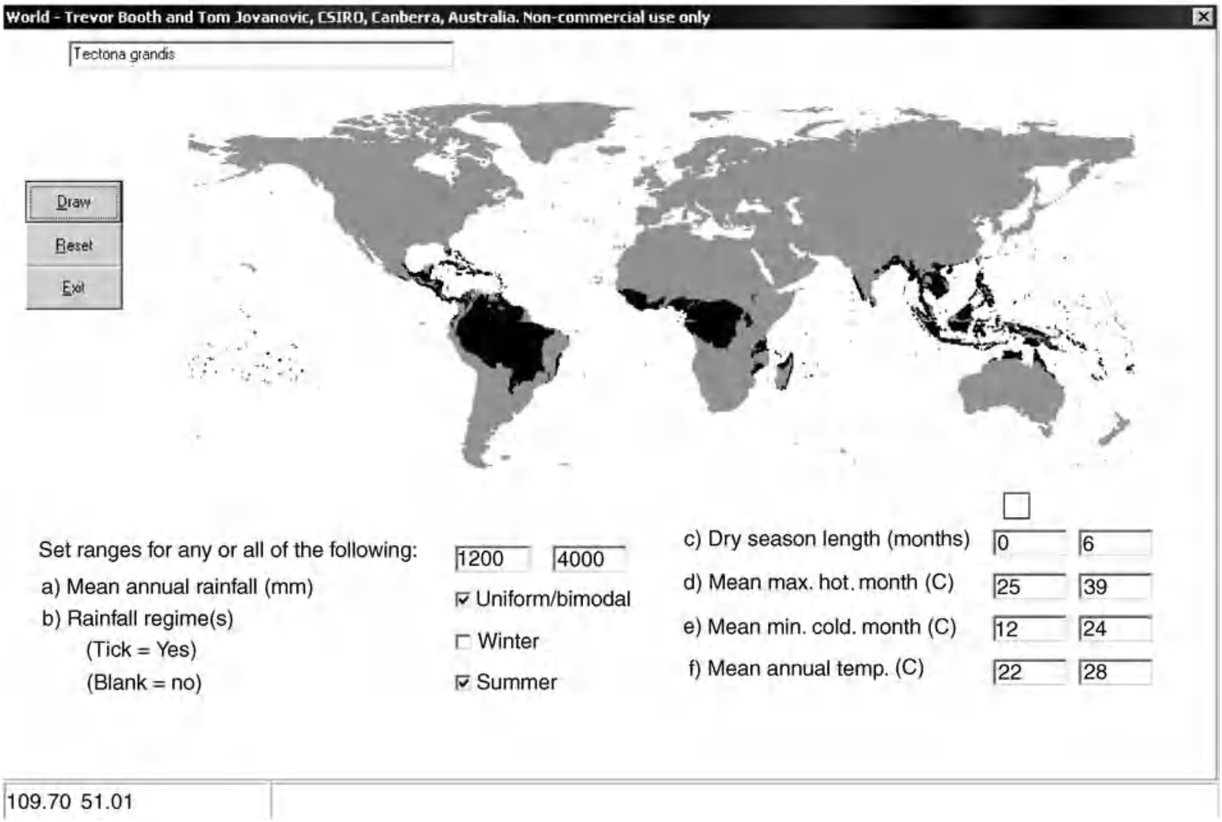

Figure 3 World climatic mapping program – black areas are climatically suitable for *Tectona grandis* according to description in CAB International (2003) *Forestry Compendium*. Wallingford, UK: CAB International. Available as CD-ROM or online at: www.cabicompendium.org/fc.

Tree Growth Models

When choosing species for planting it is useful to know not only where a particular species will grow, but also how well it is likely to grow at selected locations. Considerable progress has been made in recent years in developing simple tree growth models, such as 3-PG and ProMod. These take in simple information on climatic and soil conditions and predict likely growth rates for particular species. Models of this sort can be used to estimate potential productivity at individual sites or run for many hundreds or thousands of gridded sites to produce an indication of potential productivity across broad regions.

Economic, Social, and Environmental Suitability

In addition to local testing a consideration of the social and environmental implications of introductions should also be part of the tree selection process. This is particularly important if the species is an exotic. In the past, economic considerations have tended to dominate the choice of tree species. Economic considerations remain important, but social and environmental issues should also be assessed.

Social issues should involve a consideration of the likely impacts of tree species introductions into a particular region. Many social issues, such as the replacement of agricultural land by forestry plantations, may not be related to species choice, but visual impact is an example where species selection may be important.

Environmental issues include questions such as the decision whether to use native or exotic species. Biodiversity is an important environmental issue and use of native species may be preferred for this reason. However, use of highly productive plantations of exotic species may allow larger areas of native forest to be used as nature conservation reserves.

Water use is emerging as a major issue in many countries, so the efficiency with which different species use water may need consideration.

Opportunities for Future Developments

In the past the emphasis on tree selection has been at the species level. Some information about important hybrids and provenances is provided in the Forestry Compendium, but generally existing tree species selection systems provide little or no information at the provenance or clonal levels. In the future more information will be included in selection systems about requirements of particular genotypes, including provenances, hybrids, clones, and genetically modified material. For the present, field trials are essential before embarking on any large-scale afforestation program. Improved genetic material developed for another region may not necessarily perform any better than the best natural provenances when introduced into a different environment.

Improved genotype–site matching will require more detailed information on both tree growth and site conditions. Comparing the results of trials in many different countries and areas would be assisted by the development of an internationally agreed minimum dataset for evaluating tree growth and environmental conditions at trial sites. This dataset will need to include information about soil physical and chemical status to assist predictions of potential productivity and sustainability. If an agreed minimum dataset could be established it would be logical to develop an international database, similar to TREDAT, which contains information on observations from individual sites, as well as summary data of the type in the Forestry Compendium database. It would also be desirable to collect minimum dataset information on growth and environment for sample locations within existing plantations, so that production level performance could be more reliably compared with results from small-scale trials.

Improvements in remote sensing will allow more reliable growth predictions to be made for different genotypes over broad areas. Remote sensing is already beginning to provide some useful information on important soil properties such as water-holding capacity and nutrient conditions. However, validating remote sensing observations by selective on-ground sampling is likely to be required for the foreseeable future.

Though great improvements have been made in estimating mean climatic conditions over broad areas, more could be done to evaluate climatic variability. Improved climatic data are becoming available for factors such as rainfall variability and frost risk. Greater use of this information should be made in species selection systems.

In the past climatic databases have typically used monthly mean data. Data storage and transmission speeds have increased so greatly that access to actual time series data of hourly rainfall and temperature data for many years is now becoming practical. These datasets will allow factors such as insect development and leaf wetness to be estimated for potential planting sites. This will allow pest and disease risks to be more reliably estimated.

If predictions of climatic change are realized, this factor may also need to be considered in species selection. At present regional predictions of climatic change are not sufficiently accurate for forest managers to include this factor when selecting trees for planting.

Great progress has been made in developing methods to fulfill the need identified by John Evelyn in 1665 of identifying the fittest trees to be cultivated on any particular site. However, even better tree selection methods will be required to realize the full benefits of the improved genetic material that is becoming available for planting.

Ground Preparation

A Baldini and W Alfaro, Corporación Nacional Forestal, Santiago, Chile

Introduction

Ground preparation is defined as the set of preliminary operations on soil that are required for effective establishment of tree seedlings. The main objective of ground preparation is to assure access to nutrients, air, and water for the seedlings to be planted.

Ground preparation is associated with site preparation. Ground preparation is more focused in soil treatment for plant establishment, considering the simple meaning of ground as 'solid surface of the earth' or 'the upper soil.' Site preparation may be understood as a wider concept referring to a modification of the surrounding environment for plant establishment. In this sense, site preparation may include operations prior to ground preparation.

Thus, site preparation includes clearing, soil cultivation, and also protection operations, such as management of pre-existing vegetation especially weeds, fencing and other animal control systems, protection of plants against frost and wind, etc. Conversely, ground preparation as a normal step leading to plant establishment is concerned with soil cultivation, including either drainage or water storage according to site conditions.

As a major operation for ground preparation in planting sites, soil cultivation frees ground and it facilitates a deeper penetration of water and air into the root zone and therefore, it allows root systems better access to soil nutrients and assists their correct placement, anchorage, and development. Also, draining facilitates aeration for roots in extremely wet and waterlogged fields. Furthermore, water harvesting increases soil water availability in dry zones.

Intensity of the operations for ground preparation may be defined in terms of work or power per unit area, which varies from site to site, depending on constraints of cost, plantation objectives, and site conditions. Ground preparation work may be classified as low intensity operations or high intensity operations. Low intensity operations include basically manual support and simple soil cultivation. High intensity ground preparation includes the use of agricultural machinery and mechanical support for soil cultivation.

Operations for ground preparation may be further classified according to their use of labor or machinery. Thus ground preparation may be implemented through a manual support system, a mechanical or machinery support system, or a combination of both systems. Ground preparation with manual support is normally preferred in low intensity ground preparation and small-scale operations such as the construction of furrows, mounds, bunds, ditches or trenches.

In general terms, field conditions such as slope, deepness, and stoniness are not limiting factors for manual ground preparation, which is performed by using hand tools such as shovels or spades, *azadas*, or a plow drawn by animals. Also, ground preparation with manual support may be used for smoothing and compaction of mounds and bunds, when combined with machinery or mechanical support operations.

Ground preparation with machinery or mechanical support is used for large-scale operations and it cannot be used on steep slopes because its application requires gentle to moderate slopes. Operations of ground preparation with mechanical support involves plowing, disking, or bedding, mounding, also scratch or spoil drain mounding, ditching, ripping, subsoiling or scarifying operations. However, disking and ripping are the most widely used operations of this type.

Machinery used for mechanical support operations consists of tractors or dozers with special attachments, especially blades, disks, rippers, rutters, or excavators, among other devices. Agricultural equipment may be used in most operations for soil cultivation in planting sites, where field conditions are not too rugged or stony. Heavy machinery should be used if there are relatively adverse conditions such as heavy clay soils, moderately steep slopes, or stoniness in the field.

Thus mechanical support to ground preparation can be classified into three categories of equipment: (1) machines for vegetation cutting and stump removal; (2) machines for vegetation cutting plus breaking up the ground up to certain depth; and (3) machinery that breaks ground structure to a deep level (**Table 1**).

For example, bulldozers may be used to remove remaining trees and stumps. A rotovator works over ground vegetation and it turns over the upper soil

Table 1 Equipment required for ground preparation, according to field conditions

Fields conditions	*Operation*	*Machinery recommended*
Deep soil; light soil density; flat to gentle slope	Cultivation without restriction	Low intensity work: agricultural disks on tractor
Deep soil; light soil density; flat to gentle slope	Ripping and mounding without restriction	Low intensity work: winged ripper on tractor; disk mounder on tractor
Deep soil; heavy soil density; moderate slope	Cultivation with restriction	Moderately high intensity work: heavy disks on tractor
Moderately deep soil; very heavy soil density; moderately steep slope	Ripping and mounding with restriction	Very high intensity work: ripper on bulldozer; 'Savannah' type mound plow; excavator on hauler
Shallow soil; steep slope	Machinery operation restricted	Manual support system recommended

layer. Rippers are typical devices for breaking up soil in depth. A mechanical excavator may be used for ground preparation in areas with heavy slash where stump and debris removal should be done prior to any plant establishment operation.

Appropriate operations for ground preparation depend on soil physic features, relief, water regime, and previous management. Field conditions requiring ground preparation are related to dense grass cover, detrimental field disturbance, compaction, heavy bulky soils, waterlogging, or dryness. Analysis of these conditions allows definition of needs for clearing, land reclamation, soil cultivation, drainage, or water harvesting.

Clearing

Clearing is an important preliminary matter in ground preparation and it is carried out to remove cover, specially shrubs and trees. Clearing allows effective soil cultivation, improving access for establishment operations. Clearing for plantation development may include the removal of posts from old fencing, stump and timber removal, and filling of holes.

Areas carrying a dense cover of grass require special attention because they put up competition with tree seedlings. First, grass needs to be eliminated with herbicides and allowed to decompose prior to working for complete breakdown of the sod. Then, soil cultivation may be required and appropriate cultivation might be considered, such as line cultivation with a heavy disk, mound plow, or ripper if necessary.

Soil cultivation is strongly recommended in sites carrying bracken (*Pteridium aquilinum*) or light scrub. Soil cultivation should be done twice in dense bracken or scrub cover: once in autumn; then again in the following summer. Over winter the sod and rhizomes break down and any new spring germination is removed in the second cultivation. In this case, the rhizomes mat of bracken has to be completely broken before plant establishment and seedlings planted into mineral soil.

Land Reclamation

Management conditions leading to soil cultivation for plant establishment are related to disturbance during harvesting. Site disturbance may be considered desirable for forest regeneration. However, site disturbance may occur under inappropriate conditions, e.g., a high risk of compaction, erosion, or soil mass movement, especially when soil is water saturated. Thus, land reclamation may be performed if disturbance becomes detrimental.

For example, compaction may occur due to machinery travel during harvesting operations, e.g., where conditions in soil water content are not appropriate for machinery operation such as skidders or feller buncher harvesters. Land reclamation is intended to return the site as closely as possible to its initial level of productivity in such a manner that the site will maintain that level of productivity without further management.

Land reclamation is often very expensive and does not guarantee that an area can be returned to its former level of productivity. Therefore, prevention is always the best way to deal with detrimental site disturbance. The first step in undertaking reclamation work is the development of the reclamation plan. The reclamation plan should include specific instructions and procedures for different treatments.

A reclamation plan must be based on specific site conditions, such as: moisture regime; soil texture; nutrient status; range and wildlife interests; possible negative consequences of the reclamation; locally available resources; and special concerns for the given site. Some of the options currently being explored i.e. the process of land reclamation are: recontouring of steep cuts; loosening the soil; revegetation; restoration of organic matter; fertilization; and, finally, monitoring.

As an example, soil can be loosened by a variety of methods, including a ripper, winged ripper, winged subsoiler, excavator with bucket, or excavator with fork. The winged subsoiler and ripper are usually more applicable to large areas of continuous disturbance, such as roads and landings.

Revegation is an important measure for land reclamation because vegetation plays an important role in maintaining soil structure, and when it is removed, exposed mineral soils are more susceptible to compaction damage. High root activity helps restore and maintain soil structure. Traditional approaches for revegetation have been to plant grass plus legume mixtures, which are useful in extreme situations where erosion control is necessary. However, there are circumstances where these types of mixtures may compete for moisture with seedlings or may increase the risk of frost damage.

Organic matter may be restored by moving forest floor or logging debris from slash piles or roads. The layer of organic material on the forest floor surface serves many important functions: it is often an important nutrient reservoir; it prevents soil erosion; and it protects soil from compaction after the removal of vegetation. Straw is a suitable mulch, because of its relative unpalatibility and low carbon/nitrogen ratio. Hydroseeding mulches may be used in certain cases, or plants such as rye grain, which generally do not survive in extreme conditions and die after 1 year, leaving a layer of organic matter on the ground.

Fertilization replaces nutrients lost from the site, stimulates biological activity to speed up the process of soil structure restoration, and accelerates ground-cover development. Nutrient application may also help to offset an anticipated decline in productivity when other means are not practical.

Compaction

The physical effect of compaction on soils is an increase in soil bulk density. Other effects of soil compaction are: reduction of porosity and thus aeration and useful water retention; loss of soil structure; reduced hydraulic, thermal, and gas conductivity; and increased dry strength or shear stress. Thus, soil compaction may affect root growth, limiting the roots' ability to explore the soil volume for nutrients and water moisture.

Other side effects of soil compaction include: increased risk of ponding of water; greater depth of soil freezing; and reduced growth of soil organisms. Any of these changes can contribute to short-term reductions in tree growth or long-term reductions in site productivity.

Cultivation

Cultivation is carried out to improve soil physical conditions, to allow improved root growth and therefore tree anchorage, to improve root access to soil nutrients and moisture, and to improve the quality of planting. Also, cultivation removes competing weeds, thereby improving moisture and nutrient availability to planted seedlings; and it provides a surface to which herbicides can be effectively applied.

It is important to determine the optimum technique for ground preparation in any particular field condition. A balance of cost to effectiveness must be achieved; on some sites, e.g. sites with heavy weed infestation such as blackberry (*Rubus fruticosus*) or gorse (*Ulex europaeus*), it will not be economically possible to establish plantations due to high costs of controlling this type of weeds. In addition, poor cultivation may increase erosion. Farmers should be aware that preparation equipment can be very specific where heavy work is required; in such a case special care must be taken to minimize erosion.

Soil cultivation should be contoured on all soils of high or very high erosion class such as silty or granitic soils, and on slopes greater that 15% for the moderate to high erosion class. All cultivation must avoid disturbing flowlines. In areas of very high rainfall cultivation may be undesirable for some moderate and moderate to high erosion class soils above 15% slope.

Soil cultivation lines oriented at right angles to the contour will facilitate machine access for subsequent establishment and harvesting operations on other than high and very high soil erosion classes and on slopes over 15% on moderate to high soil erosion class.

Soil cultivation must be done when the soil is friable, dry enough to crumble from cultivation but not so dry that it pulverizes. The soil should only be lifted enough to cause fracturing and then dropped back without any inversion of the soil profile. Soil cultivation is normally performed through disking.

Disking

Disking is an operation for ground preparation using disks as attachment devices on a tractor. Disking may be used to improve soil structure; to break down compacted surface horizons; to break up sods or bracken rhizomes; or to prepare a cultivated weed-free surface for herbicide application. Disking may be carried out on soils not requiring subsoil ripping.

Disk type will depend on the field conditions. Soil should be cultivated as deep as rocks and roots permit and to a minimum depth of 0.20 m. Heavy disks should be used, because smaller disks do not cultivate to sufficient depth. Mounding disks are used for drainage and water harvesting systems.

Disking is effective in soils with compacted surface and it promotes infiltration. Nevertheless, disking may reduce medium pore soil volume in dry areas and therefore it may affect water availability for plants. Also, disking may affect soil organic matter.

Ripping

Trees form shallow root systems where there is any impediment to root penetration. Shallow root systems make trees susceptible to windthrow, and to summer drought stress. Thus, ripping is required on compacted and heavy clay soils. Ripping breaks up subsoil, promoting root penetration to a reasonable depth. Grassland soils should benefit from ripping. In general, light density soils such as sandy soils do not require ripping.

Normally, ripping is carried out with a winged ripper. Ground preparation of planting sites by cultivation with a winged ripper will break up hard soil pans, increasing infiltration, and enhance early root development and subsequent tree growth. The wing on the ripper spreads the shattering effect of the ripper by lifting the soil as the ripper is pulled through and then dropping and shattering it behind the ripper.

Ripping should ideally be carried out to a depth of 1 m, or a minimum of 0.7 m for satisfactory results. Subsoil shattering occurs over most of the planting site when soils are relatively dry. Under this condition, subsoil shattering is obtained at a reasonable speed. Speed of ripping is important for shattering soil and large machines capable of reasonable speed should be used where possible.

Rippers shatter compact soils and provide easy access to the ripped profile for roots when fitted with a wing at least 0.40 m wide, mounted at the toe, and angled rear-upwards. Narrow boot rippers without wings produce very narrow shattering and can cause trenching in moist soils. Suitable rippers are commercially or locally made.

Subsoil plows are designed to provide full ground preparation treatment in hilly areas worldwide. Subsoil plows are designed for areas where the dozers available are lower in horsepower. More maneuverable than a heavy trailing unit, subsoil plows are very rugged machines designed for use with 225–350 HP dozers. The design may include a heavy-duty coulter and swept-back tine, and a choice of two or four disks. Subsoil plows may have the ripper shank and the disk body both in the swiveling frame, for high maneuverability on sloping ground. Also, some equipment includes a disk coulter ahead of the ripper shank.

High-performance plows may be used for bedding and soil structure improvement at higher speeds. They can use a four-point linkage lift kit, a 48-inch coulter, ripper shank and either two or four 36-inch cultivating discs. High-performance plows have a new design of hubs and spindles, which are massively stronger than previously. Bodies have been completely redesigned to allow up to 34-inch high-lift jump height. It is now very unlikely that a jump-arm would ever hit against the mechanical stop and it will be rare for the weight of the plow to be placed on the disk spindles, even in extremely high stump conditions. As an example, the action of the 'Savannah' jump arm raises the disk higher with a minor angle of cut and a greater rolling effect over a stump, eliminating stresses on the disk and spindle in straight-line plowing.

Effective depth of subsoiling has been a matter for debate around the world. Effectiveness is one criterion, but economy is a better approach for foresters to use. Generally, it may be much better to have a slightly shallower depth using a winged ripper tip, than to deep rip using only a standard ripper tip. The standard ripper tip will not create any fracture zone in plastic or wet soil condition. On the other hand, using a wide-winged tip and with plenty of longitudinal surface area, it is possible to break out plastic soils right to the surface. Thus, a subsoiling operation may be effective if it can produce additional growth in trees to justify expenses.

Mound Plowing

Mound plowing is an operation that raises the level of ground surface on planting spots. Mound plowing is often carried out on low-lying, flat areas, wet and poorly drained sites, and shallow infertile soils. It enables low, wet parts of generally better sites to be developed and planted. Mound plowing may be applied if 20% maximum of the field area is affected by waterlogging. Mounds can increase runoff on poorly drained sites and large mounds may provide a better rooting medium on wet or shallow soils. Mounds can be used in dry areas to retain runoff and therefore increase moisture content in soil.

Mounding is more effective on fine-textured soils. Soil is well aerated by mounding but it may need consolidation before planting. This can be achieved by rolling or by allowing the soil some time to settle, about 1–2 months before planting. Mounding delineates rows and it leaves an obvious planting line thereby reducing planting cost. Planting holes may be dug easily in loose soil. Seedling roots may be arranged neatly, minimizing shock or damage. These conditions allow seedlings to begin to grow earlier, increasing the length of the first growing season.

Mound plowing is often done in conjunction with ripping. Mound plowing allows planting directly over the ripped line. Mound plowing is best carried out when soils are moist but not wet. Plowing should be complete by early autumn to allow time for the mound to pack down before planting.

Various mound plows are available for use. Normally a set of tandem offset 600–800 mm diameter disks is attached to a tractor or dozer, which works well in easy conditions. Much heavier disks are available, and the recommended big disk for special operations is the 'Savannah' plow, which is mounted directly onto a large bulldozer.

Operational Impacts

Ground preparation has both positive and negative effects on soil properties. Use of proper equipment and correct timing of preparation will reduce any detrimental impact. **Table 2** describes the potential impact of ground preparation operations on soil properties.

Drainage

Draining is a special operation in waterlogged fields, and its objective is to promote aeration for root systems. Normally, draining is carried out by ditching, bedding, or mounding. Ditching allows water to be discharged towards lower areas. Bedding and mounding raises ground allowing a water-free zone on upper soil.

Spine drainage is a typical example for ditching drainage systems. In this system, a central trench is excavated in the slope direction. Lateral trenchs regularly spaced on both sides are connected to the central trench that receives their discharge. Spine drainage is a very efficient system for depleting local water table in planting sites; however, it has significant impacts on sediment yield and is therefore falling out of use.

Bedding and mounding are the preferred systems to address drainage in planting sites. These operations raise the ground to a position free of water, increasing available root depth and protecting seedling stems from low temperatures occurring during frost over the ground surface. Most of the better results in tree growth are obtained by placing seedlings over the top of the mound.

Bedding is an operation more appropriate for clear areas, because it is difficult to get a continuous line of plowing for bedding under conditions such as heavy slash or high stumps. Therefore, mounding should cope better with irregularities on the ground surface.

Table 2 Potential impact of ground preparation operations on soil properties

Soil factor	*Operation*		
	Disking	*Ripping*	*Mounding*
Compaction	+ SI (r–2-LT)	+ HI (r–1-LT)	+ SI (r–1-LT)
Soil moisture	+ SI (r–2-LT)	+ HI (r–1-LT)	+ HI (r–2-LT)
Soil organic matter	– LI (r–2-LT)	O	– LI (r–1-LT)

Impact sign: +, positive; –, negative.
Impact magnitude: O, no effect; LI, light effect; I, significant effect; HI, very significant effect.
Importance: 1, point; 2, local.
Reversibility; r, reversible effect; p, irreversible effect.
Duration: SD, short-term effect; LD, long-term effect.

Water Harvesting

In dry areas, water harvesting must be considered in order to supply water if it is deficient during establishment and early growth of plantation. Water harvesting should gain massive adoption in the near future because of the excellent results obtained in the afforestation of areas with rainfall as low as 80 mm year^{-1}. Most harvesting systems are designed for flat areas. Nevertheless, higher steep slopes also may be treated with the systems for water collection. There are many water harvesting systems that can be applied for improving forest plantations. For example, microcatchments or 'negarims,' contour bunds, contour stone bunds, semicircular bunds, individual terraces, 'limans,' 'kasukas,' permeable rock dams, subsurface dams, and others.

Water harvesting systems are ground preparation systems with a high cost and a considerable amount of ground disturbance. Nevertheless, water harvesting systems can make feasible afforestation in dry zones, achieving good success in tree growth. As an example, **Table 3** shows the earthworks required for three of the most popular water harvesting systems.

Water harvesting systems should be considered as soil and water conservation systems, because besides harvesting water for the trees, they simultaneously conserve soil. Dimensions of water harvesting systems are based on the catchment area size required to provide an additional supply of rainfall. Under extreme conditions of drought there must be a minimal runoff in the area. The design of water harvesting systems must also consider maximum discharge in order to avoid destruction of the structure. Larger structures may take more labor per unit volume of earthworks than smaller structures such as negarim microcatchments, because of the increased earthmoving required.

Negarim microcatchments are diamond-shaped basins surrounded by small earth bunds with an infiltration pit in the lowest corner. Runoff is collected from within the basin and stored in the infiltration pit. Microcatchments are mainly used for

Table 3 Minimum earthworks required by typical water harvesting systems

Additional rainfall supplied by water harvesting system (mm)	Runoff (mm)	Crop area to catchment ratio	Trees per hectare	Earthworks with a minimum cross section of 0.08 m^2 and a forest crop area of 4 m^2 ($m^3\,ha^{-1}$)		
				Microcatchments	Contour bunds	Semicircular bunds
200	10	1 : 20	125	208	48	80
150	20	1 : 7.5	330	288	128	211
100	30	1 : 3	850	464	200	326

growing trees or bushes. This technique is relatively easy to construct and appropriate for small-scale tree planting in areas with moisture deficit. A modified system is used in Latin America by a double plowing at right angles to get the diamond shape over the ground. Also, the soil in the pit is removed and placed in the top of the bund at the lowest corner of the diamond and one to three seedlings spaced at 0.4–0.6 m are planted at that point. This planting method is named the 'taba-ue' system from its original name in Japanese. The cluster of plants creates its own environment and the synergy effect can improve their survival and growth.

Contour bunds are a simplified form of microcatchments. Bunds follow the contour at regular spacing. Small earth ties perpendicular to contour prevent collapse of the system under high intensity rain events. Construction of bunds can be mechanized and the technique is therefore suitable for implementation on a larger scale. Bund construction is relatively economical particularly for large-scale implementation on even land. Contour bunds are suitable for trees and also for the cultivation of crops or fodder between the bunds.

Semicircular bunds are earth embankments in the shape of a semicircle with the tips of the bunds on the contour. Semicircular bunds are used mainly for rangeland rehabilitation or fodder production, with varying dimensions. This technique is also useful for growing trees and shrubs and, in some cases, has been used for growing crops. They may be placed as an *in situ* short slope catchment or an external long slope catchment, depending on the location and the chosen catchment to cultivated area ratio. Semicircular bunds, 'half moon' or 'demi-lune' in francophone Africa, are recommended as a quick and easy method of improving rangelands in semi-arid areas, and may be used in afforestation projects. Semicircular bunds are more efficient in terms of impounded area to bund volume than other equivalent structures such as trapezoidal bunds, for example.

Contour ridges, sometimes called contour furrows or microwatersheds, are used for crop production, and the technique may also be applied for afforestation purposes. This is a microcatchment technique where ridges follow the contour at a spacing of usually 1–2 m. Runoff is collected from the uncultivated strip between ridges and stored in a furrow just above the ridges. Crops are planted on both sides of the furrow. Contour ridges are simple to construct with manual or machinery support, and this can be even less labor intensive than the conventional tilling of a plot. The yield of runoff from microcatchment lengths in contour ridging is extremely efficient and when designed and constructed correctly there should be no discharge out of the system. Contour ridges provides even growth because each plant has a similar contributing catchment area. Contour ridges is a technique being tested for crop production in Africa.

Trapezoidal bunds have a layout with shape of a trapezoid, a base bund connected to two side bunds or lateral walls, which extend upslope at an angle of usually 135° or higher. Trapezoidal bunds are used to enclose larger areas up to 1 ha or more. In this system, runoff is harvested from an external catchment area. Crops such as trees are planted within the enclosed area. Overflow may discharge throughout a spillway constructed over the central bund or as a channel at the end of the lateral walls. The main advantages for this technique are simplicity of design and construction, and the minimum maintenance required.

Contour stone bunds are used to reduce runoff speed, thereby promoting infiltration and collecting sediment. The water and sediment harvested improve crop growth. Bunds construction is a traditional practice in many parts of the world and villagers may be trained effectively in its application. Stone bunds are well suited to small farmers because of their low cost and simplicity. Improved construction and alignment along the contour makes the technique considerably more effective. Stone bunding techniques are used for hillside terracing around the world, specially in the Andean zone. The supply of stones may be a constraint for application of this technique. The filtering effect of the semipermeable barrier along its full length spreads the runoff, avoiding concentration and resultant damage. Systems based on stone do not need spillways and they require much less maintenance.

Permeable rock dams are a floodwater farming technique where runoff waters are spread in valley bottoms for improved crop production. The structures are typically long and low dam walls across valleys. Rock dams have been developed mostly in West Africa, and the technique had grown substantially by the end of the 1980s. The technique is labor intensive and needs a group approach, as well as some assistance with transport of stone.

Water spreading bunds are often applied in situations where trapezoidal bunds are not suitable, usually where sudden runoff discharges may be extremely high and would damage trapezoidal bunds or where the crops to be grown are susceptible to the temporary waterlogging, which is a characteristic of trapezoidal bunds. Water spreading bunds are usually used to spread floodwater which has either been diverted from a watercourse or has naturally spilled onto the floodplain. The bunds, which are usually made of earth, slow down the flow of floodwater and spread it over the land to be cultivated, thus allowing it to infiltrate. Water spreading bunds may be combined with the construction of a ground dam, which is a long structure that retains subsurface flow.

Final Remarks

Several ground preparation operations and their uses have been described. Tree growth following different treatments for ground preparation should be monitored and integrated on information systems. Further progress in forestry may be supported by information systems about the results of different treatments for ground preparation under specific field conditions.

Stand Establishment, Treatment and Promotion – European Experience

J Huss, University of Freiburg, Freiburg, Germany

Introduction and Definitions

There are many aspects to the establishment of forest stands, which are reflected in a number of definitions:

- Reestablishment of existing forests is possible by means of generative or vegetative renewal. Strictly speaking, stands are regenerated only when grown from seed. This may occur through natural or artificial regeneration:
  - Natural regeneration takes place when seed is dispersed without human interference.

Figure 1 High forest in different manifestations: (a) even-aged pure Norway spruce (*Picea abies*) plantation (Riedenburg, south-east Germany), (b) uneven-aged naturally regenerated silver fir (*Abies alba*) and Norway spruce selection forest (Rippoldsau-Sch., south-west Germany).

   - Artificial regeneration involves direct seeding, as well as planting.

Both natural and artificial forest regeneration using seed results in high forests (**Figure 1**).

Vegetative renewal is the result of resprouting from the stumps left behind following harvesting. Most broad leaves sprout freely, giving rise to coppice forests (**Figure 2**). Such forests were widespread throughout Europe for centuries, and were an important source of firewood. A tree's ability to resprout from its stump, or to produce root suckers, decreases with age. Coppice forests are normally harvested after two to four decades and form relatively low forests. Vegetative renewal from the stumps is, strictly speaking, not regeneration, as the root systems are not regenerated and continue to age and deteriorate.

A combination of vegetative and generative renewal takes place in coppice forests with standards ('middle forests') (**Figure 3**).

- Reestablishment of forests is often referred to as reforestation and takes place shortly after the previous stand has been harvested, at which point the soil still predominantly exhibits characteristic forest soil properties.

Figure 2 Beech (*Fagus orientalis*) coppice stand shortly before next harvesting (Akcakoca, north Turkey).

Figure 3 Coppice with standards (mainly *Quercus petraea*) shortly after harvesting of the coppice shoots (Neuf-Brisach, France).

Figure 4 Norway spruce (*Picea abies*) plantation following afforestation of an old meadow (Hinterzarten, south-west Germany).

- Afforestation, on the other hand, takes place when areas have been used for purposes other than forestry for more than 50 years, according to a Food and Agricultural Organization definition (**Figure 4**). From a less precisely defined ecological viewpoint, afforestation is the restocking of sites which have lost their forest soil characteristics. This may arise as a result of various land-use types, such as agriculture, or degradation caused by erosion, and may occur over much shorter periods, depending on the local climatic and soil conditions.
- Stand establishment – depending on silvicultural systems – may take place under the canopy of old trees (**Figure 5a**) alongside forest stands (**Figure 5b**) or on large open areas resulting from clearcuts or other land uses (**Figure 4**). One of the main objectives of each of the silvicultural systems is to create microclimatic conditions appropriate to the ecological demands of the young plants of the different tree species.

  The larger the open areas, the greater the climatic stress conditions may become and the more tolerant the young regenerated plants have to be of such stress, for example, drought, heat, and early and late frosts (**Figure 6**). Usually a sheltering effect can be observed extending a distance across the regenerated area equivalent to the height of the neighboring stand. Generally, bare land conditions develop in areas larger than 0.5–1 ha. Large open areas (clearcuts) may be >5 ha, and very large ones >50 ha.
- The regeneration period largely depends on the type of regeneration and the silvicultural system employed. At one extreme it may require only 1 day to plant a small clearcut area, provided no beating-up is necessary in the succeeding years. The other extreme can be found in selection forests, where regeneration is a continuous process.

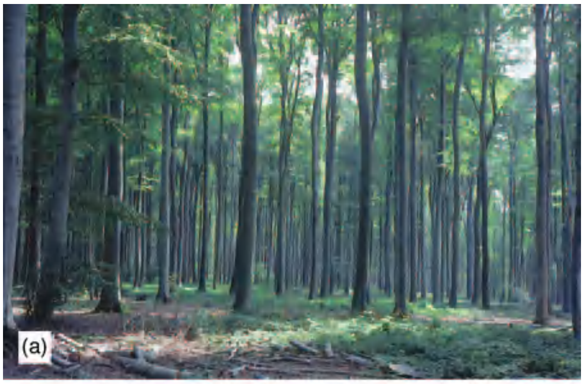

Figure 5 Natural regeneration with shelter for regrowth: (a) beech regeneration (*Fagus sylvatica*) under a shelterwood system (Bourbonnaies, France); (b) Norway spruce (*Picea abies*) regeneration under a strip-cutting system (Zeil, south-west Germany).

- The terms regeneration, planting, restocking, and afforestation denote processes, the results of which are seedlings, saplings, regrowth, plantations, and restocked forests, to mention but a few. In forestry practice, however, strict application of these definitions is seldom observed.

Figure 6 Norway spruce (*Picea abies*) although not very sensitive to frost, often suffers from late frost on large bare land areas (Pforzheim, south-west Germany).

Tree Species Selection

The tree species selected for restocking an area depends on several preconditions, such as the prevailing ecological conditions on the one hand, and the objectives of the forest owner and society on the other. These are illustrated in **Figure 7** and are explained in the following text.

Site Classification

The success of restocking an area is highly dependent on the site conditions. Sites are characterized by their climatic conditions and soil properties. Climate is the dominant site factor in mountainous as well as high mountain regions, and often negates the soil characteristics. Soil characteristics exert a greater influence on forest growth at lower elevations where the climatic conditions are relatively favorable.

Site classification systems, therefore, include two steps:

1. The demarcation of regional landscape units to characterize the predominant climatic influences.
2. The delineation and mapping of local forest site units within regional units, representing similar growing conditions for the tree species and including comparable risks.

Only a few Central European countries like Austria, Germany, and Switzerland currently possess area-wide maps providing elaborate site property

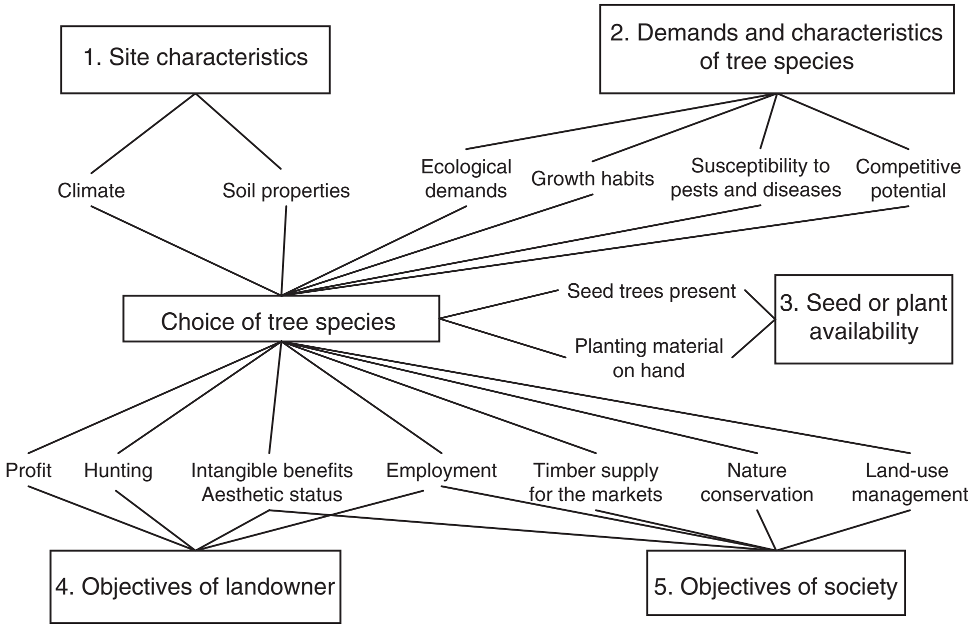

Figure 7 Preconditions and objectives influencing the choice of tree species when restocking forests.

information, enabling detailed planning of the optimum site-adapted stocking. Most European countries, however, possess maps indicating climatic or vegetational zones, which are of some help in the selection of site-adapted tree species.

As the majority of sites are located at lower altitudes and on soils mostly favorable to forest growth, the forest owners are free to select from many tree species for restocking. Other aspects may also be taken into consideration. The more extreme the sites become – high or very exposed elevations, very wet, dry or shallow soils – the fewer the options a landowner has in this regard.

Figure 8 Although clearcuts are diminishing in Scandinavia and Central Europe, an increasing area of bare ground has resulted from hurricanes over the last two decades (south-west Denmark).

Demands and Growth Characteristics of the Tree Species

The prevailing ecological conditions over an area to be restocked may also influence species choice. A large clear-cut or storm-damaged area (**Figure 8**) with a harsh climate, for instance, may be suitable for light-demanding yet stress-tolerant pioneers such as birch (*Betula verrucosa*, *B. pendula*), aspen (*Populus tremula*), or rowan (*Sorbus aucuparia*), whereas late successional species like beech (*Fagus sylvatica*) or silver fir (*Abies alba*) require the protection of a canopy of old trees against late frosts, drought, and high temperatures. Late successional tree species, therefore, cannot be regenerated on bare ground susceptible to the afore-mentioned stress factors unless a nurse crop is established to act in the same way as the old trees.

In order to reduce the microclimatic stress for young regrowth it proved effective to establish nurse crops through natural or artificial regeneration of pioneers (**Figure 9**).

All European forest tree species thrive best on relatively well drained soils, facilitating root growth, and with a sufficient nutrient supply in a moderately temperate climate. On these optimal sites, all species will exhibit their highest production rates. Which species dominates in the long run, however, is determined by the competitive strength of the tree species. Pioneer species, both long- and short-lived, are less competitive than the late successional species. Growing in mixtures, they usually have to be actively favored by management if they are to survive against the more competitive species.

Figure 9 Nurse crops as a means of overcoming adverse bare-ground conditions: birch (*Betula pendula*) planted in a storm-damaged forest acting as a nurse for young oak (*Quercus petraea*) planted shortly afterwards (Kirchberg, south-west Germany).

Seed or Plant Availability

The choice of tree species is highly dependent on the presence of seed trees, which may also provide shelter against microclimatic stress conditions, in the event that natural regeneration is desired, or on the availability of adequate plant material from nurseries.

Objectives of the Forest Owner

Only a minority of forest owners can use their forests exclusively for hunting or pleasure. Most regard their forests as major sources of income and employment, but may take into consideration other functions and objectives in the management of their properties. Therefore, they choose productive species promising good prices in the market. Additionally, the costs of establishing a new stand are of great importance. The greater the emphasis placed on calculating the return on their investment, the more likely they are to choose the species that are easiest to plant and clean.

In most parts of Ireland, for example, oak forests (*Quercus petraea*, *Q. robur*) would be natural and suitably site-adapted. Oak forests are expensive to establish and require intensive weeding, however, and ultimately produce relatively low volumes of timber over long rotations. Planting of Sitka spruce (*Picea sitchensis*), on the other hand, costs much less and the revenue from the fast-growing species is much higher. It is, therefore, easy to understand why most private owners plant Sitka spruce instead of oak.

Objectives of Society

Society is currently seeking to play an active role in influencing the production, appearance, and services provided by forests, as they are an important part of the landscape, and represent comparatively natural ecosystems.

Additionally, an increasing fascination for nature protection ideas to counterbalance modern urban life may favor the reestablishment of 'natural forests.' Employment for rural populations and the supply of a large variety of timber assortments for the markets, on the other hand, is a more general public issue.

Tree species choice is, therefore, a complex decision process and many interest groups may take part in it.

Types of Stand Establishment

Forest stands can be established by means of natural regeneration, direct seeding, or planting. The details, advantages, and risks of each procedure are discussed in the next section.

Natural regeneration is recommended where the following preconditions are met:

- Presence of seed-bearing trees on or in the vicinity of the area to be regenerated
- Existence of site-adapted tree species and provenances
- Seed production reasonably frequent. Some species, such as beech and oak, used to have good seed years at intervals of >5 years. Over the last three decades, however, the frequency of flowering has increased dramatically as a result of more frequent warm summers, which induce the formation of flower buds. Forest practitioners are, therefore, under less pressure to regenerate large areas immediately when the time comes to do so.

  Nevertheless, foresters can to a certain extent increase the intensity of flowering and seed production by promoting crown development of the final crop trees by means of consistent crown thinnings. Early and intensive thinnings ensure that the dominant trees will have developed large crowns decades before seed production becomes essential for regeneration. Some shade-tolerant tree species, however, such as beech, exhibit reactions to increased crown space even at advanced ages
- Soil conditions favorable to germination. Layers of litter, raw humus, and/or ground vegetation may seriously impede natural regeneration. The soil surface conditions may, therefore, require soil treatment in order to expose the mineral soil, thereby providing a favorable seed bed (**Figure 10**)
- Low risk for the development of seedlings. Mice (*Apodemus* spp.), voles (*Microtus* spp.), insects such as the pine weevil (*Hylobius abietis*), and deer (such as *Capreolus capreolus*, *Cervus elaphus*, *C. nippon*, *Dama dama*) may greatly endanger the young seedlings (**Figure 11**). Voles and beetles are less of a problem if the young plants are regenerated in the more moderate microclimate under the shelter of an old stand. Deer, however, can only be effectively excluded by fencing, which is very expensive.

Natural regeneration is only possible if old stands are remaining or have been rehabilitated through afforestation and allowed to reach seed-producing ages. This is the case in most Central and Eastern European, as well as Scandinavian, countries. Therefore, there is a growing tendency to make use of the opportunity to regenerate forests naturally. In these countries, the current aim is to reestablish at least half of the forest area naturally. In Eastern and southern European countries, however, most forests have only been established in the last decades and generally do not as yet produce sufficient seed numbers.

Direct seeding – though considered artificial regeneration – holds an intermediate position between both regeneration types. It combines the advantages of natural regeneration (low cost input; high number of plants per unit area, which is important in the case of broad leaves as it ensures a high rate of natural pruning, a precondition for valuable timber; and undisturbed root development) with those of planting (choice of tree species independent of the presence of seed-bearing trees;

Figure 10 Minor soil preparation to improve germination conditions. (a) Strip ploughing to encourage beech (*Fagus sylvatica*) nuts (Lembeck, west Germany); (b) strip ploughing to help Scots pine (*Pinus sylvestris*) seeds germinate (Bamberg, south-east Germany).

even tree cover over the whole area despite minor site differences caused by the site mosaic).

Direct seeding of acorns (mainly *Q. petraea*) has long been and still is important in forestry practice, as it is difficult to store them over winter. Therefore, the acorns are normally sown in ~5 cm deep furrows and covered with soil for protection (**Figure 12**).

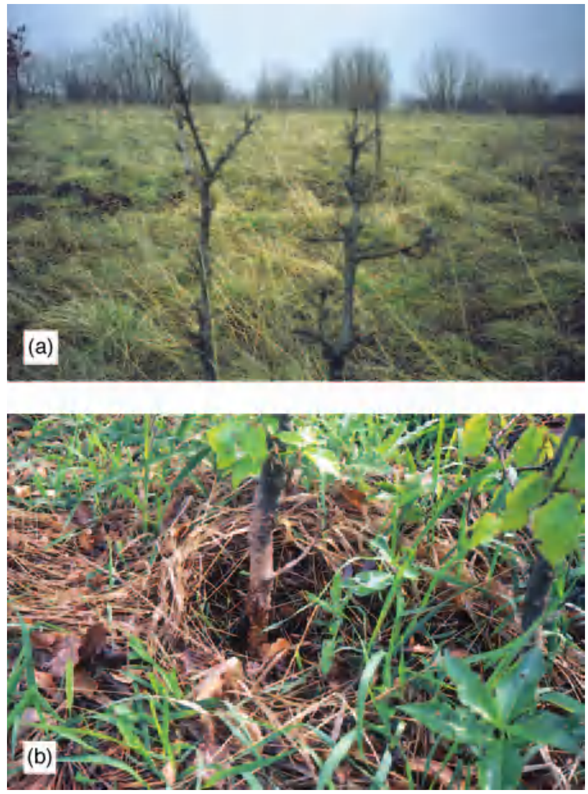

Figure 11 Damage caused by deer and voles. (a) Young oaks (*Quercus petraea*) heavily browsed by red and roe deer (*Cervus elaphus*, *Capreolus capreolus*; Hainich, east Germany); (b) young beech (*Fagus sylvatica*) ring-barked by voles (*Microtus agrestis*) (Zwiefalten, south-west Germany).

Direct seeding of birch (mainly *Betula pendula*) has recently received renewed attention as a means of restocking areas and establishing nurse crops after damage caused by hurricanes and SO_2 emissions (**Figure 13**).

Planting is the general alternative if the preconditions for natural regeneration are not met. The following are some of the advantages of planting over natural regeneration:

- independence with regard to tree species selection (from existing old growth)
- independent of mast years
- even, and calculable, stocking levels across the entire area
- reduction of the vulnerable period for young trees.

The possible objectives of planting are detailed in **Table 1**.

Planting can be carried out under the shelter of existing stands, as well on open areas, thereby resembling natural regeneration in some respects.

Figure 12 Successful direct seeding of acorns (*Quercus petraea*) (Rohrbrunn, south-east Germany).

Figure 13 Rehabilitation of forests following emissions. (a) Dead stand as a result of SO_2 emission (Ore Mountain, east Germany); (b) birch (*Betula pendula*) established by direct seeding on snow as a nurse crop. Beech (*Fagus sylvatica*) to be planted shortly afterwards under its shelter (east Germany).

Plant Types

A large variety of forests plants varying in their stage of development, size, sturdiness, source of origin, and type of production (bare-rooted or container plants) are available according to the different needs of the forester (**Table 2**).

Generally, small plants can be used when the subsoil texture is similar to that found in agriculture. In the past, soil preparation was commonly undertaken to reproduce similar conditions.

The increased vigor of ground vegetation species in the last three decades has meant an increase in the loss of young trees through competition. Additionally, deer browsing has become a serious problem regionally because of higher deer populations. Consequently, there has been a shift towards taller and sturdier plants (**Figure 16**).

Transplants and container plants are predominantly produced by large private nurseries (**Figure 18**).

In the EU the collection of seeds, plant production and distribution are organized according to legal regulations and special laws in several countries, in order to ensure that the origin of the seeds is documented through all stages of production down to the receipt by the consumer. In spite of these regulations, grave cases of willful deceit have occurred, resulting in the closure of several nursery enterprises.

The globalization of plant production in different countries has generated increased problems in ensuring

Table 1 Objectives of different planting types and planting procedure

Planting objective	*Procedure*
Production forest	Mainly planting across the entire area with one species only
Protection forest	Great differences according to the protection objectives, for instance: • erosion control • nature protection: reintroduction of rare species by planting single trees at varying distances or on special sites, increasing biological diversity
Recreation forest	Concentrating on forest edges: favoring esthetic values, avoiding straight lines, increasing visual diversity
Nurse crop	Planting of a pioneer species on large exposed open areas in order to create favorable ecological conditions under the shelter of which the final crop is later established
Underplanting	Planting shade-tolerant trees with a silvicultural function (shading the valuable trunks of dominant trees against epicormics, shading the forest floor to prevent the development of ground vegetation, an obstacle to later natural regeneration)
Enrichment planting	Introduction of additional tree species into incompletely regenerated regrowth (mainly after natural regeneration; **Figure 14**)
Filling-in	Stocking areas of unevenly developed naturally regenerated regrowth with plants of the same species
Beating-up	Replacement of dead plants 1 or 2 years after establishing the original plantation

Figure 14 Norway spruce (*Picea abies*) enrichment planting in a gap naturally regenerated by beech (*Fagus sylvatica*) (Donaueschingen, south-west Germany).

an appropriate control over the genetic quality of the plant material. Some forest enterprises, have, therefore, intensified natural regeneration and the collection of wildlings on their own property.

Planting Techniques

Although a great number of tools and machines have been developed during the last 200 years, hoes that produce narrow slits are still dominating (**Figure 19a**). New techniques even for steep terrain are under construction (**Figure 19b**).

Plant Density

The number of plants per unit area may vary between 6000 (beech) and 500 (poplar) plants per ha depending on the tree species and on several preconditions and characteristics of the plant material and the restocking area (**Table 3**).

Spacing

Row or quadrangular spacing is common on large areas. Common spacings are 3×1 m or 3×1.5 m and 2×2 m or 2.5×2.5 m. Row spacing involves lower planting costs, as well as savings later during tending operations, such as weeding, and has, therefore, increased importance.

Trials have recently been established to study the effect on saplings of planting in small groups (nest-planting, e.g., 100 nests per ha with 25 plants each, with 1×1 m spacings within the nests), with the spaces between groups left to natural succession, or else either sown or planted. The numbers of plants required, and as a consequence the costs, are lower than for traditional planting designs. Final results are not yet available, however.

Group Mixtures

There is an increasing tendency to establish forests with two or more species in the canopy. Unlike traditional plantings, these mixtures should always be established in groups of at least the size of the crown of a final crop tree (i.e., 50–150 m^2), thereby ensuring that the species which grow more slowly initially will not be overgrown by the faster ones.

Mixtures in rows have mostly proved unsuccessful because one species suppresses the other during a certain phase of development (**Figure 20**).

Plantation as a System

Plantations are in a certain sense a system, based on a combination of many preconditions and procedures. When establishing a new stand, on many sites the forest owner has the following options:

Table 2 Plant types used in forestry practice

Plant type	*Description/suitable for*
Seedlings	Seedlings spend 1 or 2 years in the seed bed; 10–30-cm tall seedlings are planted in the open if no humus layer is present. Litter and ground vegetation impede planting and seedling development. Although attractive for their low prices and planting costs, seedlings may be susceptible to high risks, for example, deer browsing (**Figure 15**)
Transplants	After 1–2 years in the seed bed, the seedlings are transplanted and left for 1–3 years in a new bed ($1+1$ to $2+3$), attaining heights of 30–80 cm. Transplanting reduces height growth, but favors the development of a compact root system with more fine roots, thereby simplifying the planting procedure and improving growth in the field. Undercutting plants in the seed bed also stimulates development of a compact root system. Due to the high costs of transplanting, undercutting has gained popularity. Transplants remain the most commonly used in practice, however (**Figure 15**)
Saplings	Plants of >1 m in height. Mainly broad leaves. Most common in horticulture. Important in earlier centuries for establishing standards in coppice stands and as solitary oaks. Increasing importance today because less susceptible to competition from ground vegetation and deer browsing. New planting techniques may lead to a reduction of the high planting costs (**Figure 16**)
Wildlings	Naturally regenerated young plants, 30–100 cm tall, extracted for the purposes of filling up incomplete young stands, for underplanting and for transplanting in a nursery. Wildlings have a proven site adaptation. A further great advantage is their availability. They often suffer from dieback if transplanted into open land, however, due to poor root development
Container plants	Seedlings grown in blocks of containers under semiindustrial conditions in plastic greenhouses for a few months. Low costs because of integrated lines from production to planting. Highly attractive to large-scale forest enterprises in the boreal zones. Of little importance in temperate zones because they are too small to withstand the intensive competition posed by the ground vegetation (**Figure 17**)

Figure 15 Beech (*Fagus sylvatica*) seedlings and transplants: $1+0$-year-old seedling only reach ~10 cm in height and normally cannot be used in the open; $2+2$-year-old transplants, however, reach ~80 cm in height and are able to withstand most of the dangers in the open.

- In order to save money in the first year the forest owner may choose small plants, which are cheap and easy to plant, but normally require intensive soil preparation. In the following years, however, several clearings of the competing ground vegetation may be necessary, as well as protection by fencing.
- As an alternative, the forest owner may buy saplings, which are much more expensive and difficult to plant, but do not require any further expenditure.

Upon reaching the thicket stage, the sum of the costs may be much lower using the second alternative and, additionally, the stand has reached this stage in a much shorter period of time. Apart from the differing growth rates and requirements of the young plants and the varying intensity of ecological influences, the economic aspects, such as the time of investment, as well as the interest rate, may strongly influence the owner's decision. Unfortunately, little experimental work has been carried out by forest research institutions and forest enterprises in order to obtain reliable data comparing the advantages and disadvantages of all of the factors and procedures influencing the establishment of young forest stands. In fact, this is a very complicated aspect of silvicultural research for the following reasons:

- Experiments of this type require long observation periods (10–20 years).
- There are many factors to be considered, not to mention their interactions.
- Some factors, such as weather conditions, browsing pressure, and ground vegetation competition, may vary from one year to the next.
- The conditions in forest practice are never stable over long periods of time.
- Finally, all these factors may have very long-lasting effects and even influence the final products.

Figure 16 Saplings do not need cleaning and fencing. (a) Beech (*Fagus sylvatica*) saplings planted in a gap caused by storm in a Norway spruce (*Picea abies*) stand (south-east Germany); (b) sycamore (*Acer pseudoplatanus*), ash (*Fraxinus excelsior*) and wild cherry (*Prunus avium*) saplings planted in a wet area within a young beech stand (Ettenheim, south-west Germany).

Figure 17 Container types commonly used in Sweden. (a) Container with small root volume for Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) (Kopperfors multi-pots); (b) modern, much larger star pots for rough subsoil conditions.

Treatment and Promotion of the Regrowth

When young plants have reached an average height of ~50 cm, the differences between naturally and artificially established young stands tend to even out, except possibly for differences in density . Therefore, they can be discussed jointly.

Some of the following procedures may be essential in order to achieve the goals mentioned previously.

Regulating the Light Conditions

Young plants growing under the canopy of old trees increasingly need sufficient light, regardless of the type of establishment. A progressive opening of the canopy is an essential silvicultural procedure during the early phases of development. The speed at which the canopy is opened depends on the light requirements of the different tree species, and may take between 5 (oak) and 20 years (beech; **Figure 21**), or possibly even longer (silver fir).

Removal of Damaged Young Plants

The felling of canopy trees over existing regrowth often results in damage to some of the young plants during both harvesting and extraction procedures. These damaged saplings tend to become malformed, and should therefore be removed by cutting them down to the stump. Broad leaves tend to resprout

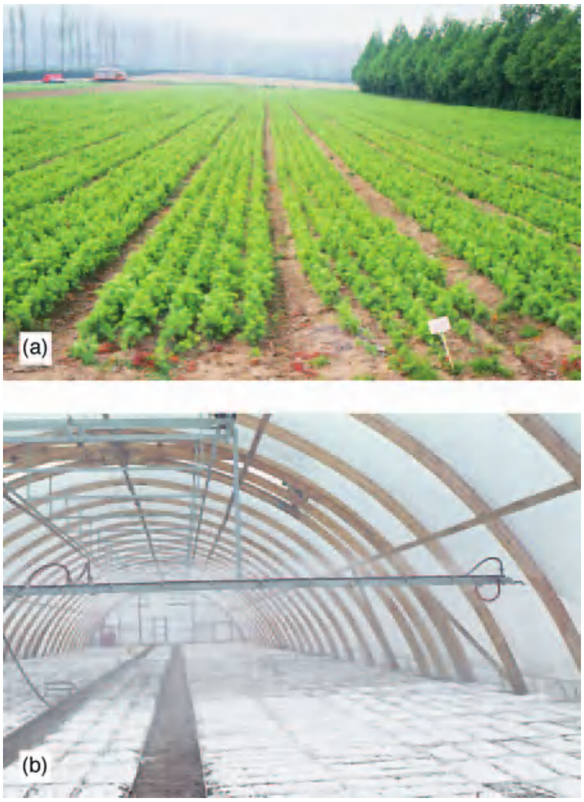

Figure 18 Private nursery (a) with long machine workable beds (west Germany) and (b) modern fully equipped, automatically managed greenhouse (Sweden).

Figure 19 (a) Various modern planting hoes; (b) modern sapling planting machine.

immediately, replacing the damaged individuals with straight and vigorous sprouts within a few years.

Regulation of Mixtures

Young naturally regenerated stands often contain more than one tree species. This species mixture has to be regulated prior to reaching the thicket stage (2–3 m in height). As has been mentioned already, the most common type of mixture is that of two or more final canopy species. If not planted in groups, the individuals of the different tree species should at this point be arranged into groups of at least the size of a grown crown. This ensures that none of the tree species will be entirely suppressed by the others because of diverging growth dynamics in particular development periods.

Regulation of Density

Naturally regenerated stands often exhibit very high tree densities. Plantations, too, are often naturally enriched by wild seedlings of pioneer species.

Very dense regrowth of certain species, for example, Norway spruce, often requires a long time to differentiate and to start developing. A systematic reduction of the plant numbers, e.g., in the form of line thinnings, or the selection of dominant individuals and the elimination of some of their competitors prior to reaching the thicket stage, therefore, helps to initiate differentiation within the young stand and improves its further development immediately.

Removal of Ground Vegetation and Climbers

Grasses especially may cause fire hazards in dry periods and may have to be cleaned even if they are no longer competitors for the saplings (**Figure 22**). In some areas, moreover, climbers such as *Rubus fruticosus* or *Clematis vitalba* may impede the development of the saplings even when they have already reached a height of some meters.

Negative Selection, Shaping, and Pruning of Saplings

There are several situations which may justify tending measures in the early stages of young stand development, i.e., before they have reached the thicket stage:

1. Some very dominant individuals already display poor form. These young trees will suppress their better-formed, but slightly less competitive

Table 3 Factors affecting the plant density of plantations

Factor	*Influence on plant density and the subsequent procedures*
Natural pruning ability of the tree species	Most broad leaves lose their branches easily when densely planted, thereby ensuring a high-quality lower stem. They are, therefore, maintained at close spacings in their youth. Poor self-pruners, including most conifers, poplars, and wild cherry must be pruned artificially if high-quality timber is desired
Quality of planting stock	Freshly harvested plant material exhibits higher survival rates. Therefore, the plant numbers can be reduced
Weather conditions at time of planting	Rainy weather with low temperatures at planting and for some days after improves successful establishment. The choice of an appropriate planting season will also allow for a reduction in the number of plants
Plant size	Seedlings and small transplants may experience higher losses after planting. Therefore, more plants are required than is the case with taller plant material
Type of restocked area	Young plants growing under the canopy of the old stand are less susceptible to climatic stress, and attacks by insects and mice, and will therefore survive better. Their stem form also benefits from the shade. Consequently, the number of plants can be reduced
Vigor of ground vegetation	Thick layers of grasses, brambles (*Rubus fruticosus*), and bracken (*Pteridium aquilinum*) result in high losses. Therefore, taller and more vigorous plants are necessary
Anticipated browsing pressure by mice and/or deer	Based on experience, damage by deer and mice has to be anticipated and compensated for with greater plant numbers

Figure 20 Line planting normally results in pure stands because one species will always dominate, and should, therefore, be avoided.

neighbors before they reach the thinning stage. Timely elimination of these individuals will raise the quality of the whole stand and improve the selection of potential crop trees at a later stage.

2. Removal of forks of dominant individuals (often called 'formative pruning') may improve their quality, where only a limited number exist.
3. Pruning of big side-branches in groups of naturally regenerated regrowth may also help to improve the quality of the whole stand.

Early tending normally significantly reduces the effort required during the thinning phase.

Figure 21 Final stage of beech (*Fagus sylvatica*) shelterwood system (Czech Republic).

Final Considerations

Stand establishment and early treatment procedures have a direct influence on the intensity of the subsequent measures. Carefully established and well-treated young stands will later need little input in terms of the regulation of mixtures, increasing the proportion of valuable timber or aesthetic

Figure 22 Dry grasses often cause fires in young plantations (Kelheim, south-east Germany).

improvements. Initial omissions, on the other hand, may later require a great deal of energy and financial input in order to achieve the original goals. Often it is not possible to compensate for a delay in tending in the early phases of stand development. The stand will never reach the possible optimum in terms of quality or fulfillment of its functions and services.

Apart from these direct interactions between early and later interventions, the intensity of stand establishment procedures has an effect over the whole life of a stand. The species distribution, horizontal texture, and even to some extent vertical structure are largely fixed and adaptation to suit new management concepts is limited – even more so with increased age.

All procedures necessary to establish and treat young stands are investments in a distant future. Many forest owners, and society as a whole, are not willing or able to spend much money and effort on forests which they will never harvest. Furthermore, it is almost impossible to predict the future needs of society with regard to production and services of the forests. For instance, is it possible that today's quality standards for the production of valuable timber will no longer be needed in the future?

Intensive and high-quality stand establishment and treatment, therefore, require a more ethical approach: how much should the current generation invest in the future of its children and their progeny?

AGROFORESTRY

F L Sinclair, University of Wales, Bangor, UK

Introduction and Definition

Agroforestry is a term for practices where trees are combined with farming, as well as for the interdisciplinary subject area embracing land use systems, at a range of scales from that of the field to the planet, that involve interactions amongst trees, people, and agriculture. Put simply, agroforestry is where trees interact with agriculture. There is a long tradition of agroforestry practice in many parts of the world, but it has come to scientific prominence, and has emerged as a major focus in international development, only during the last quarter of a century. The term clearly derives from uniting two subject areas, forestry and agriculture, which for a long time, but not necessarily for good reasons, were institutionally separated the world over, in terms of education, research, policy development, and its implementation. As such, agroforestry has been at the forefront of much recent innovation in both farming and forestry. The principal forces driving this innovation have been the introduction of a more human perspective from the agricultural tradition into forestry, while emphasizing a more ecological as opposed to agronomic perspective in agriculture, including the longer time horizons and larger spatial scales that forestry has always embraced.

Why Agroforestry?

Interactions between trees and agriculture are clearly manifest at a range of scales from that of the field, the farm and the landscape, to that of the whole planet. Trees provide a range of valuable products such as food, fuel, fibers, fodder, and medicines that make important contributions to the rural economy, as well as influencing ecosystem services such as biodiversity conservation, water yield and quality, carbon storage, and soil conservation. Agroforestry research and development seek to improve rural livelihoods by producing more products of higher value from trees and associated crops or livestock, while conserving the resource base, in terms of ecosystem attributes like biodiversity and soil fertility, from which they are ultimately derived. Because of their large stature and longevity, trees often make important contributions to the sustainability of productive landscapes.

The Significance of Scale

At a field scale, trees may be grown in intimate mixtures with crops or grazed pasture, or cropping or grazing may occur in forests. At a farm scale, areas of farm woodland may interact biophysically and economically with crop or livestock enterprises on the farm. Biophysical interactions, for example, occur where woodland shelters an agricultural field or acts as a reservoir for crop or livestock pests or their predators. Economically, there are interactions through resource allocation of land, labor, and capital amongst competing activities in an integrated farm business.

At a landscape scale and beyond, the pattern of tree cover and agricultural land uses may combine to determine a range of productive and service functions. These include food and fuel production and their importance to the rural economy, water yield and quality across catchments, and regional biodiversity. Nutrient transfers across landscapes are often important. The soil fertility on privately owned crop land in the Nepalese mid-hills for example, is sustained by nutrient transfers via livestock from common property forest and grazing areas. Islands of fertility develop around trees in dry areas, as a result of tree litter inputs beneath the crown and animals congregating around trees and depositing nutrients there. In terms of biodiversity, farm trees in the landscape surrounding cloud forest reserves in central Costa Rica are vital for conservation of migratory birds like the resplendent quetzal. The birds are crucial to the burgeoning ecotourism industry in the country, but if they are to be retained in the reserves, then there has to be sufficient tree cover in the farming landscape for them to make their passage from the cloud forest to the coast and back.

On a continental scale, there are now attempts to manage tree cover to create a contiguous Mesoamerican corridor of tree cover connecting North and South America, and the shade trees in pastures and on coffee and cocoa farms in the region may be a vital component of this. At a global scale, it is clearly interactions amongst agricultural and forest land uses across the land surface that determine the terrestrial sink and emission of carbon and hence impact on global climate change.

Agroforestry Practices

Trees and Arable Crops (Silvoarable)

Agroforestry practices predominantly involving trees and crops are known as silvoarable or agrosilvicultural practices. These include ‘taungya,’ where farmers are allowed to cultivate crops amongst young trees during forest establishment, and various traditional and novel ways in which farmers retain or plant trees in crop fields. Important examples include extensive parkland systems that cover much of West Africa, as well as savannas more generally around the world, where farmers retain valuable and predominantly naturally regenerated native trees in their crop fields, in addition to the modern technology of hedgerow intercropping (also referred to as alley cropping), where fast-growing shrubs, that are often nitrogen fixing, are grown between strips of crops and periodically cut back to provide a nutrient-rich mulch to fertilize the crop. When practiced on slopes, as contour hedgerows, and specifically sited and spaced to reduce soil erosion, hedgerows are effective because the rate of water infiltration is increased thereby reducing runoff, and soil builds up behind the hedgerow creating biologically, as opposed to mechanically, constructed terraces.

Trees, Livestock, and Grazed Pasture (Silvopastoral)

Combinations of trees with grazed pasture are referred to as silvopastoral practices. These include various forms of forest grazing as well as trees retained in pasture to provide fodder and either shelter or shade, or both, for animals. Forest grazing may occur for predominantly productive or conservation purposes. In the UK for example, periodic grazing is now being used as a management tool to maintain open canopy woodland habitat and to retain understory ferns that would otherwise be outcompeted by grasses. In northern Europe, there has been a resurgence of interest in pasture woodland and parkland, both from a historical perspective as examples of a biocultural heritage, and for conservation of some rare lichens and fungi. Further south in the Mediterranean, the Spanish 'dehesas' that combine grazing and acorns from cork oak as fodder for pigs are of similar conservation interest, because they are the last remnants of habitat for the Iberian lynx. Dispersed trees in seasonally dry tropical pastures have recently been found to be far more important contributors to dry-season cattle diets than previously thought. In these and wetter tropical pastures, trees may also make important contributions to nutrient cycling and regional biodiversity conservation, and are an important tool for ecosystem rehabilitation in areas where forest conversion to pasture has been followed by ecosystem degradation.

Trees and Animals without Pasture

There are also agroforestry practices involving more direct interactions between trees and animals without a pasture component. These include fodder banks, where fast-growing trees in blocks provide a cut-and-carry fodder resource for livestock, and sericulture, which for 4500 years in China, has involved feeding mulberry (*Morus alba*) leaves to the domestic silkworm (*Bombyx mori*) and then harvesting silk by unraveling the cocoon. It takes over 4 tonnes of mulberry to produce a silk blouse!

Plantation Tree Crop Agroforestry and Multistrata Systems

Another important group of agroforestry practices involve combining plantation tree crops such as cocoa, coconut, coffee, oil palm, rubber, and tea either with shade trees or by intercropping between the tree crop rows. Intercropping is generally practiced amongst immature tree crops to provide short-term income before the tree crops yield, such as banana grown with rubber up to canopy closure in Sri Lanka, but there is scope for understory crops or pasture beneath mature stands of some tree crops with light canopies like coconut and rubber, or amongst cocoa bushes in extensive smallholder agroforests. For example, there is currently much interest in the understory herb *Thaumatococcus daniellii*, which grows well under mature rubber. This plant is the source of thaumatin, a substance 3000 times sweeter than sugar that is used as a natural sweetener and was selling on the London market in 2003 at over £4000 kg^{-1}, so could provide useful supplementary income for smallholder rubber growers in West Africa. Although coffee, cocoa, and tea can be grown in open conditions with high levels of inputs and intensive management, farmers often plant or allow regeneration of interspersed trees to reduce inputs required for the tree crop, modify the microclimate to control pests and diseases, or provide additional sources of income from fruit or timber. So, although often called shade trees, shade may not be their primary function. For example *Cordia alliodora* is commonly found in central American coffee plantations, as an important timber resource, whereas *Erythrina* spp. in the same plantations may be heavily pollarded and used to fix nitrogen and recycle nutrients. Income from some fruit trees such as *Dacyroides edulis* in Cameroon can be more valuable than the cocoa crop itself in smallholder multistrata cocoa agroforests.

There has been much recent interest in extensive areas of multistrata agroforests in Southeast Asia, Africa, and Latin America. Cocoa agroforests in West Africa and coffee and cocoa systems in Latin America have already been alluded to. In Southeast Asia, there are an estimated 3 million ha of jungle rubber in Indonesia, where a long rotation slash-and-burn cycle is used to produce secondary forest enriched with rubber. In northern Thailand, there are extensive areas of thinned hill evergreen forest enriched with tea that are now being considered for management as buffer areas around less disturbed forest. The forest functions provided by extensive and contiguous areas of these perennial agroforests, or land use mosaics of which they are a significant part, contrast sharply with intensive monocultural agricultural alternatives but the challenge is to ensure that they are also as productive for people whose livelihoods depend on them.

Forest Gardens and Gathering of Non-Timber Forest Products

There is a blurry distinction between these multistrata agroforests, predominantly enriched with a particular tree crop such as rubber, tea, or cocoa and more diverse forest gardens, usually close to settlements, that are used to derive a wide array of household subsistence items and some produce for sale. Often these are homegardens with a predominant tree component, as in the Kandy forest gardens on lower slopes in upcountry Sri Lanka. They are characterized by their species diversity and are usually supplementary to other field agriculture, such as paddy rice cultivation in valley bottoms in Kandy. Forest gardens appear in many forms throughout the world, with varying ratios of planted to naturally regenerated trees, from enriched forest to completely planted and manicured tree gardens, and so they vary in the extent to which their structure and species diversity is forestlike and hence their environmental significance over and above the direct benefits obtained from them by farmers. There is also a host of non-timber forest products (NTFPs) including products from undomesticated trees, herbs, and fungi, as well as insects and wild animals, that may be harvested from forest. Where people are making a regular harvest from forest resources, we see the first stages of agricultural use of forest resources, and hence an important form of agroforestry.

Reliance on Wild Trees in Agroforestry and Opportunities for Domestication

Despite their importance to local livelihoods and as foreign-exchange earners for some countries in their range, many valuable agroforestry trees remain essentially wild and hence threatened because their exploitation, without steps being taken to ensure conservation and regeneration, may be unsustainable. There is also a vast untapped potential to obtain higher value from these trees by more controlled production and marketing. Some well-known trees fall into this category, such as the shea butter in West Africa (*Vitellaria paradoxa*), from which comes a range of local foods, as well as expensive cosmetic products and a cocoa substitute sold in industrialized countries (in 2003 pure shea butter was selling in the UK for over £140 per liter as a skin cream). The baobab (*Adansonia digitata*) is a distinctive landscape feature in farmers' fields across much of Africa, from which fibers, fodder, and many other locally important products and cultural values are derived. Marula (*Sclerocarya birrea*) is a locally important fruit in southern Africa, high in vitamin C, used to flavor an internationally marketed liqueur, and is also the source of a high-quality oil derived from the kernel, which is now the basis of a new cosmetic range retailing in Europe. There are also some useful closed forest species, such as *Prunus africana* from which an effective cure for benign prostatic hyperplasia is derived. This is a condition affecting more than half the men over 60 in industrialized countries, and harvesting of bark of the tree has led to threats of local extinction in parts of its range around Mount Cameroon and in Madagascar.

While both shea and marula are marketed in Europe as sustainable tree products, from fair trade with African women in Burkina Faso and Namibia respectively, there are concerns about the age and sex ratios of some marula populations. Marula is dioecious, with different male and female trees, and it appears that there may be a tendency for people to remove male trees because they compete with crops but do not fruit. Once many males have been removed, the female trees are less likely to get pollinated by the bees that transfer the pollen from male to female trees, and so they too produce less fruit and hence become vulnerable to removal. Stopping such a spiral of decline requires research on pollination, to determine how many male trees need to be retained over what distances in the landscape; this should lead to the establishment of social structures that allow management of tree numbers at a landscape scale, involving groups of villages each comprising many individual farmers. Such links between ecological and social issues are characteristic of agroforestry. There are also a host of NTFPs including herbs and fungi that are presently harvested from the wild, from wild ginseng (*Panax quinquefolius*) in upstate New York in the USA to *Thaumatococcus daniellii* in the moist forests of Ghana and the Ivory Coast. The domestication and commercialization of these wild trees and other NTFPs to ensure sustainable production into the future is a main thrust of international agroforestry research and development.

Agroforestry as a Science and in Development

Recognition of the Importance of Agroforestry

In its short history as a scientific subject and an international development imperative, agroforestry has developed rapidly and it continues to do so. Recent trends in the focus of agroforestry research and extension are informative. We can chart its entry to the international stage, by the emergence of ICRAF, then the International Council for Research in Agroforestry, now the World Agroforestry Center, in 1978. This was 5 years after the Center for Tropical Agricultural Research and Higher Education (CATIE), which pioneered research, education, and extension on agroforestry with perennial tree crops in Latin America, had come into existence. For the first decade or so, the focus was on describing various traditional agroforestry practices around the world and developing methods for analyzing land use systems involving trees and their potential improvement paths, by drawing on contributing disciplines. These included ecology, anthropology, agronomy, soil science, and forestry. There was also intensive, predominantly agronomic, research on a few technologies, most notably alley cropping pioneered at the International Institute of Tropical Agriculture (IITA) and closely associated and sometimes confused with this, on contour hedgerows. This agronomic research was accompanied by conventional tree improvement of a few exotic, nitrogen-fixing, tree species, used in these technologies, principally *Leucaena leucocephala* and *Gliricidia sepium*. As a council, ICRAF did not have a remit to do research itself, but to coordinate research with national partners.

Changing Imperatives and Farmers' Priorities

In the early 1990s ICRAF joined the Consultative Group on International Agricultural Research (CGIAR) system and became a research center. This coincided with results emerging from well-funded and rigorous scientific research on tree crop interactions and a shift away from the centralized development of one or two technological interventions on research stations for widespread dissemination to farmers, towards encouraging local development of a wide range of tree species, in various productive and environmentally protective niches on farms and in farming landscapes. This more closely matched what farmers were doing and wanted. While contour hedgerows were a successful centrally developed and promoted technology, alley cropping with fast-growing exotic shrubs had been somewhat oversold as a panacea for replenishing and maintaining soil fertility. It was realized that it was only likely to be useful in a rather limited domain, where there was already sufficient soil fertility for fast growth of shrubs and not too much competition for water, and where land was scarce relative to labor. Improved fallow interventions, where fast-growing shrubs are grown sequentially between cropping phases rather than simultaneously with the crop, were found useful, especially in drier conditions.

There have also been a number of spectacular problems with widely used germplasm of some shrub species as, for example, the *Leucaena* psyllid that spread around the world devastating susceptible stands owing to their narrow gene base in Africa and Asia that had been selected in environments free from pest pressure. This was coupled with a realization that conventional tree improvement, involving selection for only a few traits under controlled conditions, led inevitably to trees suitable for monoculture rather than polyculture; and this spawned a move to encouraging local, village level domestication. This involved selection for improvement within, rather than outside, the farming system for which the trees were to be used. This had advantages of maintaining a broader genetic base and ensuring that people currently benefiting from exploiting the wild resource were involved and benefited from the domestication process. Emerging results of research on local knowledge revealed that farmers often already used sophisticated criteria to evaluate attributes of trees that affected both how the trees interacted with crops and soil, and how they were productive, in terms of understanding variability in fodder value and fruit quality.

In temperate regions, agroforestry gained considerable credence in the USA, Australia, and Europe as agricultural policy increasingly sought to balance environmental and productive goals.

Moving to Larger Scales and Trade-Offs Between Production and Ecosystem Services

Most recently, the scope of agroforestry research and development has on the one hand expanded to encompass landscape, regional, and global issues, while on the other it has concentrated on delivering impact locally. The landscape scale has emerged as a key focus of research and development, requiring explicit trade-offs to be made amongst stakeholders and between the productive, food, fuel, and income-enhancing functions and ecosystem services. This involves addressing natural resource management issues, involving complex interactions amongst disciplines, over large temporal and spatial scales and with groups of people with diverse interests. This has brought into sharp focus the need to develop appropriate policy environments in tandem with developing technical understanding. It is also imperative to find inclusive interdisciplinary and participatory methodologies that are rigorous enough to cope quantitatively with specific natural resource management issues, while remaining transparent enough to engage a broad enough range of stakeholders.

Biodiversity in Forests

H G Lund, Forest Information Services, Gainesville, VA, USA
F Dallmeier and A Alonso, Smithsonian Institution, Washington, DC, USA

Introduction

Interest in biodiversity began in the mid-1980s with the Biodiversity Symposium, held in Washington, DC, sponsored by the National Academy of Science. Within increasing human populations and rising demands for resources and living space, the need to conserve biological diversity rose to the forefront with the development of the Convention of Biological Diversity (CBD) in 1992. The purpose of the Convention is to conserve biological diversity, promote the sustainable use of its components, and encourage equitable sharing of the benefits arising out of the utilization of genetic resources. Biodiversity inventories provide the building blocks upon which to carry out the intent of CBD and to meet local needs. Using inventories as the base, industry and other development opportunities should incorporate biodiversity within their management practices.

The concept of biological diversity is defined in Article 2 of the CBD as follows:

> 'Biological diversity' means the variability among living organisms from all sources including, *inter alia*, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems.

It is widely recognized that the earth's biodiversity is poorly known. Although 1.75 million species have been discovered and described, the number will be much greater once we include bacteria, viruses, most of the marine species, and most of the arthropods. There is no doubt that we are now destroying this diversity at an alarming rate. No one knows exactly what the current extinction rate is, but recent calculations put it at between 1000 and 10 000 times greater than it would naturally be. The rate of extinction also appears to be increasing. Species are threatened in every habitat on every continent, though the severity of threat varies from place to place. A vital question is how badly this loss affects ecosystem functioning and our eventual well-being. Although current studies are impressive, they are tiny in comparison to the amount of unknown diversity and the urgency and importance of finding out what are available and taking steps to preserve and sustainably use the remaining.

The CBD obliges signatory nations to undertake an inventory of their biological diversity to provide basic information about the distribution and abundance of biodiversity. Such data are necessary for the long-term sustainable management, use, and conservation of biodiverse areas. Parties are to monitor the elements of biological diversity, determine the nature of the urgency required in the protection of each category, and sample them in terms of the risks to which they are exposed. They are to report on the biotic wealth and national capacity, the goals and gaps, strategic recommendations, and characteristics of the action. Specifically, under Article 7. Identification and Monitoring, nations are to:

- Identify components of biological diversity important for its conservation and sustainable use
- Monitor components of biological diversity, paying particular attention to those requiring urgent conservation measures or which offer the greatest potential for sustainable use

- Identify processes and categories of activities which have adverse impacts on the conservation and sustainable use of biological diversity, and monitor their effects
- Maintain and organize data derived from identification and monitoring activities.

Forest certification systems resulting from agreements in the United Nations Conference on Environment and Development (UNCED), Agenda 21, include criteria, indicators, or principles that address biodiversity as a critical component to sustainable development.

In order to meet the above requirements, parties need inventories of biological diversity. The objectives of biological diversity inventories may be to:

- Identify priority conservation areas
- Provide the necessary baseline data for monitoring the effects of anthropogenic disturbance or climate change on the biota
- Detect changes in ecological diversity that exceed the range of natural variation, across a range of spatial and temporal scales
- Provide an 'early warning' of impending irreversible changes
- Provide reports to the public on the status of ecological diversity in a timely and accessible manner
- Meet national and international commitments for monitoring biodiversity
- Provide data consistent with the requirements of forest certification programs.

Biodiversity Types

CBD addresses three types of diversity: genetic, species, and landscape or ecosystem. Each has special features and challenges for inventory.

Genetic Diversity

Genetic diversity is the degree of variability of the genetic material of an organism. Assessment of genetic diversity is time-consuming and prohibitively expensive, requiring modern laboratories and expensive chemicals. Species are defined by the differences in their genes. Therefore, one often uses species diversity to estimate genetic diversity.

Species Diversity

Species diversity encompasses the number, types, and distribution of organisms found in a given area. Species diversity is the standard unit of measurement in most biodiversity surveys. The advantage of inventorying species is the advantage of being natural biological divisions and that they are easily identifiable. Many people already know high-interest organisms such as flowers and birds so identification of these organisms is relatively easy.

However, there are a very large number of species. A high proportion of them, particularly invertebrates, are as yet undescribed. Moreover, the identification of described species often requires a high level of expertise. Identifying all species in even a limited area is generally impracticable.

A common solution is to select certain taxa as indicator groups to act as surrogates for the whole biological diversity. Using indicator species can reduce the cost of the survey. The following options for indicators are in order of preference.

1. Best estimates: using genealogy to predict genetic or character richness.
2. Popular estimates: using species richness.
3. Practical estimates: using higher taxa or environmental variables as surrogates.
4. Relationship among estimates: a scale of surrogacy for mapping more of biodiversity value at lower cost.

To be effective, indicators should be:

- readily quantifiable
- easily assessed in the field
- repeatable and subject to minimal observer bias, and cost-effective
- ecologically meaningful – that is, to be representative of the taxic variation, microhabitats, and trophic diversity in the area and in close association with, and identification of, the conditions and responses of other species.

Scarce and less familiar species with short mean generation times may respond most rapidly to environmental deterioration. Thus these may make better indicators for environmental monitoring than the larger, better-known organisms.

Landscape Diversity

Landscape diversity refers to the spatial heterogeneity of the various land uses and ecosystems within a larger area. Surveys of landscapes are useful for locating and prioritizing areas to protect. The natural environment is a highly variable continuum and is difficult to divide into a series of discrete, discontinuous units. Remote sensing and geographic information systems (GIS) obviate the need to develop the complex habitat and ecosystem classifications. Different, measurable attributes of the environment can be stored in separate layers within a GIS, such as soil characteristics, altitude, rainfall, percent canopy cover, mean height of dominant vegetation, and distributions of individual species. These can then be played back in any number of ways.

Inventory Challenges

When compared to traditional forest surveys, the challenges for biodiversity inventories include the number of species, their mobility and/or seasonality, and time and resources available.

There are between 10 and 20 million species on earth. This is about 10 times as many as have been formally described by taxonomists in the past 250 years or so. Most species occur in the tropics, where taxonomic resources are scarcest. When considering all the species that may be present in an area – from insects to mammals, and from fungi to trees – it is generally impossible to enumerate and count each and every species in a given area. Consequently, taxonomically complete inventories are rarely conducted unless the area is very small.

Because of the vast differences in goals and areas to be surveyed, there are no well-defined rules as to how to perform biodiversity surveys. Unlike trees, fauna are mobile. Some flora and fauna may only be found during certain times of the year. Selecting the time to do an inventory is a major challenge.

Lastly, inventories take time – for planning, execution, and analysis – and time is running out for many species. Any inventory is costly. Inventories involving biological diversity are exceptionally costly, primarily because of the expertise necessary to locate and identify species. Taxonomic resources available to undertake large-scale inventories are few and far between. Accurate inventory requires access to reference collections and literature. These resources are primarily concentrated in the large museums of a few temperate countries.

To be able to make judgments concerning status and changes we have to have methods of measurement. Information on the identity, location, population size, or community distribution of a resource is obtained initially by field inventory and frequently displayed as resource maps. Inventory and monitoring of biological resources provide baseline information on the presence and distribution of biological resources and biological information necessary to implement adaptive management.

Types of Biological Surveys

There are two general types of biological surveys – taxonomic and abundance. Taxonomic and abundance surveys may be scientifically designed, where the sampling is repeatable, or search-based inventories, where it is not. The limitations of search-type inventories include nonrepeatability due to lack of predetermined and documented sampling protocols. The advantage of searching is that it may provide the most taxonomically complete inventory.

Taxonomic Surveys

Taxonomic surveys are undertaken to locate and document occurrences of particular species, in other words, what species exist in forest A. The primary goal of surveying the flora and fauna is to develop a list of the different species that are present on the site and not necessarily their numbers and condition. The data gathered are used to identify new occurrences of sensitive species, monitoring endangered populations, evaluating conservation priorities of an area, and bioprospecting. Sampling should take place in both undisturbed and disturbed areas.

The sampling of vegetation is more or less straightforward – plots and transects. The survey of fauna – things that move – is slightly more difficult. As a result, we see more subjective and opportunistic methods being used.

Vegetation is frequently observed and measured using fixed-area nested plots. The size of the plot or subplots will depend on the vegetation being observed. Large plots, such as 5×20 m, may be used for recording trees where plots as small as 2×0.5 m may be used for herbaceous vegetation. A series of permanent nested plots may provide information on spatial patterns of species and allow for statistical comparisons and can be used to detect trends in richness over time.

Transects for noting both flora and fauna biological diversity often utilize gradient-directed sampling. Transects are selected to transverse the steepest environmental gradients present in the area, while taking into account access routes. This technique is appropriate for rapidly assessing species diversity, while minimizing costs, since gradient transects usually capture more biological information than randomly placed transects of similar length.

Arthropods are often sampled using pan traps or pit-fall traps placed in microhabitats. Microhabitats may be identified based upon soil particle sized, amount and type of litter, surface moisture, vegetation structure, dominant plant species, and degree of shade. Voucher specimens are also used to sample invertebrates since most species are poorly known and difficult to identify.

Amphibians and reptiles are sampled using a variety of methods, including visual and audible searches along transects and within quadrats, sticky traps, and pit-fall traps. Sites are often subjectively selected to ensure sampling of all habitats and to minimize the number of species encountered.

Birds are sampled using mist-netting, point counts, and transects. The advantages of mist-nets are that:

- relatively little training is necessary to set up the nets and collect the birds
- identification tools may be used with birds in hand
- the method does not require vocalization knowledge
- the repeatability and accuracy of the data collected are high
- data can be collected on the physical condition of the birds
- recapture provides demographic data
- secretive and inconspicuous species may be detected.

Vocalizations and observations are used in point counts and transects. They have the advantage that they are less labor-intensive than mist-netting, they sample a larger proportion of the bird community, and estimates of population density may be obtained. The main disadvantage is the significant training in recognizing the birds and their calls.

Trapping is often used to sample small mammals. The advantage of trapping is that it may also provide voucher specimens.

Large mammals are surveyed using direct observations, aural identification of animal vocalizations, scent-post surveys, use of mammalian signs, and trapping.

Abundance Surveys

Abundance surveys focus on the number of given species – in other words, how many gold finches are found in forest A? They are used for developing and evaluating management plans. These generally use remotely sensed data, GIS systems, preexisting cartographic maps and inventories and field sampling. One may collect either qualitative data (presence/absence, also known as binary) or quantitative data, in which the numbers of individuals for each species are counted.

Biodiversity Inventory Strategies

There are two strategies for conducting biodiversity inventories – those for rapid assessment and those for baseline. Both may be used as a base for monitoring.

Rapid Assessment

Rapid-assessment methods and sampling for indicator species are designed to identify and monitor selected biotopes of critical value. These surveys are often conducted on a regional or national basis to supply information necessary for the selection of conservation areas and other types of land-use planning. They may also be conducted locally where some type of land-use activity is planned. Speed is critical. Thus it is natural to focus on well-known and easily recognized organisms, such as mammals, birds, trees, and butterflies.

These assessments often employ a ‘top-down’ analysis that begins with an assessment of the natural communities present and their relative quality and condition. This information is subsequently used to determine where different species-oriented surveys should be conducted. This approach, commonly referred to as ‘coarse filter – fine filter,’ concentrates inventory efforts on those sites most likely to contain target species. These are very quick surveys that can be used to identify, with high spatial resolution, and within a short time frame, priority areas for the conservation and sustainable management of biodiversity.

Rapid assessments are carried out to identify areas quickly that need immediate protection. They usually consist of mapping out areas to be preserved. They are often conducted by teams of scientists and local experts aimed at identifying areas that have or are likely to have considerable diversity of species – especially those that may be considered rare or endangered.

Baseline Assessment

Once one has established conservation areas or areas of concern or importance, then there emerges the need for monitoring and for knowing what is present in order to manage the resource. This requires the second type of inventory – baseline assessment, which focuses species. Baseline assessments are designed to find out what is in a given area and may include taxonomic surveys or abundance surveys. They are used as a foundation for monitoring change.

Sources for baseline assessments include satellite data, aerial survey, existing maps, field survey, and expert advice. One can combine these disaggregated data sets in a GIS to generate maps according to need.

Monitoring and Evaluation

Monitoring is the act of observing something, especially on a regular or ongoing basis, and keeping a record of observations made. The main objective of monitoring is to reveal discrepancies between forecast and achievement in time for remedial actions to be taken. It also provides critical information to identify natural changes from human-induced changes.

Repeated surveys allow examination of time and spatial changes. Monitoring sites may consist of both permanent sites (visited one or more times each year) and nonpermanent sites. The permanent sites may be stratified across the different kinds of habitat/plant communities, replicated for each habitat/plant community monitored, and reflective of the different grades of habitat quality or condition. Landscape-level monitoring at the ecoregion level is often dependent on acquiring the appropriate GIS-based vegetation maps.

Monitoring can serve as a warning system, alerting managers that change in biodiversity may require changes in management regimes to ensure protection of scarce resources. Monitoring involves the repeated collection and analysis of observations and measurements to evaluate changes in populations of species and environmental conditions.

If there is the possibility that a sampling area may again be visited again, permanently mark the plots for remeasurement. Use care in remeasurement, take care to prevent an area from being overly disturbed. Permanent monitoring plots that collect reliable data can also act as standard reference points for the interpretation of changes observed by satellite.

Monitoring often occurs at the population (individual or multiple species) or ecosystem (individual or multiple habitats/plant communities) levels to facilitate tracking trends in resource size or distribution. Monitoring may also be conducted to obtain information on the condition of the resource and includes tracking characteristics such as contaminant concentrations, health of individuals, population vigor, and habitat quality. Lastly, monitoring can occur at regional scales that enable tracking changes in land use and fragmentation patterns.

For monitoring to be effective:

- Baseline (i.e., inventory) information must be collected or available.
- Monitoring objectives must be established.
- Monitoring actions must be repeated over time using consistent, standardized procedures.
- Monitoring results must be interpreted relative to the baseline information and the monitoring management objectives.

Quantitative data are more desirable for monitoring. They allow changes in the population to be measured instead of the population simply being recorded as present or absent.

Steps for Developing a Biodiversity Inventory

The steps are similar to those for developing most any other type of resource inventory and monitoring program:

1. Carry out a stakeholder consultation to identify the issues.
2. Gather known information.
3. Define assessment and baseline programs together with management objectives.
4. Define the issues and develop options throughout the process.
5. Implement assessment.
6. Implement adaptive management, assess and monitor.

Carry out a Stakeholders' Consultation to Identify the Issues

Develop and record the long-term rationale, objectives, and design of the monitoring program. Establish goals and objectives and the biodiversity endpoints that an agency, organization, or company wishes to assess and maintain.

Gather Known Information and Lay Necessary Groundwork

Make use of existing biodiversity-related data and analyze in a GIS-based format if possible. Existing information may consist of maps, reports, data, taxonomic specimens, personal knowledge, and remote sensing imagery. Information on areas similar to the one under study is also helpful.

Define Assessment and Baseline Programs Together with Management Objectives

The purpose may be to determine the extent, distribution, and condition of existing vegetation types, the probable distribution of species of concern, and the distribution (and intensity) of stressors (e.g., habitat fragmentation). Establishing baseline conditions may require the integration of monitoring programs and data-sharing among other landholders and resource agencies within the ecoregion.

- Delineate areas of high species richness and endemism, as well as areas and ecosystems at high risk of impoverishment because of their particular susceptibility to human-induced stressors. The preceding areas warrant more intensive monitoring.

- Identify indicators of structural, functional, and compositional biodiversity at several levels of the hierarchy that correspond to endpoints.
- For each major class of habitat (which may contain different plant communities), identify control areas (i.e., generally free from human-induced impacts) and areas subject to more intensive management or environmental stress.

Define the Issues and Develop Options Throughout the Process

Through the stakeholder workshops and consultation process, identify critical biodiversity issues related to the operation. Formulate specific questions to be answered by monitoring. Typical questions may include:

- Are populations of species of concern declining, stable, or increasing?
- What are the patterns of species diversity across habitats and plant communities?
- Is the diversity, at its different levels of organization, declining, stable, or increasing?
- How are the size, distribution, and condition of native habitats and plant communities changing? How does biodiversity differ between natural and artificial ecotones (i.e., transitional areas between ecosystems or plant community types)?

Specify thresholds for the biodiversity endpoints that will trigger the need for changes in management practices.

Identify resource needs Understanding the resource needs and ascertaining the level of support are essential to ensure success of the biodiversity inventory. Critical resources may include time, commitment, and funding allocated to the project, as well as a sufficient number of people trained to conduct biodiversity assessments, devise the monitoring strategies, and improve the sampling protocols. These elements need to be balanced with professional expertise, adequate technology to manage information and voucher collections, and an appropriate budget for field equipment, data management, and publications.

Define spatial and temporal scales The scale at which the survey is carried out depends upon the goals of the project and on the unit of biodiversity being used. The scale should be appropriate to the organisms being surveyed.

The frequency of monitoring depends largely upon the goals of the project and the life history of the species; population changes that may be the result of regular cyclical fluctuations may appear drastic if the cycle is not known. Consideration of such natural cycles is important to the monitoring of populations.

Design protocols The next step is to design a monitoring protocol to address issues such as sampling design, data management and analysis, interpretation of results, and reporting mechanisms. Design requires a balance between time and effort and interpretability of data.

For taxonomic surveys, sampling effort can be expressed in many ways: as search time per site, as search within a given distance of a reference point or line, or as total number of sites or replicates needed to find a pattern. Setting a definite time limit also allows the survey to be more standardized and results can be compared from year to year.

For a survey to be considered scientific, it should be random. Consider using a grid covering the entire area of interest. A systematic network of fixed sample points across the entire region is one approach that would sample most vegetation types proportional to their size and at the same time be low-cost.

Different data collection approaches may be used to meet the above objectives.

Respond to emerging lessons and reassess objectives Ask:

- Have the objectives been clearly stated and are they realistic?
- What monitoring protocols are required to achieve the biodiversity conservation objectives? What is the timeline for accomplishing the objectives?
- Will the information that is gathered assist managers in making informed decisions?
- Can the results of the management decisions be statistically analyzed?
- Has a cost – benefit analysis been completed?
- What is the scale of the monitoring program?
- What kinds of teams and organizations are required to achieve the objectives?

The monitoring strategy will continually evaluate the relevance of its biodiversity endpoints, the questions asked, the indicator variables selected for monitoring, and their relationships. Changes to the monitoring strategy and its in-the-field protocols will be made as necessary.

Implement adaptive management, assess, and monitor Assessment and monitoring protocols are essential to develop a solid scientific foundation for biodiversity monitoring. In recent years, there has been an increased emphasis on standardizing monitoring protocols to facilitate comparisons among different projects. The long-term data obtained from implementation of such protocols are helpful in detecting the magnitude and duration of change, how related taxa are changing, and early-warning indicators of ecosystem health. They serve as the basis for formulating additional research hypotheses, and most importantly, the data can be used to guide management decisions for biodiversity conservation.

The results of monitoring should be analyzable in a statistically rigorous manner. Also, the results should be capable of synthesis into an assessment that is relevant to policy-makers and that can be used to make positive changes in management direction.

Continually evaluate how well the selected indicators correspond to the biodiversity endpoints of concern. The results of the biodiversity monitoring effort should be used as an important component of adaptive management. If monitoring indicates an adverse change in the resources then the monitoring results should be used to formulate appropriate changes in management actions.

Linking with other Inventories

Biodiversity inventories, by design, are often limited to very specific sites. However, such inventories may overlook other sites that need protecting. Therefore some types of broad area inventories are desired. Where possible and feasible, these inventories should be incorporated within existing resource management inventories such as forest surveys by adding new variables to be collected in the field such as:

- characteristics of habitats (springs, moist land, land with a high biological value)
- characteristics of forest/vegetation margins (length, form, and structure)
- description of vegetation in the grass, shrub, and tree strata
- effects of other uses of the land (agriculture)
- geohydrological features: surface and subsurface water resources
- land-use history and changes over time (grazing, agriculture, special practices)
- quantities and dimensions of standing and fallen dead trees, and of rotten trees, and the extent of such rot
- soil and the land form/geological features, including variables subject to change over time
- remarkable vegetation from the viewpoint of their phenotype.

Such additions to ongoing natural resource inventories may effectively improve our knowledge of the biological resources with minimum effort.

Plant Diversity in Forests

D F R P Burslem, University of Aberdeen, Aberdeen, UK

Measurement of Diversity

Diversity can be measured either as species richness, the number of species per unit of land surface area or per unit number of individuals in a sample, or as a derived index that attempts to reflect the variation in relative abundance within a community as well as its richness. Commonly used indices of diversity are the Simpson's index (D) and the Shannon index (H), which are defined as follows:

$$\text{Simpson's index } D = \frac{1}{\sum_{i=1}^{S} P_i^2}$$

and

$$\text{Shannon index } H = -\sum_{i=1}^{S} P_i \ln P_i$$

where S is the total number of species in the community and P_i is the proportion of individuals represented by the ith species. These indices have the useful property that their values increase with greater evenness in the relative abundance of species for a given species richness.

Distribution of Diversity at Large Scales

At a global scale, the diversity of plants in forests, as in all plant communities, varies with climate and soil conditions, although there is also a pervasive imprint of history that disrupts large-scale relationships between plant diversity and biophysical conditions under some circumstances. The relationship between climate and plant distribution was promoted by the systematic collation of climate data by the German ecologist Heinrich Walter that allowed him to conduct a comparative analysis of the distribution of diversity at large spatial scales. By representing climates using a standardized format (referred to as a 'klimadiagram'), Walter proposed a hierarchical classification of world vegetation in which vegetation 'types' are nested within vegetation 'zones.' Four of Walter's vegetation zones possess vegetation types that can be described as forests: the tropical-cum-subtropical, warm temperate, cool temperate and cold temperate vegetation zones (the fifth, the Arctic vegetation zone, does not possess forests although dwarf trees are present in Arctic vegetation). Walter determined that the distinction between vegetation zones was determined on the basis of temperature, and that the series of vegetation types within each vegetation zone were differentiated on the basis of rainfall-related criteria.

Temperature

Classifying vegetation was the first step to obtaining a mechanistic understanding of the distribution of world vegetation. Subsequent work has refined our knowledge of the distribution of diversity, and robust generalizations are now possible. First, it is evident that forests lying closer to the equator possess a higher plant species richness and diversity than forests at higher and lower latitudes. This statement assumes that the comparison being made is of forests at the same altitude, subjected to equivalent rainfall regimes and excludes forests growing on soils that are deficient in their availability of plant nutrients, such as N, P, or K, or supply an extreme of potentially toxic elements such as Ni or Al. Thus a hypothetical transect starting on the equator in wet evergreen tropical lowland rainforest in Southeast Asia and running north through the warm temperate evergreen and cool temperate deciduous forests of eastern Asia and thence into the cold temperate (boreal) forest of eastern Siberia would encounter forests of decreasing plant diversity with increasing latitude. This gradient in plant diversity is expressed among the trees that form the forest canopy, but is also observed among other life-forms such as shrubs and herbs. Some life-forms (such lianas and epiphytes) are rare or absent outside the tropics. Similar transects running north from equatorial forests in Africa and South America would not encounter such a well-ordered sequence of vegetation zones. The southern hemisphere lacks cool temperate deciduous forests at low altitudes and lacks boreal forest entirely because the continental land-masses do not extend sufficiently far south. Diversity of plants in forests also declines with increasing altitude on mountains at all latitudes, although the precise nature of these changes varies as a function of local site conditions.

Rainfall

The second most important factor influencing the distribution of plant diversity at large spatial scales is the amount and seasonal distribution of rainfall. Walter recognized series of vegetation types related to such changes in moisture regimes within each of the five vegetation zones, and in climates that are capable of supporting forests, vegetation types are synonymous with forest types. Within the tropical-cum-subtropical vegetation zone, which lies at the lowest latitudes in South and Central America, Africa and Madagascar, South and Southeast Asia, and the Pacific, plant diversity in forests decreases along the series of vegetation types represented by tropical lowland evergreen rain forest, tropical semievergreen rainforest, tropical deciduous forest and Savanna. At these latitudes, plant diversity is lowest in semidesert and perennial plants are absent from true deserts, but these are not forests. Along this series, mean annual rainfall declines from approximately 1800–5000 mm in climates supporting evergreen tropical forest to approximately 250–700 mm in climates supporting Savanna vegetation, while the number of dry months per year (defined as months that receive <100 mm on average) increases from 0–4 to 7–11 for the same comparison. Both total annual rainfall and the seasonal distribution of rainfall have important influences on plant distribution and diversity in the tropics. At the wetter end of the gradient, the transition between vegetation types is driven by the number of dry months rather than the total annual rainfall, but the converse is true at the drier end of the main climatic gradient.

Series of vegetation types related to variation in moisture regimes can also be recognized in the warm, cool and cold temperate vegetation zones and in the (nonforested) arctic vegetation zone, and plant diversity in forests declines in successively drier climates at these cooler latitudes, as it does in the tropics. The warm temperate series possesses just two vegetation types that can be described as forests: warm temperate rainforests in wetter environments and Mediterranean-type forest (or Savanna or scrub) in sites that experience a winter maximum of rainfall and a distinct cool season. Warm temperate rain forests tend to occur on the eastern fringes of continental land-masses (for example in Japan, south-eastern Australia, and New Zealand) and are intermediate in species richness between evergreen tropical rainforests and temperate deciduous forests. Both the cool and cold temperate vegetation zones also contain two vegetation types that can be described as forests. Cool temperate rainforests occur in areas with a maritime climate that receive winter rains and no summer drought in both the northern hemisphere (in a coastal strip from northern California to Canada) and the southern hemisphere (coastal areas of southern Chile). The characteristics of these two blocks of cool temperate rainforest differ considerably: in the northern hemisphere the characteristic tree species are gymnosperms and include, for example, the redwood (*Sequoia sempervirens*), while the southern hemisphere equivalent is dominated by species of southern beech (*Nothofagus* spp.). In less distinctly maritime temperate climates the dominant forest trees are deciduous and these conditions give rise to the cool temperate deciduous forests of eastern North America and western Europe. There is no southern hemisphere equivalent of these cool temperate deciduous forests. At higher latitudes in the northern hemisphere there is a transition to forests in which gymnosperm trees become dominant across the landscape and in which plant diversity is markedly lower than in the cool temperate forest types just described. These are the cold temperate or boreal forests that circle the northern polar regions. In Europe these forests are referred to as 'taiga' and are dominated by just two species (*Pinus sylvestris* and *Picea abies*), while the North American and East Asian boreal forests are more species-rich. In the most continental climates (i.e., those that experience the lowest winter temperatures and the lowest annual rainfall) of the boreal forest region in eastern Siberia, the evergreen forest gives way to a species-poor forest of deciduous conifers such as larch (*Larix dahurica*). Larch forests clothe 2.5 million km^2 of eastern Siberia, but there is no equivalent climate or forest type in North America.

Soil Conditions

The third factor in the hierarchy of determinants of the distribution of plant diversity in forests is soil conditions. This term by itself obscures a variety of different factors that contribute to plant diversity, and global generalizations are unlikely to be satisfactory. Theoretical models of plant competition can be interpreted to predict either an increase or a decrease in plant diversity along a gradient of soil fertility, and empirical tests of these ideas are few in number. Part of the difficulty with testing these ideas is that changes in soil conditions rarely occur in isolation of changes in climate, in part because climatic conditions themselves influence physical and chemical processes in soils. However, two examples from tropical forests can be used to infer an influence of soil nutrient availability on forest plant diversity.

First, lowland forests in relatively aseasonal environments in the western part of the Amazon basin possess a higher diversity and richness of forest trees than forests in equivalent climates in the eastern Amazon. One potential cause of this difference is the greater nutrient availability in the relatively young volcanic soils in the western Amazon, although it may also be relevant that forests of the western Amazon are exposed to a higher frequency of disturbance by meandering rivers. Disturbance may influence plant diversity in a variety of ways as described below. The second example is less equivocal. Among the tropical lowland forests of both South America and Southeast Asia are patches of forest on highly nutrient-starved podzolic soils characterized by a thick organic layer and a bleached sand-rich mineral horizon. These forests are referred to as 'kerangas' in Southeast Asia and by a variety of labels, including 'caatinga,' in South America, and in both cases they are examples of heathland ecosystems. They are all characterized by a low richness of plant species, including trees, when compared to adjacent forests on richer soils. The mechanisms that determine the relatively low species diversity of tropical heath forests are unknown, but it is possible that the physiological and morphological trade-offs required to tolerate low nutrient conditions have evolved relatively infrequently in tropical lowland tree floras. Similarly, forests growing on soils that supply an excess of plant nutrients that are also potentially toxic at high concentrations (such as Ni in ultramaphic vegetation) are species-poor compared to adjacent forests growing on less extreme soils. Mangrove forests are also species-poor relative to dry-land forests in similar climates, presumably because the physiological adaptations required to tolerate high internal Na concentrations have evolved only rarely.

Other Determinants of Plant Diversity

Taken together, the interpretation presented above could be taken to imply that variation in plant diversity can be explained on the basis of deterministic processes that are driven by the biophysical environment. However, this would be an oversimplification of the origins of variation in forest plant diversity. At least three additional factors must be considered as important in any explanation of diversity: these factors are biogeographic history, the size of the local and regional species pools, and disturbance.

Biogeographic History

The effects of biogeographic history pervade the distribution of diversity, particularly at large spatial scales. Regional differences in diversity have arisen because the distribution of the continents has changed during the evolution of land plants, and because climate itself is not constant in time at any one locality. Thus the effects of tectonic drift and climate change are superimposed on contemporary climate and soil conditions as important determinants of present-day plant diversity. Two examples will be used to illustrate these processes. First, it is well known that the diversity of forest trees in the cold temperate deciduous forests of eastern North America is greater than in the equivalent forests of western Europe, despite the equivalence of the current climate of these regions. This difference has been explained by the difference in the ease of migration of forest trees in North America (where the mountains run north–south) and Europe (where the mountains run east–west) in response to Pleistocene glaciations. As mountains might represent a barrier to plant dispersal, it has been suggested that in Europe plants are prevented by the Alps and the Pyrenees from migrating into relatively warm climates during the onset of glacial conditions in north and west Europe. Similarly, recolonization of formerly glaciated landscapes in northern Europe from refugia in south and eastern Europe is slowed by these montane barriers to dispersal. These barriers to the movement of plants do not exist in eastern North America because the dominant mountain chain (the Appalachians) runs north–south, and dispersal can occur along lowland valley corridors.

The second example illustrating the importance of biogeography derives from the observation that the lowland tropical forests of Africa are less rich in species than forests of tropical South America and Southeast Asia, when sites with a similar contemporary climate are compared. Again, it is possible to interpret this difference as a reflection of changes in climate during the Pleistocene interacting with differences among the continents in the distribution of land at different altitudes. The cumulative frequency distribution of land surface area with increasing altitude rises much faster for Africa than for either of the two other continents, which suggests that average elevation of lowland tropical forest sites is greatest in Africa. Under current climates these differences are not sufficient to fragment lowland forests in Africa, but during drier and cooler phases of the Pleistocene the proportion of the landscape that would have provided climatic conditions suitable for the maintenance of a lowland tropical forest flora would have been much lower in Africa than in South America or Southeast Asia. Thus the African forests would have become more fragmented, and extinctions of forest trees would have been more prevalent. The differences we observe today are a reflection of these interactions between landscape structure and climate change.

Size of the Species Pool

The second major factor that might disrupt the relationship between biophysical conditions and forest plant diversity is the size of the local and regional species pools. As discussed above, historical explanations can account for some differences in the number of species available to colonize a site, but other factors are also involved. These ideas were brought together in MacArthur and Wilson's theory of island biogeography, which was originally formulated as a theoretical exploration of the effects of island size on species richness, but has now been applied to island-type ecosystems on nonislands. MacArthur and Wilson proposed that the number of species occupying an island could be explained in terms of a dynamic equilibrium between local immigration, emigration, and extinction events. Since the probability of colonization and extinction can be modeled as a function of factors such as island size and remoteness from a source population, it is possible to derive theoretical predictions for island species richness as a function of these factors. The most important of these functions is the species-area relationship, which takes the following form:

$$S = c.A^z$$

where S is species richness, A is island area, and c and z are constants. This function implies that the log of species number is a linear function of log island area.

There are many demonstrations of the effect of increasing area on species richness, including some for forest trees. However, there is also controversy in the ecological literature over whether the increase is driven by a pure 'area effect,' or whether larger areas of island or habitat-island are richer because they contain a greater diversity of habitats. Nonetheless the theory of island biogeography helps explain why remote oceanic islands, such as Hawaii and the Galápagos Islands, possess relatively species-poor floras for their climate and may help to explain why habitat fragmentation reduces forest plant diversity.

Disturbance

The final factor that must be considered in any consideration of the mechanisms driving forest plant diversity is disturbance. Disturbance is defined and described elsewhere in this volume (*see* **Ecology**: Natural Disturbance in Forest Environments). Forests are subjected to a variety of types and scales of natural disturbance processes, and are also heavily influenced by human activities. By definition, disturbance has short-term negative impacts on diversity at the scale at which the disturbance occurs, for example by removing individuals through tree mortality. However, the relationship between disturbance and diversity at larger and longer spatial scales is complex and not necessarily predictable. One of the most influential theoretical models of the relationship between disturbance and diversity is Connell's intermediate disturbance hypothesis (IDH), which proposes that diversity of plant communities is maximized at the mid-point of plant succession, and in communities that are subjected to intermediate intensities or frequencies of disturbance. According to the IDH, sites very early in succession or those that suffer a high frequency or intensity of disturbance have a low diversity because relatively few species possess the traits associated with colonizing unoccupied or heavily disturbed sites. Diversity initially rises through succession because site conditions are ameliorated by the earliest colonizers, and because species accumulate by random dispersal events, but declines in late succession because a small number of competitively superior species are able to co-opt the available resources and exclude the early colonizing species. However, in most communities the low diversity, late-successional communities rarely arise before a new disturbance event sets back succession to an earlier stage. Thus, diversity is maximized at the mid-point of succession when early-successional, disturbance-dependent species coexist with late-successional competitive dominants.

The IDH is a controversial concept and has rarely been tested adequately for forests. However, in one recent test in a lowland tropical forest in French Guiana it was found that tree species diversity was greater in lightly logged forest than in unlogged forest or forest that had been heavily logged, in support of the IDH. Other attempts to test the IDH in forest communities have either failed to find support for it, or have been flawed in their design or interpretation.

Disturbance to forests by anthropogenic activity can reduce plant diversity, particularly in the tropics. The principal drivers of disturbance are clearance for permanent agriculture and plantation forestry, shifting cultivation, and logging. Fragmentation has independent effects on forest plant diversity because fragmentation increases the amount and importance of edge habitats and brings forest edges close to species that inhabit the forest interior. Small forest fragments also reduce the effective population size of plants and thus increase their probability of extinction (*see* **Ecology**: Biological Impacts of Deforestation and Fragmentation).

Conclusions

Although patterns in forest plant diversity at large spatial scales are now well described, there are still substantial lacunae in the record that can only be resolved by additional botanical exploration. In some parts of world (for example, areas of the Philippines, Indonesia, and the Atlantic forest of Brazil), it is likely that deforestation and forest fragmentation have already eliminated any further scope for describing natural patterns of forest plant diversity at a more local scale. The mechanisms that determine the large-scale patterns in plant diversity remain poorly understood and are likely to vary substantially between regions and localities. Current theories suggest that the diversity of forest floras reflects a balance between biophysical, historical, and anthropogenic causes, but robust predictions of diversity at a local scale are not yet possible.

Endangered Species of Trees

G T Prance, University of Reading, Reading, UK

Introduction

Unfortunately the topic of endangered species of trees is a vast one because of the extensive loss of their habitat in most parts of the world and in many cases because of overexploitation. The World Conservation Union's (IUCN) *Red List of Threatened Plants*, published in 1997, lists almost 34000 species of plants that are now threatened with extinction. That is just over 10% of the total number of plant species in the world. These lists include many species of trees. Red data lists exist for many countries and are catalogs of species where future survival in nature is uncertain. Most threatened species of trees are those of the tropical regions and on oceanic islands, in the tropics because of habitat destruction and because of the enormous diversity and often localized distribution of individual species, and on islands because they tend to have many unique endemic species, but also because of habitat destruction and the introduction of alien invasive species that take the place of the native flora. For example, about 85% of the Madagascan flora is endemic to that island nation and only 20% of the original vegetation remains. It is therefore inevitable that some species have gone extinct and others are under threat. A recent red data book for the ten countries of southern Africa cataloged 3900 taxa that are threatened with extinction and listed 33 that are recorded as being extinct.

Areas of the world such as Madagascar where wildlife and plants are richest and are most endangered have been termed 'hot spots' by ecologist Norman Myers. It is in these areas where most species of trees are also endangered. One particularly critical hot spot is the Atlantic Forest Region or *mata atlântica* of Brazil. This narrow strip of rainforest along the coast contains many endemic species of plants and animals. A study of a sample of tree species from that region carried out in 1981 showed that 53.8% of the sample of 127 tree species were endemic to the Atlantic forest and another 11.8% endemic to the coastal forest plus some part of the rapidly disappearing forests of the Planalto of Central Brazil, for example jequitibá (*Cariniana estrellensis*) (see **Figure 3**). It has been estimated that 6000 species of plants are endemic to the coastal forest hot spot. This region is classified as a hot spot because only about 7% of the original vegetation remains. The forest has been replaced by sugar cane, cattle pasture, and cacao plantations. Many species of trees that were collected and classified during the nineteenth century have not been re-collected in recent times. For example, *Roupala thomesiana* (a species of *Roupala*, a genus of trees whose wood is much used) was collected in the forests of Bahia state by Swiss botanist Jacques Samuel Blanchet in 1833. It has never been seen since the original collection and this is a common feature of Atlantic coastal forest species.

Another important hot spot for trees is the Guinean forests of West Africa that extend from Sierra Leone to Cameroon. The entire Guinean forest ecosystem has been reduced to a series of small fragments in each of the countries where it occurs. It is estimated that only 14.3% of the original closed canopy forest remains. This area too, like the coastal forests of Brazil, houses many endemic species of trees with at least 25% of the vascular plant species endemic to the hot spot.

The Wallacea hot spot includes the central islands of Indonesia from Sulawesi to Ceram and from Lombok to the Tanimbar Islands. This area named after the co-discoverer of evolution, Alfred Russel Wallace, contains many endemic species of animals and plants including many commercial timbers such as kawi (*Agathis* spp.) and the magnificent yellow-flowered legume *Pterocarpus indicus*. It is in many of the 27 areas defined as hot spots that the greatest number of tree species are endangered.

Here a selection of endangered tree species from different places and endangered for different reasons, have been chosen to illustrate the situation.

The Conifers or Softwood Species

The cone-bearing trees are some of our most ancient species that have survived through the ages and many changes in world climate. The data from the World Conservation Union estimate that 327 of the 586 species of Pinopsida (pines and their close relatives) are threatened. 133 species or 53% of the pine family (Pinaceae) are listed in the *Red Data Book*. Conifers include many magnificent trees such as the giant redwoods of California and are still one of the major sources of timber and so it is unfortunate that so many species are under threat of extinction.

The Wollemi Pine and the Dawn Redwood

The Wollemi pine is an Australian conifer that was only discovered in 1994 in a gorge only 150 km from Sydney. It belongs to an evolutionary line thought to have been extinct for many millions of years. Studies of fossil pollen showed that this genus was once widespread and abundant in Australia. Its population declined for natural reasons and one small population has survived in the Wollemi National Park. It is a member of the plant family Araucariaceae which include the much cultivated species the monkey-puzzle tree from Chile (*Araucaria araucana*) and the Norfolk Island pine (*Araucaria heterophylla*). Once it was discovered, the Wollemi pine soon became listed as rare and endangered and considerable efforts are being made by the Royal Botanic Gardens in Sydney to protect and propagate this species, of which fewer than 40 individuals exist in the wild.

A similar situation occurred for the dawn redwood (*Metasequoia glyptostroboides*) from China. This living fossil was discovered in the early 1940s. Since over 2000 trees of this species existed, seeds have been widely distributed to gardens around the world to ensure its survival as a species.

Alerce: The Patagonian Cypress

Alerce (*Fitzroya cupressoides*) is a magnificent tree of the forests of southern Chile and Argentina. The huge trees are slow-growing and take many hundred years to reach their full height of 50 meters and up to 2 meters diameter. Trees of 70 m × 4 m have even been recorded. The timber of alerce has been much used in house construction and for roof shingles and even for boat building. As a result of its valuable timber this species has become so rare that it is listed both in *Red Data Books* and in the Convention on Trade in Endangered Species (CITES). The pressure on this species is from overuse rather than rarity. Clandestine shipments of alerce wood are still occasionally apprehended by UK Customs. Many of the conifers that are endangered are so because of overuse of the timber and poor management of the resource.

Monterey Cypress

The Monterey cypress (*Cupressus macrocarpa*) is a small to medium-sized tree now confined to two small groves on the Pacific coast of central California. This picturesque tree has a small often contorted cone-shaped crown. It is not of importance as lumber, but is now often cultivated as an ornamental and in windbreaks and hedges. This is endangered in the wild because of the destruction of its native habitat, but is unlikely to become extinct because of its wide use in gardens around the world. Fortunately the entire wild population is protected within the Point Lobos Reserve and the Del Monte Forest and so it is unlikely to become extinct.

Bermuda Cedar

The Bermuda cedar (*Juniperus bermudiana*) is the last conifer discussed here. It is under threat for another reason. Approximately 90% of the trees died between 1944 and 1950 because of infestation by two accidentally introduced scale insects, the juniper scale (*Carulaspis visci*) and the oyster-shell scale (*Lepidosaphes newsteadi*). This tree, which dominated the forests of Bermuda, was a great loss and many exotic species were introduced to replace it. Some trees have survived but destruction of habitat for tourist resorts has reduced the possibility of reafforestation efforts. The species itself is unlikely to become extinct because it is now grown elsewhere and has become common on the island of Saint Helena. Many island species around the world have become endangered through the introduction of alien pests and diseases, or even other species of trees such as *Eucalyptus*, which take over at the expense of the native forest.

The Monocotyledons

The flowering plants have generally been divided into two major groups, the monocotyledons and the dicotyledons, based on the number of seed leaves in the embryo. Most of the monocots are narrow-leafed with parallel veins and are herbaceous, but one group, the palms, are secondarily woody and constitute one of the most important components of tropical rainforest. Since many palm species are critically endangered, a few examples are discussed here. Of the approximately 3000 species of palm, 869 (26%) are listed in the IUCN *Red Data Book*.

Madagascan Palms

There are about 170 species of palm in Madagascar and all but five are endemic. Many of the palms have very restricted distribution and are known from areas of less than 1 square kilometer in the wild. Since natural habitats are being destroyed so rapidly in Madagascar, a large number of the palm species are critically endangered. The species *Voaniola gerardii* was only described in 1989 in the Masoala Peninsula of northeastern Madagascar. Fewer than ten trees of the robust forest palm that is 15–20 m tall are known to exist. The fruit are a rich red-brown and seeds have been collected and germinated at Kew. *Voaniola* is also of interest because it has 596 chromosomes, the most ever recorded for a monocotyledon. Apparently this palm has been much harvested destructively to collect the palm cabbage or heart-of-palm for use as a salad vegetable. The ravimbe palm (*Marojejya darianii*) is another recent discovery that was named in 1984. This magnificent large-leafed palm reaches 15 m in height. It is only known from a single locality in swamp forest near Maroantsetra also in the northeastern part of the country. Unfortunately one of the threats to the existence of *Marojejya* has been the destructive collecting by palm fanatics, who often collect all the seed from a tree. A tree of the rare *Beccariophoenix madagascariensis* was actually cut down to obtain seed. At Mantaly where one of the two known populations of this tree occurs, in July 1992 nine mature trees had been felled for their palm-heart, leaving fewer than 20 mature trees alive. *Lemurophoenix halleuxii* (**Figure 1**) is probably the most majestic palm of the whole island. The 50 remaining trees are not regenerating well because the seeds are much sought after and regularly harvested for export to palm enthusiasts. The wonderful selection of palms from Madagascar are in a precarious state through destruction of habitat, harvesting for timber and palm-heart and collecting by palm fanatics and so it is probable that several species will soon be extinct in the wild (**Figure 2**).

New Caledonian and Other Island Palms

New Caledonia is another island territory where the majority of plant species are endemic. All 31 species of palm and all but one of the 17 genera are endemic and at least eight species are highly endangered. *Burretiokentia hapala* with its bright green trunk marked with pale rings of the leaf scars is an elegant palm that is known only from a few individuals in two localities. *Cyphophoenix nucele* is known from a single small population on the island of Lifou. The only other species of this genus, *C. elegans*, is also found in a very small population which is

Figure 1 The palm *Lemurophoenix halleuxii* from Madagascar. There are only about 30 individuals left of this majestic species. Photograph courtesy of H. Beentje.

Figure 2 The palm *Orania ravalea* from Madagascar was only described as new in 1995 and fewer than 500 individuals remain of this elegant tree. Photograph courtesy of H. Beentje.

endangered by frequent forest fires. Thus the whole genus *Cyphophoenix* is endangered, as is the case with many other genera of palms. Most tropical islands have listed species of palms and could be mentioned. There are several endangered species of palms in Hawaii in the genus *Pritchardia* and the once common vuleito palm of Fiji (*Neoveitchia storckii*) is reduced to a single population of about 150 trees. The only palm of Easter Island, *Paschalococcus disperta*, is extinct and was only described from subfossil fruit. The chonta palm (*Juania australis*) of Juan Fernández Islands or Robinson Crusoe Island is highly endangered from illegal felling and habitat destruction by grazing animals.

Continental Palms

It is not just island palms that are endangered, there are also many examples from continental areas. The IUCN *Red List* names three species of *Maxburretia* from Thailand and the Malay Peninsula. The most endangered is *M. rupicola* which is confined to three limestone hilltops all near to the city of Kuala Lumpur. One site is threatened by quarrying and another experiences frequent fires caused by careless climbers. The palm genus *Aiphanes* has 22 species most occurring along the Andes in Colombia, Peru, Ecuador, and Bolivia. Most of the species are narrow endemics in an area where much destruction of the natural vegetation has occurred. It is hardly surprising that 17 of the 22 species have found their way into the IUCN *Red Data Book*. For example, *Aiphanes duquei* is now restricted to two National Parks in the Cordillera Occidental of Colombia.

The urgoun or dalla palm (*Medemia arjun*) of Egypt and Sudan was abundant there in ancient times. The population has been decimated by exploitation of the leaves for making mats and by destruction of its habitat by irrigation schemes along the River Nile. It was known only from three localities in Egypt and one in the Sudan. Two of

Figure 3 This lone individual of the jequitibá tree, *Cariniana legalis* (Lecythidaceae) remains in the botanical garden in Rio de Janeiro. (It is believed that this same tree was once kissed by Einstein.) Because of its excellent timber it is becoming rarer even in the conserved remnant of Brazil's Atlantic coastal rainforest.

these localities have only a single tree left and it is dubious that any trees remain at the third.

These few examples serve to show that many palms around the world are severely threatened and some even extinct. Palms are one of the most useful of all groups of plants and it is tragic that so many are being lost forever.

The Dicotyledons

This vast group includes all other trees that are not either conifers or palms. There are many endangered species of dicots (**Figure 3**) and a few are highlighted here to illustrate what is happening to trees around the world.

South American Mahogany

This species (*Swietenia macrophylla*) grows in Central America and in Mexico and in an arc around the western and southern fringes of the Amazon basin. It is severely threatened due to overexploitation for its much sought-after timber and because of habitat loss. Mahogany is the most valuable timber of the American tropics. The area where it grows in southern Amazonia is also one of the major areas of deforestation. Mahogany, due to its high value, has been logged illegally from parks, reserves, and indigenous areas. For several years efforts to have this species listed in the CITES treaty was resisted by the principal exporting countries such as Brazil and Colombia, but in 2002 it was finally included in Appendix II which means that companies will have to alter the way in which they harvest the species and prove that it was obtained legally from a sustainable source. This was a major step forward because mahogany logging companies opened many roads to reach the scattered populations of wild mahogany which gave farmers access to remote areas. This process will now be slowed down by the listing of mahogany and will help to spare other trees. Mahogany has largely been harvested from wild trees because it has not done well in plantations due to attack from the shoot-boring insect *Hypsipyla grandella*.

Brazilian Rosewood

Rosewood (*Aniba rosaeodora*) contains the essential oil linalol which has become much used by the perfume industry. To harvest linalol, trees are felled and the wood chipped and steam distilled. Local distilleries have been built in many parts of Amazonia and teams sent out to harvest all the trees within range. This means that this species is now rare and as a consequence the level of harvesting has also decreased considerably, but not before the species has become threatened.

Saint Helena Ebony and the Toromiro

The ebony (*Trochetiopsis melanoxylon*) was the major timber of the island of Saint Helena in the South Atlantic (**Figure 4**). It was much sought after by trading ships for its wood and was believed extinct from the beginning of the nineteenth century. However two depauperate trees were discovered on a cliff in 1970 and cuttings taken from them have been successfully propagated in efforts to reintroduce the species. Like many island endemics it quickly suffered from both overuse and habitat destruction. It is notable that many of the most endangered species of trees are also those of most use. Another example of this is the toromiro tree (*Sophora toromiro*) from Easter Island in the South Pacific. The toromiro was also a useful timber that was much used by the natives for their elegant wood carvings. By 1917 only

Figure 4 *Trochetiopsis melanoxylon*, the Saint Helena ebony, was reduced to two impoverished individuals in the wild which were growing on a cliff face. Propagation and reintroduction programs of several institutions have assured the survival of this species that was on the brink of extinction.

one tree remained and fortunately explorer Thor Heyerdahl collected seeds before it was exterminated by grazing in 1972. The toromiro has survived in botanic gardens from the seeds collected by Heyerdahl and also in a few private gardens in Chile. From this genetically small population efforts are now being made to reintroduce to Easter Island what was once its most useful species of tree.

Brazil Wood

Brazil is the only country named after a wood. The Brazil wood (*Caesalpinia echinata*) is native to the Atlantic coastal forest hot spot and is listed as vulnerable in the IUCN *Red Data Book*. Within Brazil it is listed as endangered in five eastern coastal states. This wood was much sought after for the purple dye that was mainly exported to Portugal, often in exchange for enormous numbers of cattle. The heartwood is still much sought after for violin and cello bows. The species was almost eliminated by overuse, but since it is a national symbol, widespread replanting is taking place and this is a species that is unlikely to become extinct.

Meranti and Balan Woods

There are 357 species of the meranti and balan genus (*Shorea*) of the Dipterocarpaceae family of the Asian tropics. *Shorea* is the most important timber genus in tropical Asia and species grow in Sri Lanka, to South China, Malaysia and throughout Indonesia. Many species of this genus have localized distributions on one or only a few islands and so are particularly vulnerable to over exploitation. It is sad to see that 72 species of *Shorea* are listed in the IUCN *Red Data Book* as well as seven species of the related timber genus *Parashorea*. *Shorea fulcata* from Vietnam is listed as recently thought to have become extinct. The cause of endangerment of species of *Shorea* are mainly from habitat destruction. Many of the more commercially important species are now in managed forests and plantations, but all the wild species could be of importance to future breeding programs and would be a serious loss to forestry if they should become extinct.

Sapele

The sapele (*Entandophragma cylindricum*) is a mahogany relative that occurs in West Africa from the Ivory Coast to Nigeria in the Guinea hot spot. The wood is much exploited and is sought after for veneer, doors, and furniture. Over harvesting is occurring and it has been listed as a priority for genetic resource conservation before all the best timber trees are removed. The IUCN stated in 1996 that 'harvest and milling of the current species mix based on sapelli and sipo (*Entandophragma utile*) is clearly not sustainable ecologically or economically.' This is unfortunately true for many timber species of the tropics in America, Africa and Asia.

Endangered Trees Mean Endangered Wildlife

Many species of animals are dependent on trees for their existence and so the endangerment of trees also means the endangerment of animals that feed on their leaves, nectar, or fruit, or depend on trees for shelter. In 1992 entomologist Terry Erwin showed that rainforest canopy contains an incredible amount of insect diversity and that much of this is specific to individual species of tree. Therefore to lose a species of tree is also a threat to the many species of insects and other organisms that depend upon it for their existence. Likewise trees are dependent upon animals for their pollination and the dispersal of their diaspores. Pollinator extinction is becoming an increasing threat to many species of plant. For example Hawaii's native screwpine (*Freycinetia arborea*) was once pollinated by four bird species that are now either extinct or endangered: the Hawaiian crow (*Corvus tropicus*), the o'u parrot (*Psittirostra psittacea*), the Kona grosbeak (*Ehloridops kona*), and the palila (*Loxioides japonica*). The screwpine might have become extinct had not the introduced Japanese white-eye (*Zosteropsis japonica*) become a substitute effective pollinator.

Fruit bats play an important role as pollinators and seed dispersers of many species of trees in the Old World tropics and many oceanic islands. The Rodrigues flying fox (*Pteropus rodricensis*) once

Figure 5 This maçaranduba tree (*Manilkara huberi*) was felled to collect a few dollars worth of latex and illustrates the wanton destruction of many forest trees for little gain.

Figure 6 This rare treelet, *Rhabdodendron macrophyllum*, grows only in white sand areas around the city of Manaus, Brazil. Most of its habitat has been destroyed as the building industry mines the sand for house construction in the city.

occurred on both the islands of Rodrigues and Mauritius in the Indian ocean. It was exterminated from Mauritius many years ago but remained abundant on Rodrigues until, by the mid-1990s, its population was reduced to fewer than 100 animals through a combination of habitat destruction, hunting, and cyclone damage. Reforestation and protection of the bats has now increased the population to almost 2000 individuals, so there is renewed hope for the bat and for the plants that depend on it for their pollination and dispersal.

Selective logging often removes trees that provide important resources for forest fauna, such as timber species that provide fleshy fruits eaten by birds and frugivore mammals. The maçarandaba tree of Amazonia (*Manilkara huberi*) is an important timber tree (**Figure 5**) that is being logged but its fruit are eaten by parrots, monkeys, coati, deer, and tortoises. The populations of some vertebrate frugivores and seed predators can markedly decline in logged forests.

The important Brazil nut tree of the Amazon forest depends upon two species of bee to pollinate its flowers and the agouti to disperse its seeds. Many such interdependencies between trees and animals exist and to avoid extinction it is vital to maintain habitat that allows this web of biological interaction to continue.

Conclusions

The examples of threatened species of trees chosen here are just a few of the many that are now listed, but they show that wherever humans are active in a forested region of the world, often the most useful species of trees are becoming rare through over-exploitation and loss of habitat (**Figure 6**). From the Amazon to Asia, from Africa to Australia important tree species are under threat of extinction. Particularly susceptible are those on islands such as Saint Helena, Hawaii, New Caledonia, and Madagascar where endemism is high but habitat destruction and introduced alien species are both also rife. Trees are vital to the survival of many other organisms and each tree species has many other species that depend upon it for survival. Much more still needs to be done before it is too late to ensure that some of the most useful species of trees are not lost forever. We also need the large variety of trees that exist to sustain climate and ecological balance and perhaps even the future of all life on earth.

Plant–Animal Interactions in Forest Ecosystems

J Ghazoul, Imperial College London, Ascot, UK

Introduction

Flowering plants, being sedentary, have co-opted animal partners for purposes of gene exchange and propagule dispersal, through pollination and seed dispersal. To secure these services plants provide a variety of flower or fruit rewards creating some of the most common and obvious mutualistic interactions in the natural world. However, plants are also eaten by animals which graze on leaves, bore through stems, or predate seeds. Plants have therefore evolved mechanisms to promote the efficiency of mutualistic interactions and protect against herbivores and seed predators. This article describes the range of ecologically significant plant–animal interactions that commonly occur in temperate and tropical forest systems.

Mutualistic Interactions

Pollination

Most flowering plants are animal pollinated, and indeed the function of flowers is to attract animal vectors for pollen dispersal. Most flowers offer a reward to pollinators which is usually nectar or pollen, but can also include resins (e.g. Clusiaceae), waxes, or oils (orchids). Pollinators attracted to flowers collect the resources and in the process pick up pollen through contact with the anthers and deposit pollen they are carrying onto the stigma where pollen germinates and ultimately fertilizes the ovules. Not all flower visitors act as pollinators, however, and there is widespread ‘theft’ of floral resources where animals benefit from the floral resources but fail to pollinate the plant, either because they are the wrong size or shape to contact the anthers or stigma, or because they obtain nectar by piercing the sides of the corolla thereby bypassing the reproductive tissues.

Pollinators vary in their degree of effectiveness, and the extent to which they are specialized to pollinate one or a few flowering species. Pollination can be passive, where pollen is picked up and deposited inadvertently by the pollinating vector, or it can be active where pollinators seek out pollen. Active pollinators often have specialized morphological traits, such as the pollen combs and baskets on the hind legs of honeybees, used to collect and store pollen.

Some plants have developed alternative and deceptive ways of securing pollination services by temporarily trapping pollinators or by attracting them with floral displays that offer no reward. Other plants, including some large dipterocarp trees in Southeast Asia offer only pollen as a reward which, although consumed by the pollinators, is also carried by them to neighboring plants.

Pollinators range in size and diversity from tiny fig wasps and thrips to large fruit bats and terrestrial mammals, although by far the most important pollinators are bees. Honeybees pollinate many forest trees in tropical regions including many large canopy species, but solitary or semisocial species are also widespread pollinators occurring in forest canopy and understory. Although honeybees are very effective pollinators they are generalist in their foraging behavior and forage preferentially on species occurring at highest frequency or density. Such frequency-dependent foraging behavior does not, therefore, favor rare or highly dispersed plants which become more dependent on pollinators that may be more specialist in their floral resource requirements. Many anthropogenically altered forest habitats have suffered a decline in the richness of pollinator communities and introduced honeybees may to some extent ameliorate these impacts. Plants with generalist pollination systems may be resistant to such changes but plants pollinated by insects and animals other than common bees could potentially suffer a decline in reproductive output through pollination failure.

Other invertebrate pollinators include beetles, flies, butterflies, moths and thrips. Flowers pollinated by each of these groups have, evolved morphological structures and phenological patterns to increase the probability of successful pollination and to limit access to the flowers by other flower visitors that are relatively ineffective as pollinators. Tropical forests contain many invertebrate-pollinated species, while in temperate forests wind pollination is more widespread.

Vertebrate pollinators primarily include birds and bats, but a variety of terrestrial mammals also act as pollinators, including possums and shrews. Even lizards have been noted to pollinate some plant species but such examples are notable by their rarity.

One of the best known highly specific interactions among plants and animals is the fig pollination system. Fig species (*Ficus*) have evolved to be entirely dependent on specialized fig wasps for pollination. The tiny wasps live as adults for only a few days and spend almost their entire life within figs. Figs are actually clusters of flowers enclosed within a spherical or cylindrical structure termed a syconium. Female wasps enter the syconium through a narrow hole to seek out the tiny flowers upon which they lay their eggs. Wasp larvae feed on floral tissue destroying ovules in the process. Larvae develop into adult wasps that emerge into the central chamber of the syconium where they mate, after which the males die. During this time pollen either adheres to female wasps passively or is actively collected by them prior to their emergence from the syconium in search of another fig tree. Pollination occurs when the wasps enter another syconium to lay eggs. Although many flowers are destroyed, sufficient remain to produce pollen and seed. This highly coevolved system is all the more remarkable in that each *Ficus* species is exclusively pollinated by a single, or rarely two, fig wasp species. Despite the potential vulnerability of such highly specialized mutualisms to the loss of one of the partners, the fig–fig wasp mutualism seems very resistant to anthropogenic impacts on forested landscapes.

Seed Dispersal

A second mutualism associated with plant reproductive processes is that of dispersal of seed by animals. In the immediate vicinity of the parent plant competition for resources is intense and the risk of death from pathogens or seed predators is disproportionately high (see below). Thus if seed production is to be translated into seedling recruitment dispersal of seeds away from the parent into uninhabited sites suitable for growth is necessary. Plants achieve this by a variety of biotic and abiotic mechanisms. In tropical moist forests transportation by biotic mechanisms is much more important than it is in temperate or tropical dry forests where wind is an effective dispersal agent.

Plants that use animal agents to disperse seeds may offer inducements in the form of a nutritious reward to attract dispersal agents. Many tropical plants, as well as temperate ones, surround their seeds with fleshy fruit that is sought by animals that consume the fruit and in so doing disperse the seed. The seeds are spat out or may be swallowed along with the fruit, only to be ejected with the feces having passed through the digestive tract unharmed. Indeed, many seeds require exposure to digestive acids in vertebrate guts before they are able to germinate. Dispersal of internally transported seed is a function of animal movement and the duration of passage through the gut. Asian rhinoceroses and elephants both consume and defecate seeds, but while elephants defecate at more or less random locations, rhinoceroses repeatedly visit latrines that can accumulate tens of thousands of seeds.

Animal foraging behavior also dictates the pattern of dispersal. Many forest rodents ‘scatterhoard’ seed, that is they store a little food in each of numerous caches which results in widely dispersed small seedling clumps. Burial of oak seeds by squirrels, for example, results in seedling distribution that is not unlike dispersal by wind, where most of the seeds are within a few meters of the parent tree with a much smaller proportion distributed further away. Such behavior is contrasted with ‘larderhoarding’ in which all food is stored in one or very few locations, resulting in a much higher density of seedlings per clump. Seed hoarding by animals can be a highly effective means of dispersal. Jays that hoard pine nuts in North America can disperse seed 20 km from the trees at which the seed were collected.

Other plants offer a small amount of fleshy tissue that is attached to the end of the seed and serves the same function as fruit. In the case of the cashew nut trees (*Anacardium* spp.), the fleshy aril is consumed by bats usually some distance from where they were collected and the seed is discarded. Thousands of other plants offer a similar reward, termed an elaiosome, that is collected by ants. Elaiosomes contain chemicals that attract ants and stimulate them to carry the seeds back to the nest where the elaiosome is consumed leaving the seed to germinate in the environmentally nutritious and safe surroundings of the ant nest. Ant-dispersed seeds occur in a wide variety of plant families, notably the Fabaceae, Mimosaceae (acacias) and Sterculiaceae, and in several forest habitats including tropical rain, savanna, and sclerophyll forests.

Seed dispersal mutualisms are usually fairly generalist with a wide variety of animal seed dispersal vectors being attracted to the fruit of any particular tree. The fruit of bird dispersed seed tend to be smaller than those of mammal dispersed seed though there are few specialized plant-seed disperser mutualisms. One exception is the Australian mistletoe bird (*Dicaeum livuninaceum*) which specializes on mistletoes.

It is estimated that around 10% of flowering plants have fruits that bear hooks, barbs, claws or a sticky surface by which they become attached to the hair or feathers of passing animals. These seeds are passively carried by the animal until they fall off or are brushed off. Such dispersal does not constitute a mutualistic plant–animal interaction as the seeds or fruit can be an irritation to the animal concerned.

Seeds may be moved to their ultimate location in several stages, with different agents responsible for each stage. Thus a fruit that is initially dropped from a tree into a stream may be later picked up by a rodent that only partially consumes the fleshy tissue before dropping it to be harvested by ants that drag the seed into the nest. Seed dispersal can therefore consist of a complex array of sequential events involving a suite of dispersal agents.

Plant Protection by Ants

Ants are important mutualistic partners to a variety of plant species in tropical forests, protecting plants from herbivores, providing plants with essential nutrients and, as has already been described above, dispersing seeds and fruits. In most ant–plant mutualisms plants provide ants with accommodation, in the form of hollow stems, roots or thorns, or swollen petioles or leaf pouches, and food such as extrafloral nectar or food packages that are rich in protein and lipids. In return ants provide protection from herbivores by attacking any insect or vertebrate that contacts the plants. In the most famous plant–ant mutualism in central America *Pseudomyrmex* ants not only provide protection from herbivores but also clear competing seedlings from around the base of the host *Acacia* trees. Ant protection from herbivory has been observed in a wide variety of plant families common in tropical or subtropical forests. These include bamboos, fast growing pioneer species (*Macaranga* and *Cecropia*), rattan palms, and understory woody plants (*Cordia alliodora*). The mutualism is also geographically widespread and has evolved independently at least twice among *Acacia* trees in Central American dry forests and African savanna forests, and the ferocity of weaver ants (*Oecophylla*) which construct nests from freshly woven leaves of a variety of trees is familiar to forest workers throughout Southeast Asia.

In some cases (as for the plants *Hydnophytum formicarium* and *Myrmecodia tuberosa*) ants provide food for the plants by depositing their refuse in absorptive chambers that house the ants. Such specialized myrmecotrophic plants are in the main tropical epiphytes in open forests and savannas growing on nitrogen-deficient soils, thus acquisition of nitrogen from ant waste is the principle benefit to the plants. A far greater number and diversity of plants that house ants for protective purposes may additionally benefit nutritionally, though to a lesser degree, from ant waste products and discarded prey that accumulate in nesting cavities.

Ants are well known for their habit of maintaining colonies of sap-sucking homopteran insects on plants. Homopterans take sap directly from the plant phloem and excrete unwanted organic acids and sugars in the form of honeydew that is harvested by ants. The ants tend and protect the homopterans from parasites and predators, hence this interaction could be construed as being antagonistic as far as the plant is concerned. However, some evidence suggests that ants regulate homopteran populations and prevent outbreaks that might be highly detrimental to plants, and the presence of ants can also provide protection against herbivory. Currently there is little conclusive information on the balance of costs or benefits to plants of homopteran-tending ants, although in one study the presence of homopteran-tending ants on birch in Finland greatly reduced damage by leaf feeding caterpillars.

Antagonistic Interactions

Animals cause damage to plants by consuming vegetative tissue or propagules, or by mechanical destruction such as trampling. Plants tolerate a certain amount of tissue loss but such damage may make them susceptible to secondary infestation by pests and pathogens or place them at a disadvantage relative to unscathed neighboring competitors. In response to the onslaught of primary consumers plants have evolved a variety of physical, chemical, and biological defenses, albeit at some cost of production.

Herbivory and Plant Defenses

Animals that feed on plant tissue are varied and abundant. Vertebrates graze and browse leaves and gnaw at roots and tubers. Insects chew, mine, or gall leaves, as well as suck sap and bore stems, and even an entire tree may be defoliated by a single caterpillar outbreak (**Figures 1–3**). Plants can usually recover from such damage as only a portion of the plant is consumed and, owing to their repeating modular construction, lost parts can be readily renewed (although continued intensive attack will eventually kill a plant).

Despite the huge abundance of leaves in forests there are few canopy mammals that are able to effectively digest cellulose, the main component of leaves. Those that do, such as sloths and howler monkeys in the Neotropics, and orangutans, proboscis monkeys, and chimpanzees in the Old World tropics, rely on a suite of symbiotic gut microorganisms to digest cellulose in their large stomachs. Among birds, the large stomach required to digest leaf material has limited such a widespread food to only a single species, the hoatzin of South America.

Figure 1 *Alcidodes ramezii* (Curculionidae) recently emerged from the fruit of *Dipterocarpus obtusifolius* (Dipterocarpaceae). Weevils are important seed predators of many tropical trees and in some cases can destroy over 90% of the entire seed produced in a particular fruiting event. Photograph courtesy of Richard Davies.

Vertebrate grazers and browsers are, however, abundant on the ground and ruminants such as deer, giraffes, and oxen as well as other forest mammals such as elephants, consume large amounts of leaf material. Their impacts on forest composition and succession can be dramatic as they may preferentially feed on seedlings and saplings thereby preventing tree regeneration and succession to mature forest. Overstocking of deer in Scotland, for example, has a severe impact on the regeneration of native pine woods. In African savannas the balance between grazers which feed on grasses and browsers which attack trees can have long-term effects on the extent of trees in the landscape.

Figure 2 The caterpillar of the emperor moth *Imbrasia belina* (Saturniidae), commonly called the mopane worm, feeding on the leaves of its host plant the mopane tree *Colophospermum mopane* (Colophospermaceae). Mopane woodlands are dominated by this one tree species, and because few other herbivorous species find the leaves of the mopane tree palatable, *I. belina* often achieves very high population densities in sporadic outbreaks. Widespread defoliation of mopane woodlands occur during such outbreaks.

Figure 3 An unpalatable caterpillar on *Shorea leprosula* (Dipterocarpaceae). Many caterpillars sequester the toxic secondary compounds produced by leaves for their own defense against predators.

The most important herbivores in tropical forest habitats in terms of the amount of plant biomass consumed are insects, in both adult and larval forms. Grasshoppers, katydids, some beetles and ants, and the larvae of moths, butterflies, and many flies and sawflies consume vast quantities of leaf material. Many other insect grazers, such as springtails, feed on root tissues. A large number of insects belonging to the orders Coleoptera (beetles), Lepidoptera (moths), Diptera (flies), and Hymenoptera (sawflies) consume tissue between the epidermal layers of leaves creating conspicuous mines or blotches. Leaf-mining insects lay their eggs on the leaf surface or directly into the leaf. Larvae may feed on leaf tissue or just on sap exuded from damaged tissue.

In Neotropical forests leaf-cutting ants (*Atta* spp.) are the dominant herbivores consuming more vegetation than any other group of animals, and it has been estimated that 12–17% of all leaf material produced in Neotropical forests is harvested by *Atta* ants. Species selection appears indiscriminate and leaf-cutting ants will even harvest agricultural crops. Consequently, leaf-cutting ants contribute greatly to nutrient cycling in tropical forests with each colony using about 50–250 kg of dry matter each year. The underground nests of *Atta cephalotes* can cover several tens of square meters and contain up to 5 million workers. In these huge nests leaf material is used to culture specialized fungi on which the ants feed.

Gall-forming invertebrates induce plants to form abnormal growths within which the insect gains both shelter and food. Gall formers include species of mites, gall-wasps, flies, weevils and aphids and are abundant on both temperate and tropical trees, the tree families most heavily galled in Europe being Fagaceae (oaks and beech) and Salicaceae (willows and poplars). All parts of a plant may harbour gall formers, with leaves being most commonly attacked, though nematodes are unusual in attacking roots. Each galling species produces a characteristic gall structure the formation of which is usually induced by egg laying into the plant tissues. The larvae feed inside the gall where they are relatively protected from predators and desiccation. Gall-forming insects appear to increase in relative abundance with increasing aridity, presumably due to the protection a gall affords the developing larvae from desiccation.

Wood-boring beetles can cause extensive damage to trees particularly as they can also be a means of spread of pathogenic fungi. Bark beetles, for example, bore into tree trunks and excavate the wood just beneath the bark causing extensive damage. Trees often respond by flooding bore holes with sap but bark beetles may recruit to injured trees ultimately overcoming the trees' defenses.

Another important mode of consumption is to use strawlike mouthparts to suck fluids from plant vascular tissues, the phloem and xylem, which transport water, nutrients, and photosynthate. The most common sap feeders are aphids and other hemipteran bugs, although spider mites also follow this strategy.

Plants have, in turn, evolved a wide array of defensive compounds or physical structures that impede insect or vertebrate attack. Chemical defenses can reduce the digestibility of leaf tissue, or may have a toxic or repellent function. Tannins are large carbon-rich compounds that bind proteins making them difficult to digest. Toxic compounds include phenolics and alkaloids and these may poison or kill animals that consume them. Some plants have responded to attack by leaf miners by secreting latex which impedes or kills larvae. Mechanical defenses include the obvious spines and thorns to defend plants against vertebrate herbivores, and the less obvious silica structures that render grass and nettle leaves less palatable to vertebrates and invertebrates alike. Leaf hairs, called trichomes, sticky surfaces and often a combination of the two also limit herbivory, while structural tissue such as cellulose and lignin lining leaf veins is not easily digestible constraining herbivores to limited leaf areas. Plant chemical repellents may also deter insects from laying their eggs on plant tissues causing the insects to look elsewhere.

Many animals and insects have evolved mechanisms to overcome or tolerate plant defenses leading to a high degree of specialization on the host plants they infest. Insect larvae may even assimilate poisons rendering themselves unpalatable to predators. Repellents, on the other hand, do not kill herbivores so there is much weaker selection to develop counteractive mechanisms and, consequently, much less herbivore specialization.

Seed Predation

Seeds are highly nutritious packets of carbohydrates, proteins, and lipids that are readily consumed by vertebrates and invertebrates, but are only briefly available and less predictable than other plant tissues. Broadly, two groups of seed predators are recognized, those that consume seeds prior to their dispersal, and those that attack seeds that have already dispersed. Predispersal seed predators are mostly specialist sedentary feeders belonging to the insect orders Diptera, Lepidoptera, Coleoptera, and

Hymenoptera. Postdispersal seed predators are larger, more mobile, and generalist herbivores like ants and vertebrates, particularly rodents and birds. Predation rates are highly variable but can be as high as 100% of seeds produced. Although seed predation is an antagonistic interaction, some seeds that escape predation may be benefited by being dispersed into favorable microhabitats. Squirrels and other rodents cache large numbers of seeds a few of which will escape predation by being forgotten (see above). Nevertheless the vast majority of seeds encountered by seed predators are killed.

High rates of seed predation are thought to have led to the evolution of mast seeding among many tree species. Masting is the periodic synchronous production of seed that leads to such an abundance of seed that seed predators are satiated. As a result there is a greater probability of seedling recruitment following mast years. In nonmast years the dearth of seed resources may limit seed predator populations making them less able to exploit effectively periods of resource abundance. In Europe oak and beech trees produce mast crops once every two to ten years, while dipterocarp trees in Southeast Asia are well known for supra-annual mast fruiting events in which species belonging to several genera participate over areas extending to hundreds of square kilometers.

Mechanical Damage

Physical disturbance by large vertebrates is an important structuring component of forest systems. Large herbivores such as elephants can open up the canopy and disturb the soil by digging and scraping, creating opportunities for seedling recruitment especially for fast growing pioneers. In the tropical dry forest of Mudumalai Wildlife Sanctuary, southern India, very high tree mortality, largely a result of elephant damage, has been documented. Elephants are also known to play an important role in determining the abundance of trees in African savanna forests. In North America dam building by beavers can dramatically alter forest riparian habitats and, because they feed preferentially on deciduous species beavers cause an increase in the relative proportion of conifers. Animals that cause long-term and dramatic physical modification of habitats have been termed ecosystem engineers and may be important for maintaining high species and structural diversity by increasing habitat heterogeneity. At smaller scales and in temperate forests squirrels and deer cause damage to young beech and other trees by stripping bark. Such damage can cause considerable financial loss to plantation owners. Rodents attack tree roots even below ground, though such impacts are most significant in arid rather than forested environments.

Conclusion

There is a multitude of plant–animal interactions ranging from the antagonistic to the mutually beneficial. Both antagonistic and mutualistic interactions have enormous importance for the structure, composition, and functioning of forests as well as all other natural habitats. Often it is not easy to separate apparently antagonist behavior, such as seed predation, from mutualistic behavior such as seed dispersal, as the same animals often perform both functions. Furthermore, while antagonistic interactions such as herbivory, seed predation, or mechanical damage, are certainly detrimental to the individual plants affected, such behaviors may raise habitat diversity and richness by increasing heterogeneity and preventing dominance by fast-growing or competitively superior species. Additionally, many ecosystem functions are dependent on the interactions between plants and animals. Nutrient cycling and decomposition, for example, are functions of herbivory and the breakdown of organic matter by numerous soil-living invertebrates. The reproduction of flowering plants, particularly in the tropics, is dependent on the availability of pollinators. Humans are, of course, dependent on the continued functioning of these plant–animal interactions for crop production and soil fertility and the continued existence of viable diverse forests and their natural renewable resources.

Reproductive Ecology of Forest Trees

J Ghazoul, Imperial College London, Ascot, UK

Introduction

Plant reproductive processes encompass biotic interactions, such as pollination and seed predation and dispersal, and abiotic elements, notably disturbance that creates differential reproductive opportunities for plant groups and thereby maintains diverse forest formations.

There are several important stages in the regeneration of trees, the first of which is the allocation of resources to reproductive structures as opposed to vegetative growth. Among flowering plants, that comprise the majority of tree species, allocation to reproductive structures such as flowers, seeds, and fruit may vary enormously and may comprise a substantial portion of photosynthate. Even within plant families some trees (e.g., some dipterocarps of the genus *Shorea*) produce several million tiny flowers, while others (e.g., *Dipterocarpus*) produce only a few hundred relatively large flowers. Flower number and morphology reflect pollinator syndromes while the trade-off between seed size and number has also generated a huge variety of options for reproductive success. Beyond being a crucial step in seed production, pollination is the first of two stages by which gene flow is effected, by gamete dispersal within populations. Seed dispersal represents a second opportunity for gene flow as seeds are transported to new locations by a variety of dispersal vectors. Dispersed seed may enter a variable period of dormancy before germination and growth to seedling stages. Biotic agents of mortality acting at each of these life stages can reduce enormously the probability of ovule survival to maturity. Thus the diversity of reproductive strategies observed among trees reflects physical, competitive, and coevolutionary interactions among plants and their biotic and abiotic environments at each of these life history stages. This article describes the diversity of tree reproductive strategies in temperate and tropical forests, emphasizing flower and seed life stages.

General Reproductive Strategies

Vegetative Reproduction

Plants as sessile organisms reproduce by means of their modular architecture and their capacity for reiterative growth – indeed, all plants are potentially clonal in that each module contains both reproductive and somatic tissue. However, production of independent offspring by means of vegetative growth is rare among trees, although detached branches of willows and poplars can sprout if maintained in moist conditions. Most broadleaves can produce new stems from cut or burned stumps even when the rootstock is hundreds of years old. Trees cut specifically for this purpose are referred to as coppice and are an important management feature of many European woodlands. Some conifers can also coppice (e.g., redwoods), or sprout from burned trunks (e.g., pitch pine), but most regenerate from seed.

Fallen trees that retain some connection to the soil through roots may develop new stems from epicormic shoot production. Indeed, small-leaved lime in the UK has been referred to as practically immortal for both this reason and for its vigorous coppicing response. Similarly, broken crowns can regenerate through epicormic stem proliferation.

Some plants are able to produce seeds in the absence of fertilization by partial or total suppression of meiosis and fusion of gametes. Such a process is termed apomixis and may be widespread among tropical trees.

Sexual Reproduction

All trees, excepting tree ferns, are seed-bearing and reproduce sexually by wind or insect-mediated transfer of male gametophytes, as pollen, to ovules. The gametophytes of all seed plants are enclosed within sporophyte tissues and, unlike ferns or nonvascular plants, are no longer free-living at any stage of their life history. Fertilization occurs when male nuclei are transferred to an ovule by way of a pollen grain that has been received on a compatible and receptive stigmatic surface.

Seed plants are taxonomically separated into two primary lineages, the gymnosperms (about 770 species) and the angiosperms (some 235 000 species). The gymnosperms consist of four phyla that include conifers, cycads, gnetophytes, and Ginkgophyta (solely represented by the maidenhair tree *Ginkgo biloba*), of which only the conifers form forest trees. The angiosperms differ from the gymnosperms in that they have their reproductive structures contained within flowers. Pollen transfer in almost all gymnosperms is effected by wind (some gnetophytes and cycads may be beetle-pollinated) while the flowers of angiosperms evolved to attract insect and animal pollinators, although many angiosperms have secondarily evolved to be wind- or water-pollinated.

Coniferous gymnosperms Almost all trees within the gymnosperms are conifers and it is these that dominate the boreal forests of Eurasia and North America. Conifers have their reproductive parts aggregated in unisexual cones which may be borne on the same tree (monoecious) or on different trees (dioecious). Cones consist of numerous scales, each of which bears either two pollen sacs (males) or ovules (females). All conifers are wind-pollinated and, given the inefficiency of wind pollination, often produce huge amounts of pollen. Pollen grains consist of a reproductive sperm cell and a tube cell, and have two wings or air-filled bladders that aid transport by wind. Pollen grains landing near an ovule are drawn towards it by a drop of liquid that is absorbed into the female scale. Pollination occurs when the pollen grain penetrates the micropyle, a small opening in the integument of the ovule. Following pollination, the cone is sealed by a thickening of the scales. One of the two cells that comprise the pollen grain elongates into a pollen tube that, over a period of several months or more, eventually reaches the egg cell. Fertilization follows when the sperm cell migrates through the pollen tube to fuse with the egg. The embryo develops within a naked seed and, after a further year, the cones ripen, dry, and open to release the winged seeds. Most conifers differ only slightly from this general pattern of reproduction, although yew *Taxus* sp. is notable in that its ovules are solitary, its pollen grains lack the 'wings' of most other conifers, and its large seed develops in a fleshy red aril which ripens within a year.

Angiosperms Apart from the obvious presence of a flower, angiosperms differ morphologically from gymnosperms in that the female gametophytes are greatly reduced in size. Consequently, the process of development is much faster and more efficient. Unlike gymnosperms, the seed food store only develops after fertilization and is therefore not wasted if fertilization fails to occur. Increased reproductive efficiency is thought to have contributed substantially to the flexibility of reproductive strategies and to the current dominance and diversity of the angiosperms.

The ovules of angiosperms are completely enclosed within the carpel (hence angiosperm, meaning hidden seed), a development that may have arisen to protect the ovules and pollen from insects. A pollen grain landing on the stigmatic surface germinates and extends a pollen tube through the style to fertilize the ovule. The fertilized embryo develops within a seed that may be enclosed in a nut or fruit to attract animal dispersal agents, or may be formed so as to facilitate dispersal by wind, water, or passive animal transport. In many species seed germination is delayed as seeds enter a period of dormancy until such time as environmental conditions trigger release from dormancy. Some seeds can persist in a dormant stage for decades or even centuries and collectively form the soil seed bank. Other seeds (e.g., of the dipterocarps) are recalcitrant and germinate very soon after dispersal, though the seedlings may persist for many years in deep forest shade to form a seedling bank until a canopy gap forms, allowing renewed vigorous growth.

Pollination of Angiosperms

Pollination is effected by a variety of biotic and abiotic pollination vectors, with biotic pollinating agents predominating in tropical zones and wind being relatively more significant in temperate regions. About 98% of all flowering trees in tropical rain forests are animal-pollinated; bees are by far the most important pollinators (**Table 1**). Pollination by beetles, hummingbirds, and small bees is more common among subcanopy trees but even here medium to large bees form the dominant pollinator group. Wind pollination is rare and confined to very few canopy and understory trees.

Pollination by Vertebrates

Pollination by vertebrates in north temperate forests is virtually nonexistent, but it is relatively common in tropical forests, and is also important in south temperate zones in Australia and South Africa. Among vertebrates, bats and birds are the principal pollinators, although some trees may also be

Table 1 Frequencies of different pollination systems among canopy trees at La Selva, a lowland tropical rainforest in Costa Rica

Pollination vector	*Percentage of tree species*	
	Canopy (n = 52)	*Subcanopy (n = 112)*
Medium-large bees	44.2	19.6
Small diverse insects	23.1	12.5
Moths	13.5	16.9
Small bees	7.7	17.0
Bat	3.8	2.7
Wasp	3.8	4.5
Hummingbirds	1.9	5.4
Butterflies	1.9	6.2
Beetle	0	10.7
Wind	0	3.6

Data from Bawa KS, Bullook SH, Perry DR, Coville RE, and Grayum MH (1985) Reproductive biology of tropical lowland rainforest trees. II. Pollination systems. *American Journal of Botany* 72: 346–356 and Bawa KS (1990) Plant–pollinator interactions in tropical rain forests. *Annual Review of Ecology and Systematics* 21: 399–422.

pollinated by various nonflying mammals. Pollination by bats is particularly common among the Bombacaceae, and the genera *Parkia* (Mimosaceae) and *Bauhinia* (Caesalpiniaceae). Flowers of bat-pollinated trees open at dusk or soon after and are typically large, white or pale, have a musky odor, and produce copious amounts of nectar. While this is energetically costly, gene flow by bat-dispersed pollen is potentially very great.

In the neotropics hummingbirds are the main avian pollinators and feed exclusively on nectar, although they primarily visit understory shrubs rather than trees. Their Old World counterparts are sunbirds which visit a wide variety of trees but also feed on insects. Bird-pollinated flowers are typically red and contain plentiful but dilute nectar, so much so that showers of nectar are brought down when shaking the branches of the coral tree *Erythrina* spp.

Pollination by Invertebrates

Bees and wasps Bee pollination is particularly important among canopy trees in tropical forests. Two groups of bees may be distinguished as pollinators: medium to large bees, including honeybees and a variety of solitary or semisocial bees; and small, mostly social bees of the Apidae family, notably the sweat bees. Large bees appear to predominate in forest canopies while small bees tend to visit understory trees (**Table 1**), though this pattern breaks down in more open dry forest formations. A diverse array of wasps and other hymenopteran insects visit generalized flowers on trees in taxa such as Anacardiaceae and Burseraceae, but their role is minor relative to other insect pollinator groups, the exception being agaonid wasps that are specialist pollinators of fig trees (*Ficus*, Moraceae).

Moths and butterflies Moth pollination, particularly by sphinx moths, is prevalent across the tropics and includes trees within the genera *Dipterocarpus* (Dipterocarpaceae) and *Plumeria* (Apocynacea). Moth-pollinated flowers typically open at dusk and are usually pale with deep corolla tubes that emit strong sweet scents. Moths can carry substantial amounts of pollen and cover great distances between successively visited plants, making them good pollinators of widely spaced trees. Butterflies, by contrast, are rare pollinators of trees, although they do pollinate certain species-rich genera, e.g., *Eugenia* (Myrtaceae).

Beetles Beetle pollination is common among Annonaceae, Lauraceae, Myrtaceae, and Palmae. A range of beetles visit a wide variety of floral morphological forms, although most beetle-pollinated flowers open at dusk and emit strong odors. Beetles generally consume pollen and flower parts rather than nectar. In Australian rainforests up to one-quarter of all plants may be pollinated by beetles, and such plants are found in all forest strata and include trees, shrubs, and epiphytes.

Flies Flies certainly contribute to the pollination of understory forest shrubs but are probably of minor importance in the pollination of forest trees. Exceptions include cacao (*Theobroma cacao*), pollinated by midges.

Thrips The synchronously flowering dipterocarps in Asian rainforests are thought to be primarily pollinated by thrips, tiny insects that can undergo massive population increases within a very short time in response to the sudden availability of floral resources generated by a mass flowering event. Dispersal of thrips is likely to be facilitated by winds above the forest canopy. Thrips also pollinate many species of Myristicaceae.

Wind Pollination

Other angiosperms have reverted to wind pollination and consequently have much reduced flowers, as visually attractive flowers are no longer necessary for pollinator attraction. While wind is ever-present, it is not a selective pollinator and is consequently inefficient over large distances. Wind pollination is therefore favored in species-poor forests where conspecifics are closely spaced. Wind-pollinated plants are associated with abundant pollen production and synchronous mass flowering events to ensure successful pollen transfer. To maximize the probability of catching randomly drifting airborne pollen, flowers are placed at the outermost edges of the crown or in pendant catkins to maximize exposure to wind, and stigmas are usually well exposed and have large surface areas.

Wind pollination is associated with temperate forests and dry, or seasonally dry, habitats where animal pollination vectors are comparatively rare and where rainfall rarely hinders pollen dispersal. The temperate forests of northern mid-high latitudes are dominated by species such as oak, beech, and birch, that rely on wind pollination. In the temperate rainforests of Chile, New Zealand, and the Pacific Northwest of America, wind pollination is again common, despite the wet climate. Open forests and savannas are particularly well represented by wind-pollinated trees. In the dense vegetation of a rainforest wind pollination is usually restricted to emergent coniferous trees (e.g., *Araucaria* and *Agathis*) and to trees occurring on ridge tops (*Balanops australiana, Nothofagus*). Wind pollination does, very rarely, occur in the rainforest understory among more specialized angiosperm groups, including Euphorbiaceae, Pandanaceae, and Palmaceae.

Breeding Systems and Incompatibility

Individuals of most tree species bear both male and female reproductive organs, and often within the same flower. Consequently there is a high risk of self-fertilization that would restrict genetic mixing and seed viability through inbreeding. Breeding systems have therefore evolved to limit or prevent self-fertilization. Plant breeding systems range from obligate outcrossing to predominantly selfing. This range of systems is not distributed randomly among species, as woody plants are usually associated with outcrossing and annual herbs with selfing. Outcrossing can be achieved or enhanced by spatial separation of male and female flowers, either on different trees (dioecy) or within individual trees (monoeicy), or by temporal separation of male and female reproductive organs by nonoverlapping maturation times (dichogamy). Where male and female reproductive parts are not separated, physiological self-incompatibility mechanisms that block pollen tube development may exist. Other strategies include selective abortion of selfed seed. There may be considerable variation in the reliability of self-incompatibility across and within species, and the proportion of selfed seed can be highly variable among individuals within a population.

Trees in both tropical and temperate systems are mostly outcrossed, although the mechanisms by which this is achieved vary between these regions. Temperate trees are mostly self-compatible, possibly an evolutionary response to unpredictable effectiveness of the pollination vector, and selfing is limited by the spatial separation of male and female flowers. Many conifers, for example, are monoecious and seed is mostly outcrossed. Tropical trees generally have hermaphroditic flowers but are mostly incapable of self-fertilization due to physiological self-incompatibility mechanisms. Spatial separation of flowers by dioecy is also common among tropical species. In tropical lowland forests of Guanacaste in Costa Rica, for example, 22% of trees are dioecious and a further 54% are physiologically self-incompatible.

Seed Morphology and Dispersal

Seed Size

Seed size varies among flowering plants from less than 10^{-6} g in orchids to more than 10^{4} g in coco-de-mer. Small seeds can be produced in greater numbers but have less chance of establishing successfully, owing to fewer stored reserves, and size is largely a trade-off between these two selection pressures. This trade-off is subject to variation in response to physiological, ecological, and environmental conditions acting on seed and seedlings. Heavy predation of seeds, for example, near parent trees favors dispersal, which may increase or decrease seed size depending on the dispersal agent involved. The requirement for light for early seedling growth can also be mediated by seed size – large seed size confers an advantage to seedlings in low light owing to the greater reserves available to them, though this advantage is only apparent during the earliest stages of growth. Nevertheless, larger seeds are generally found among trees whose seedlings establish in shaded environments, as for tropical canopy trees.

Seeds that are mammal- or gravity-dispersed tend to be large while bird- and wind-dispersed seeds are relatively small. Thus in successional forest habitats there is increasing abundance of large-seeded species with age from the initial disturbance. This is associated with the increasing size and slower growth rates of the colonizing plants with time, and a shift from wind or bird dispersal, typical of many pioneer species, to mammal or gravity dispersal associated with canopy and emergent trees. Despite these generalizations, much variation in seed size remains unexplained and other variables, such as antiherbivore strategies, mycorrhizal associations, or soil type, might also affect seed size among forest tree species.

Seed Dispersal

Seeds are designed to be dispersed away from the parent plant to escape predation and seedling mortality near the parent, to colonize spatially and temporally ephemeral habitats, or to locate microsites suitable for establishment and growth. However, most seeds are not dispersed far from the parent. As such, seeds have evolved a variety of morphological forms to maximize dispersal efficiency by way of biotic dispersal vectors, including vertebrates (bats, rodents, and other mammals, birds, and fish), invertebrates (ants and beetles), and abiotic vectors such as wind and water.

Understory herbaceous plants in temperate and tropical forests often have barbed or sticky fruit that adhere to the coats of passing animals. Most animal-dispersed seed rely on active dispersal by offering animals a food reward in the form of a fleshy fruit. Such fruits have developed traits, such as color or odor, that increase their attractiveness to the appropriate dispersers. In tropical forest communities 50–75% or more of tree species produce fleshy fruits adapted for dispersal by birds or mammals. Many temperate forest trees are also vertebrate-dispersed, although some, such as oak, lack obvious adaptations to attract dispersers. Plant–animal dispersal interactions, as for plant–pollinator interactions, tend to be generalized, with few being highly species-specific.

Abiotic dispersal mechanisms include gravity, wind, and water. Gravity-dispersed seeds simply fall beneath the parent tree, though the fruit may be adapted to drift laterally as it falls (as for dipterocarp trees). Wind-dispersed plants are relatively more common in dry, exposed, and open habitats. In tropical moist forests where wind dispersal is relatively rare, it is generally found among canopy trees or vines rather than understory plants. Dispersal by water is common among gallery forests and seasonally inundated floodplain habitats. Seeds of some coastal trees, notably coconut, are even dispersed on ocean currents.

Seed and Seedling Banks

The seeds of many plants undergo a period of dormancy which may be very short (on the order of a few days) or prolonged (several decades or more). The advantage of dormancy is that it allows a plant population to escape from certain environmental disturbances or temporally adverse conditions. Early successional and pioneer plants tend to have delayed seed germination until such time that light or water conditions become favorable for growth. The seeds remain in the soil, forming a soil seed bank, and only germinate when an appropriate environmental cue, such as increased light brought about by a tree fall, is received. Dormancy is also an effective strategy to avoid seedling desiccation during the dry season. Dormancy can be imposed by other traits, as in seeds carried by wind that are typically desiccated to facilitate dispersal and therefore need rehydration prior to germination. Similarly, dormancy of seeds dispersed by vertebrate consumption may be necessary to survive passage through animal digestive tracts.

In the deep shade environment of a tropical forest understory, intense competition for light favors seeds that germinate immediately, leading to the establishment of seedling banks. Although these seedlings have very slow growth, they are also best placed to take maximum advantage of light upon the formation of a canopy gap.

Natural Disturbance

Disturbance is a natural feature of all forest environments. Natural disturbances vary greatly in size and frequency, and they shape forest structure and composition. Disturbance creates new opportunities for propagules to establish and grow, from vertebrates turning over soil and leaves to expose a germinating seed to light, through tropical canopy gap formation following treefalls that release seedlings from light inhibition, to extensive windthrows of balsam fir forests that initiate regeneration waves of saplings. Regeneration of many forest trees is usually confined to gaps, and composition of the regenerating community is a function of gap size, shape, and location, and the coincidence between gap formation and a fruiting event. The establishment of some tropical trees, such as mahogany, is entirely dependent on large clearings created by high winds and subsequent fires, while seedlings of other species simply need canopy openings for further growth. Yet other species, such as beech and hemlock, are shade-tolerant and regenerate under closed canopies.

Natural fires occur in almost all forest systems, although coniferous and dry deciduous forests are more fire-prone. Conifers usually burn readily and, although some are well protected by thick bark, intolerant species survive by producing many widely dispersed seeds that germinate and grow rapidly following a fire. Some species, such as lodgepole pine, even need fire to stimulate the release of seeds, which then fall on to soil fertilized by ash and which is free from other competing species. Fire is an important ecological factor in many north temperate forests and serves to maintain forests in a non-equilibrium state. Fire-prone coniferous woodland, for example, develops a broad-leaved understory which, in the absence of fire, will eventually replace the conifers.

Recruitment to seedling cohorts is frequently episodic as seed production, dispersal, and the breaking of dormancy are often facilitated by unusual or periodic climatic and disturbance events. Mast seed production is widespread among tropical and temperate trees and may be initiated by El Niño climatic events (e.g., dipterocarps in Southeast Asia) or fire (e.g., ponderosa pine in the Rocky Mountains of North America). Irregular heavy seed production may satiate seed predators, allowing for at least some seed survival, or may simply be a response to conditions that are optimal for germination. Alternatively, an episodic pattern of regeneration may be imposed at a later regeneration stage should, for example, a pest or disease outbreak cause the mortality of all young saplings.

Conclusion

Successful reproduction of trees is a function of several sequential ecological processes, pollination and fertilization, seed development and maturation, seed predation, dispersal and germination, and seedling growth, many of which are mediated by mutualistic and antagonistic interactions with animals acting as pollinators, dispersers, seed predators, and leaf herbivores. These processes unfold in the context of the disturbance regime, which creates differential opportunities for propagules and seedlings. Quite different reproductive strategies exist among forest trees within and among communities. The most obvious is the overwhelming dependence of tropical trees on animal interactors for pollination and seed dispersal, compared to temperate species, for which abiotic agents are comparatively more important. Such differences in pollination and seed dispersal vectors are reflected in the efficiency of gene transfer and patterns of gene flow, and information about seed production and gene flow is critical for the design of forest management plans and strategies for the conservation of plant genetic resources.

Currently, there is little information about the pollinators and seed dispersers of many forest trees, or indeed about the importance of flower and fruit resources to animal communities. Even basic knowledge about factors that regulate seed production, viability, dormancy, and germination for many tree species remains to be discovered, and only recently have we begun to understand the importance of natural disturbance in shaping plant communities through differential reproductive success. Our ability to rehabilitate, conserve, and manage existing forests will continue to be improved by continued research on tree reproductive ecology within the context of the natural disturbance regime.

Forest Canopies

R K Didham, University of Canterbury, Christchurch, New Zealand
L L Fagan, Landcare Research, Lincoln, New Zealand

Importance

The word canopy is derived from the Latin *conopeum*, describing a mosquito net over a bed. For canopy researchers in many tropical and temperate forests, this derivation is all too fitting. Forest canopies are home to perhaps 50% of all living organisms, many of which are uniquely specialized for life in the treetops and seldom, if ever, venture to the ground below. The canopy is the photosynthetic powerhouse of forest productivity which fuels this spectacular diversity of species. Over 90% of photosynthesis occurs in just the upper 20% of tree crowns. Here, over 60% of the total organic carbon in forests is fixed and stored, forming an important buffer in the global carbon cycle. Other ecophysiological processes within tree crowns mediate the flow of nutrients through soil, regulate nutrient cycling processes that affect site productivity and the biomass distributions of plants and animals, as well as moderate the rates of transpiration and CO_2 exchange to the atmosphere that are crucial components of regional climatic circulation. In a very real sense, forest canopies form the substrate, the buffer, and the catalyst for interactions between the soil and the atmosphere. In this article, we highlight many aspects of forest ecosystem dynamics that are controlled directly by canopy processes. More importantly, however, detailed understanding of the structural and functional complexities of forest canopies has advantages beyond the scale of ecosystem functioning of local forest stands. Forest canopy dynamics are now incorporated as vital variables when modeling forest responses to the three most pressing issues in global change biology: the maintenance of biodiversity, the sustainability of forest production, and the stability of global climate.

Definition

For much of the early development of canopy biology, the nature and limits of forest canopies have been poorly defined. In a functional sense, the forest canopy includes all aboveground plant structures and the interstitial spaces between them, which collectively form the interface between the soil and the atmosphere. Historically, there was a tendency to use more subjective definitions of the canopy that only included arbitrary portions of the upper foliage of the tallest trees. In practice, however, it has always proven difficult to objectively define vertical substrata within forests, from either a structural or functional point of view. There is now clear recognition that most forest processes vary continuously from the soil to the atmosphere and there is little utility in considering the canopy out of context from forest dynamics as a whole. After all, tree crown physiology, resource allocation, growth and reproductive fitness are all critically dependent on belowground conditions experienced by tree roots, as much as they are on aboveground processes.

Discovery and Exploration

More than 85 years ago the naturalist and explorer William Beebe wrote that

> another continent of life remains to be discovered, not upon the earth, but one to two hundred feet above it.

It would be another decade before the first intrepid biologists ventured into the tropical forest canopy in Guyana, South America, using rudimentary line-throwing catapults and local Indian tribesmen as climbers. Scientific exploration did not really begin in earnest until the 1960s with a proliferation of simple observation towers built in various parts of the world, including the Democratic Republic of Congo, Malaysia, Panama, and Uganda, site of the famous Haddow Tower. Overwhelming numbers of new species, mostly insects, have since been discovered and critical observations made on the behavior and life history of rare birds, reptiles, amphibians, and mammals in their natural habitats. However, these descriptive accounts of canopy life amounted to no more than a drop in the ocean compared to the vast expanses of unexplored forest canopies in the world. Rigorous, comparative studies of canopy communities were set back for years by the logistical difficulties of conducting treetop investigations.

The scope and extent of canopy studies expanded greatly through the late 1970s and early 1980s, with a number of research groups working largely independently of each other. Without a doubt, this period of canopy science was more tool-driven (developing new techniques) than question-driven (developing new scientific hypotheses). As a result, even after intensive forest canopy studies became commonplace in the late 1980s, the wider scientific community still viewed the emerging discipline with mild disdain – a poorer anecdotal or descriptive cousin of terrestrial biology. Today, major new developments in canopy access systems, and a changing mind-set among canopy researchers, have all but allayed these criticisms. Forest canopy studies, today, address all manner of hypotheses using rigorous, replicated experimental designs that are the equal of any scientific investigation. Liberated from the constraints of three-dimensional movement within canopies, scientists are finally appreciating that answers to many of their questions about forest ecology and the interactions between the atmosphere and the soil can only be found by incorporating within-canopy processes. Once called the last great biotic frontier, forest canopies are now better understood than ever before and better appreciated and valued for the critical roles they play in forest ecosystem dynamics.

Modern Canopy Access Systems

Advances in canopy access systems have allowed canopy biologists to address an increasing diversity and complexity of issues. The advantages and limitations of each method for addressing differing ecological questions are outlined in **Table 1**.

Methods of Access

Ground-based methods It is not always necessary to climb into the forest canopy to complete a canopy study. For example, taking advantage of a ridge-top, hill, or bridge may provide a direct view into adjacent tree crowns. Technology such as radio-telemetry, hemispherical photography, telephoto lenses, and binoculars allow similar visual access to the canopy from the ground below. Most often, however, researchers want to collect samples or specimens from the canopy as well. One of the earliest methods for ground-based observers to retrieve samples from the canopy was the use of trained monkeys tethered to ropes. This method works extremely well for intensive botanical inventories of large areas over short periods of time. Other widely used methods for collecting plants include bending branches down, using a net or pole-pruner and ‘harvesting’ foliage with a shotgun or rifle. Canopy arthropods are frequently captured from the ground using insecticidal knockdown (canopy fogging or canopy misting), light traps, and a variety of baited interception traps. Canopy birds and bats are sampled using modified mist-net systems.

Ground-based methods are popular because of their ease of sampling targeted organisms, but the scope of such studies is limited because they do not incorporate *in situ* sampling in the canopy. Disregarding *in situ* canopy sampling can lead to biased results and hinder attempts to answer larger-scale questions in forest ecology. Some of the methods

Table 1 Modern canopy access systems and criteria for the selection of an appropriate method

Method of access	*Biology of organism*			*Spatial access*			*Replication and randomization*	*Long-term monitoring*	*Impact on ecosystem*	*Logistical constraints*				*Research applications*
	Sessile	*2-D mobility*	*3-D mobility*	*Horizontal extent*	*Vertical extent*	*Access to canopy–atmosphere interface*				*Cost*	*Ease of use*	*Major constraints*	*Major advantages*	
Ground-based methods														
Trained animals	X			Wide	Excellent	Not usually	Good replication and randomization	Difficult	Negligible	Moderate	Easy; one person	Locating and training	Rapid, high replication	Botanical surveys; plant phenology
Mechanical extension samplers (e.g., shotgun, nets)	X	X		Narrow	Narrow	No; unless SRT employed	Moderately good	Yes	Low–moderate; branch and foliage damage	Low	Easy; one person	Permits; skill; reach	Large sample area; flexible	Plant–insect interactions; leaf chemistry; vegetation dynamics
Intercept traps, mist-nets		X	X	Narrow	Wide	Not usually; can be attached to towers or poles above canopy	Good	Yes	Low; rope burn on branches	Low–moderate	Easy; one person	Activity-based	Standardized; quantitative	Arthropod, bird, and bat surveys; quantitative monitoring
Insecticide knockdown			X	Narrow	Moderate–wide	No	Low replication; good randomization	No	High; kills most arthropods	Moderate	Moderate; two people	Selective sampling difficult; wind	Comparative studies; surveys of large areas	Taxonomy; arthropod diversity; community composition
Climbing and mechanical methods														
Single rope technique (SRT)	X	X		Excellent; restricted to adjacent trees at each site though	Very good	Not usually; addition of mechanical extension samplers increases access	High level of replication and repeatability; limited full randomization	Difficult	Low; rope burn; snaps branches; damages epiphytes	Low–moderate	Easy; one person; stamina required	Branch availability; restricted reach; mobility	Flexible; lightweight; portable; versatile	Varied, e.g., phenology; canopy–soil interactions; arthropod community composition; herbivory
Ladders, booms, cherry-pickers	X	X		Moderate–very good	Moderate	Not usually; depends on canopy height	Moderate–good	No	Moderate; nails; vehicle access	Moderate–high	Easy; one or two people	Limited to sites near roads or on large trees	Stable platform; good horizontal reach	Herbivory; pollination; ecophysiology; vegetation dynamics

Towers and cranes														
Meteorological towers	X			Narrow	Excellent	Yes	Poor	Yes	Site construction	High	Difficult to build; easy use	Limited replication	Stable platform for instruments	Ecophysiology; photosynthesis; gas exchange; hydrology; canopy architecture; phenology; vertical stratification
Canopy crane	X	X		Moderate	Excellent	Yes	Low	Yes	Site construction; noise	High–very high	Difficult to build; easy use	Limited to fixed site; crane driver required	Long-term collaborative studies; stable platform	Varied, e.g., phenology; plant–insect interactions; vegetation dynamics; epiphyte communities; canopy architecture
Walkways, platforms, and cable cars														
Walkways, platforms	X		X	Narrow–moderate	Narrow–moderate	No	Moderate	Yes	Initial construction	Moderate–very high	Difficult to build; easy use	Limited to fixed site	Comfortable; useful for large groups; stable	Vertebrate behavior; monitoring forest dynamics
Cable cars, trams, ski lifts	X		X	Wide	Narrow; upper canopy	Yes	Moderate	Yes	Site construction; noise	High–very high	Difficult to build; easy use	Limited to fixed site	Long horizontal transects	Animal diversity; vertebrate behavior; seasonality
Balloons and rafts														
Canopy raft and sled	X	X	X	Excellent	Moderate–wide	Yes	Limited	No	Crushes foliage and branches	Very high	Moderate; climbing skills	Limited time at one site; wind	Stable platform above canopy	Varied, e.g., herbivory; arthropod community structure
Remote sensing														
Satellite data	X			Excellent	Narrow	Yes	Excellent	Yes	No	Very high	Access to data difficult	Available technology; computer processing	Landscape-level data	Landscape-level analyses of canopy architecture, leaf chemistry, productivity

mentioned above can be modified to collect samples directly in the canopy using line and pulley systems.

Climbing techniques and mechanical methods Brazilian Indians traditionally climbed tree trunks up to 40 cm in diameter using a loop of woven vines or cloth called a 'peconha', but this method is dangerous and cannot be used on trees of a larger diameter. Safety is a high priority for canopy biologists and modern climbing techniques incorporate rigorous safety measures. There are two climbing methods in practice today. The single rope technique (SRT) uses a relatively long (up to two times canopy height) fixed static rope, anchored to the ground at one end and climbed from the other end using mechanical 'jumar' ascendors. Alternatively, the arborist method involves the climber using a relatively short (e.g., 15 m) movable rope (lanyard pulley system) and is useful for climbing very tall trees or trees with few branches, and for transferring between adjacent trees within the canopy. Together, the two methods give almost total access to the canopy, including the outer foliage.

Arborist methods and SRT are often used to set up rigging lines in the canopy which enable a variety of instrumentation and collecting equipment to be hauled up and down from the ground. Line insertion techniques vary widely depending on the tools available. For example, ropes can be thrown by hand using throw bags, hand catapults, pole catapults, line-throwing guns, crossbows, or longbows (the best option for high canopies). Ropes, together with flexible ladders lashed to the tree, can allow rapid, repeated access into the canopy. Horizontal reach can be extended by using telescoping booms, consisting of lengths of aluminum piping that slide into one another, a steel cable, bosun's chair and manual lifting gear.

A more mechanized, but still highly mobile, access technique is the use of a hydraulic cherry-picker. Of course, roads are generally required in order to drive the cherry-picker to study sites, and trees along the forest edge tend to be the only ones accessible by this method. Booms and cherry-pickers provide stable working platforms and increased access to the outer foliage than climbing methods.

Towers and cranes Towers were first utilized to study vertical gradients in solar radiation, temperature, humidity, and wind speed in the late 1960s. Towers are costly to erect, but permit a range of investigations not possible from the ground. Towers can also be combined with horizontal access systems. The planned Canopy Operation Permanent Access System (COPAS) in French Guiana has multiple towers and a connecting cable system which will give access to 1.5 ha of forest canopy and will likely provide more detailed information than a single tower alone.

Canopy cranes provide even greater vertical and horizontal access than COPAS. The use of large construction cranes in forest canopies was pioneered in Panama at the Smithsonian Tropical Research Institute. Cranes provide permanent access to a finite number of trees, limited only by the length of the crane arm. Researchers are housed inside a gondola and maneuvered to specific sites within the canopy by ascending above the canopy and then descending back down into it. There are now 11 canopy cranes in place worldwide and an expanded network of cranes is planned as part of the Global Canopy Programme initiative.

Aerial walkways, platforms, and cable cars Aerial walkways and platforms have been used extensively to allow long-term observation within the canopy. They offer a good place to observe, educate, and study in large groups for long periods of time and they can become an integral part of the landscape, allowing researchers to study animal behavior or collect samples on a regular basis. Trams (or cable cars) supported by steel towers have also been suspended in or above the treetops in many parts of the world.

Balloons and rafts The canopy sky raft ('radeau des cimes') and sled were developed by Francis Hallé of Operation Canopéé in France. The large, inflatable raft is lowered onto the forest canopy surface by a dirigible balloon and is supported by several large canopy trees. The raft only remains in place for a few days or weeks to avoid permanent damage to trees or the risk of slipping. The sled is towed underneath the dirigible and can be flown just above the top of the canopy to sample many different tree crowns over a short period of time. Both the sled and raft have stable internal platforms from which to suspend climbing ropes, thereby increasing the vertical range of sampling. Another method of balloon access is a one-man helium balloon tethered to cables across the forest canopy, giving access to the outer edges of the canopy.

Remote sensing Forest canopy structure can be measured remotely using a wide range of sensors fitted to weather balloons, planes, or satellites. Three broad classes of sensors are available: (1) optical, (2) laser, and (3) radar. Aerial photographs can be taken that measure the outlines of individual tree crowns and the spatial extent of canopy gaps. Canopy height can be estimated crudely using stereo-pairs of air-photos. Optical satellite data (such as the LandSat multispectral scanner) can be used to estimate structural properties of canopies much more accurately, and even some aspects of leaf physiology and chemistry, including photosynthesis, transpiration, nitrogen, lignin, and pigment concentrations in leaves. Laser devices, particularly light detection and ranging (LIDAR) instruments, precisely measure vertical height from the ground to the canopy (in forests with fairly open structure). For dense forests, radar images (e.g., synthetic aperture radar (SAR)) provide an excellent means for penetrating foliage and estimating canopy structure. Both LIDAR and SAR can approximate vegetational biomass from signal reflection and scatter. Combinations of these methods have proven useful in monitoring forest responses to environmental change, such as in the use of the Scanning LIDAR Imager of Canopies by Echo Recovery (SLICER) to validate SAR data in North American forest ecosystems.

Selecting an Appropriate Method

Simply getting into the forest canopy is often the easy part – choosing the most *appropriate* method of access and deciding how to collect data once you are there is much more difficult. It relies on a clear evaluation of the research objectives and the tools and skills available to implement them. There are six major considerations when selecting an appropriate canopy access system (**Table 1**).

1. Life history and biology of the organism. A recurrent problem in forest canopy studies is how to sample efficiently and adequately document the life history of canopy inhabitants. The appropriateness of sampling techniques and methods of access will depend on the species or canopy properties under study. Some ground-based methods and towers, for instance, may be well suited to studying sessile organisms or organisms with limited mobility that perceive branches as two-dimensional planes, but are not as good for highly mobile organisms.
2. Spatial extent. From a research perspective, the most crucial attributes of a climbing method are the volume and shape of the space that can be accessed. Towers limit canopy access to a vertical transect line at one location, whereas walkways and trams permit good horizontal access at one vertical height. Other methods, such as canopy cranes, provide much better access to a fixed volume of canopy space, but suffer from limited ability to relocate to a new sampling location, as can easily be done with SRT, cherry-pickers, or other techniques.
3. Replication and randomization. Spatial and temporal replication are key considerations for any canopy study. There is a clear trade-off between ease of repeated access to a single point (e.g., towers, platforms, and so on) and access to multiple replicate locations in space (e.g., SRT, canopy raft, sled, and so on). Because of safety considerations for all canopy access techniques, true three-dimensional randomization is rarely achieved.
4. Long-term monitoring, in particular, is largely restricted to permanent structures such as towers, walkways, and cranes because of the need to have fixed, stable access over long periods of time, without the risk of cumulative damaging effects on the canopies under study.
5. Impact on the ecosystem is increasingly important when selecting a canopy access system. The technique used to access the canopy should avoid any damage that may affect the variables being measured, or the health of the tree being climbed. Regular checks on permanent structures and branches that are climbed on a regular basis are essential.
6. Lastly, logistical constraints play a central role in determining which method of access to choose. However, problems caused by the physical environment, costs, or available time should not be allowed to dictate the level of replication, randomization, or spatial access appropriate to the research question being addressed.

Canopies as the Substrate, Buffer, and Catalyst for Forest Dynamics

Canopy Architecture

Canopies provide the dominant structural influence on the movement of organisms, the availability of habitat, and the interactions between species and their abiotic environment in forests. Although the importance of canopy structure is still not fully appreciated, there is a burgeoning interest in the quantitative measurement of canopy architecture – the sizes, shapes, angles, distribution, and development of tree crown elements, such as leaves, twigs, and branches, within a three-dimensional medium. The most comprehensive, qualitative system for describing the growth patterns of trees is the Hallé–Oldeman system. Architectural development of trees is viewed in terms of a genetically programmed model in which individual architectural units are reiterated throughout the growth and development of the tree (**Figure 1**). Architectural models differ in terms of the presence of vegetative branching, orientation of vegetative axes, continuous or rhythmic growth, and varying developmental patterns of terminal buds and sexual tissues. Although numerous combinations of these characteristics are theoretically possible, the growth forms of trees are remarkably restricted. It appears that only about 30 architectural models occur in plants. Even trees that are totally unrelated may share the same architectural models. The Hallé–Oldeman system provides an elegant conceptual model to unite the common features of plant growth form among species. However, variation in the expression of architectural units during development, or asymmetrical growth and damage, can cause large variation in the quantitative outcome of canopy morphology. No two trees are ever structurally identical. A more precise description of canopy structure would have to emphasize branch order, leaf arrangement, length and diameter, longevity, share in total photosynthetic activity, and reproductive output.

Most commonly, quantitative variation in canopy structure is measured using surrogate estimates of the vertical distribution of leaf area index (LAI, the ratio of the total one-sided leaf area to the projected ground surface area below, in $m^2 m^{-2}$) (**Figure 2**) or leaf area density (LAD, the mean one-sided leaf area per unit volume of canopy space, in $m^2 m^{-3}$). The utility of these measures is evident in the highly contentious issue of vertical stratification in forests. From simple observational studies, strong vertical layering of canopies was thought to be a characteristic of tropical forests, but in cases where LAI or LAD have actually been quantified, vertical stratification has been found to be indistinct or nonexistent. The problem remains, though, that a wide range of measures exists for quantifying canopy structure and each may give a different perspective on stratification. For example, silviculturists may focus on the distribution of tree heights, ecologists may focus on the distribution of tree species within the forest, and tree physiologists or atmospheric chemists may focus on the distribution of leaf surface area.

At least part of the difficulty in extrapolating forest function from forest structure is that different organisms and different abiotic variables respond to canopy architecture in differing ways. For example, LAI may be a good predictor of photosynthetic activity in the canopy, whereas leaf optical properties, leaf angles, and LAI may be required to understand light transmittance to the forest floor. Conversely, LAI may bear no relation to colonization and diversity of epiphytic plants within tree crowns, which are more dependent upon structural attributes of branches and twigs. More generally, some organisms ‘perceive’ the canopy as a true three-dimensional volume, whereas others may perceive the canopy as a set of highly convoluted, two-dimensional surfaces. For example, mites and other wingless arthropods may view canopies, for all intents and purposes, as flat surfaces, because dispersal through air is highly limited. Other organisms, such as birds or bats, clearly view the canopy as a volume. This can have important functional implications for the effect of canopy structure on the distribution and abundance of organisms (or nutrients or chemicals, for that matter). Recognition of this difference has led to some astounding developments in the quantification of canopy structure. Recent studies have reversed the

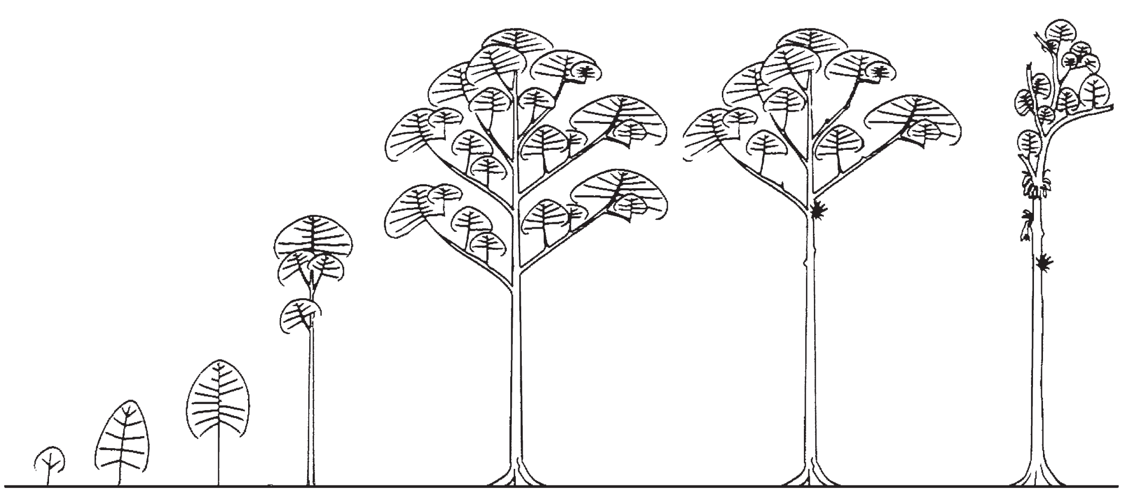

Figure 1 Schematic representation of the reiteration of architectural units during growth and development of a tropical tree. Although there are relatively few ‘ground-plans’ for crown architecture among species, every individual tree exhibits unique canopy structure due to asymmetrical growth and damage.

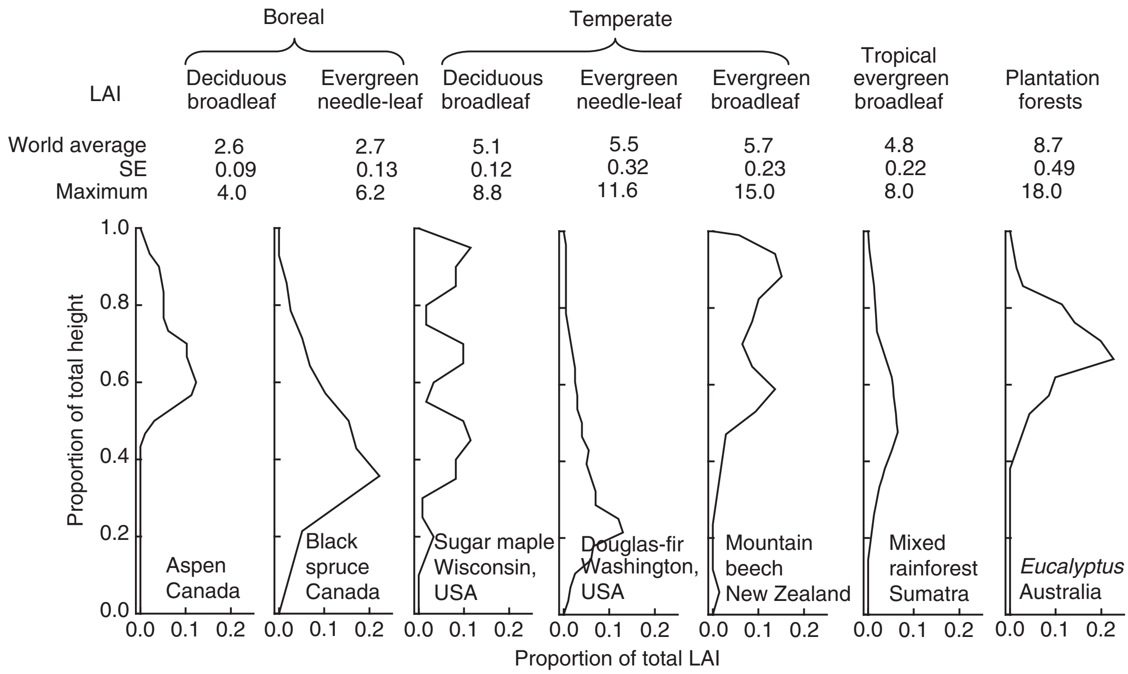

Figure 2 Summary of leaf area index (LAI) for major forest types of the world, showing the global average (in $m^2 m^{-2}$), standard error of the mean of multiple studies (SE) and maximum recorded value for each forest type. One example of vertical variation in canopy architecture is presented for each forest type. Aspen forest, Canada: canopy height (H_{max}) = 30 m, total LAI = 2.02. Black spruce forest, Canada: H_{max} = 14 m, LAI = 2.35. Sugar maple forest, Wisconsin, USA: H_{max} = 16 m, LAI = 6.10. Douglas-fir/western hemlock forest, Washington, USA: H_{max} = 56 m, LAI = 6.28. Mountain beech forest, New Zealand: H_{max} = 17 m, LAI = 6.95. Mixed broadleaf tropical rainforest, central Sumatra: H_{max} = 42 m, LAI = 7.50. *Eucalyptus nitens* plantation forest, Tasmania, Australia: H_{max} = 21 m, LAI = 7.00.

emphasis on quantitative structural elements in the canopy and measured the vertical distribution of empty space (gap size and frequency) in forests. Measurements produce a characteristic S-shaped distribution of open space with increasing height from the ground to the atmosphere above the forest.

Opportunities to integrate differing perspectives on canopy structure are expanding with the advent of remote sensing tools to more rapidly and accurately measure forest structure across large areas, and sophisticated computer software that can manipulate complex three-dimensional spatial models. The recent development of the Vertical Canopy LIDAR (VCL) has created new opportunities to remotely characterize the three-dimensional structure of the earth's surface by satellite and measure the vertical and horizontal distributions of plant structures across vast swathes of the planet. The VCL uses near-infrared wavelength laser pulses fired at regular intervals at the earth's surface. The time displacement of the reflected laser signal to the VCL determines the height above ground, with an incredible 30 cm vertical resolution, while the magnitude of signal scatter determines the absolute volume of canopy biomass intercepted by the laser. Already the VCL has produced revolutionary new views of forest canopies that would have taken several lifetimes of ground-based measurements to compile.

The measurement of canopy architecture has direct applications in a wide range of disciplines. For example, variation in forest canopy structure exerts strong regulation of radiation transfer to the ground surface, altering the extent of snow cover in forested regions of the boreal zone. Canopy removal by clear-cut harvesting slows snowmelt and markedly alters local climate compared to regions with intact canopy structure. In coniferous forests in Chile, forest canopy structure is also an important determinant of precipitation infiltration into soils, with dense canopies decreasing erosion and increasing the return time for landslide-forming events by over 20%. In other fields, quantitative models of three-dimensional canopy structures are being utilized to predict (and optimize) the dispersal pattern of pheromones released in forests to control insect pests, and drag coefficients and turbulence around canopy elements are being utilized to parameterize within-canopy atmospheric exchange models. The structural detail now being provided by high-resolution VCL remote sensing of forest canopies promises a revolution in our understanding of the relationships between (1) canopy architecture and habitat for plants and animals, (2) architecture and ecosystem functioning, and (3) architecture and carbon, water, and energy exchange.

Aboveground–Belowground Dynamics

Aboveground and belowground ecosystem processes are integrally linked by material transport between roots and crowns of individual plants and the plasticity of resource allocation among components of foliage, reproductive structures, branches, stems, defensive chemicals, roots, mycorrhizae, and root exudates. Although a full understanding of resource allocation in plants is limited by difficulties in measuring belowground processes, there is growing awareness that soil and root dynamics are critically dependent on forest canopy dynamics. Tree roots represent a major pool of stored nutrients and contribute a significant amount to total soil surface respiration in forests. For example, studies in pine forest in Oregon, USA, have shown that 18% of annual ecosystem respiration typically originates from foliage, 6% from woody debris and the remaining 76% from soil, with root respiration accounting for a massive 53% of total soil respiration. Most early studies concluded that root growth and respiration were limited by abiotic factors such as soil water content or soil temperatures, leading to concern over the effect of global warming on carbon balance within soils and possible atmospheric CO_2 emissions. However, new data suggest that root production is regulated instead by concurrent radiation interception and photosynthetic production in the canopy. Photosynthetic products are transferred below ground much more rapidly than ever previously imagined. In a remarkable experimental test of the importance of current photosynthesis to belowground respiration, researchers in northern Sweden girdled (stripped the bark from) mature pine trees over a large area to inhibit carbon allocation to the roots. Inhibition of root respiration virtually eliminated mycorrhizal fungi and reduced overall soil surface respiration by 54%, in striking concordance with findings on the importance of root respiration in Oregon.

Forest canopies also affect belowground processes by storing nutrients in foliage and regulating the input of available carbon, nitrogen, and other elements to the soil through litter fall. Despite the long-standing belief that nutrient availability in forests depends on species-specific characteristics of the chemistry and decay rates of litter on the ground, recent studies show that soil nutrient cycling is better predicted simply by the total mass of litter produced from the canopy and total nutrient content of leaves. Given that 90% of net primary productivity is channeled directly into the detrital pathway (largely via litter fall), belowground nutrient recycling, site fertility, and soil surface respiration are primarily regulated by within-canopy processes that affect foliar litter production.

Much of forest ecosystem research and global change biology is focused on understanding net ecosystem productivity – the balance between photosynthesis and ecosystem respiration – and it appears that canopy processes are not only the critical drivers of photosynthetic production in forests, but they are also important catalysts for soil surface respiration rates.

The Canopy–Atmosphere Interface

Forest canopies form an important buffer between the soil and the atmosphere, regulating the exchange of carbon, water, and energy that affects atmospheric chemistry. Forest canopies interact with the atmosphere in two important ways. First, through structural interference of airflow that creates turbulence. Second, through the interception of solar radiation and exchange of CO_2 and water vapor during photosynthesis, respiration, and transpiration.

Boundary-layer dynamics around leaves and branches are crucial to understanding atmospheric processes. This is not surprising when a single tree crown spanning just 20 m across can have 10 000 m^2 of foliage surface area. As a result, canopy leaves can filter 20–30% of bulk precipitation and intercept and concentrate even greater amounts of airborne nutrients and pollutants from the atmosphere. Lowered air velocity around canopy elements partially isolates the upper canopy from airflow in the surrounding understorey and atmosphere, creating a zone of contrasting internal dynamics. This buffering effect is explicitly recognized in the measurement of atmospheric gas exchange. Partitioning net ecosystem CO_2 exchange (NEE) between the soil, canopy, and atmosphere is a major objective for scientists studying gas exchange using the eddy covariance technique (measurement of the turbulent fluctuations of vertical air movement in conjunction with temperature, water vapor, CO_2, and other gases, calculating flux rates as the covariance of wind and one of the other variables). This has been achieved in a number of ways, including simple comparisons of below-canopy and above-canopy eddy systems, or the compartmentalized measurement of gas exchange from individual ecosystem components, such as soil, roots, wood, and foliage, using experimental chamber techniques. Results from chamber measurements are then scaled up to the ecosystem level to calculate NEE from days to several years. Another method to partition and integrate the role of forest canopies in NEE at the ecosystem level is to analyze the stable isotope ratios of carbon and oxygen in CO_2, as these vary according to the source of CO_2 exchange from different ecosystem compartments (for example, autotrophic versus heterotrophic respiration). However, canopy structure can influence the composition of stable isotopes in belowground and above-canopy compartments by modifying radiation interception and photosynthetic activity of ground vegetation, and by reducing turbulent upwelling of air from the ground and thus inhibiting the mixing of respired CO_2 from the soil. These processes make modeling and prediction of NEE heavily dependent on measurement of the characteristics of canopy structure and an understanding of within-canopy dynamics.

The Functional Importance of Forest Canopies in Global Change

Globally, forests cover over 25% of the land surface and store almost 50% of terrestrial carbon. Conversion and management of forests are altering global stability on three central fronts: (1) the ability of forest ecosystems to support a large proportion of global biodiversity, (2) the global sustainability of fiber production from forests and the maintenance of site productivity, and (3) the stability of global carbon balance, atmospheric chemistry, and atmospheric circulation patterns. Forest canopy processes are central to understanding the importance of forests in all three aspects of global change (**Figure 3**).

Maintenance of Biodiversity

Individual tree crowns often harbor rich microcosms of epiphytic life, complete with fully functioning aerial soil communities and complex food web dynamics analogous to the more extensive soil communities below ground. Over 10% of all vascular plants in the world are canopy epiphytes, often with a restricted resident fauna of vertebrates and invertebrates associated with them. The

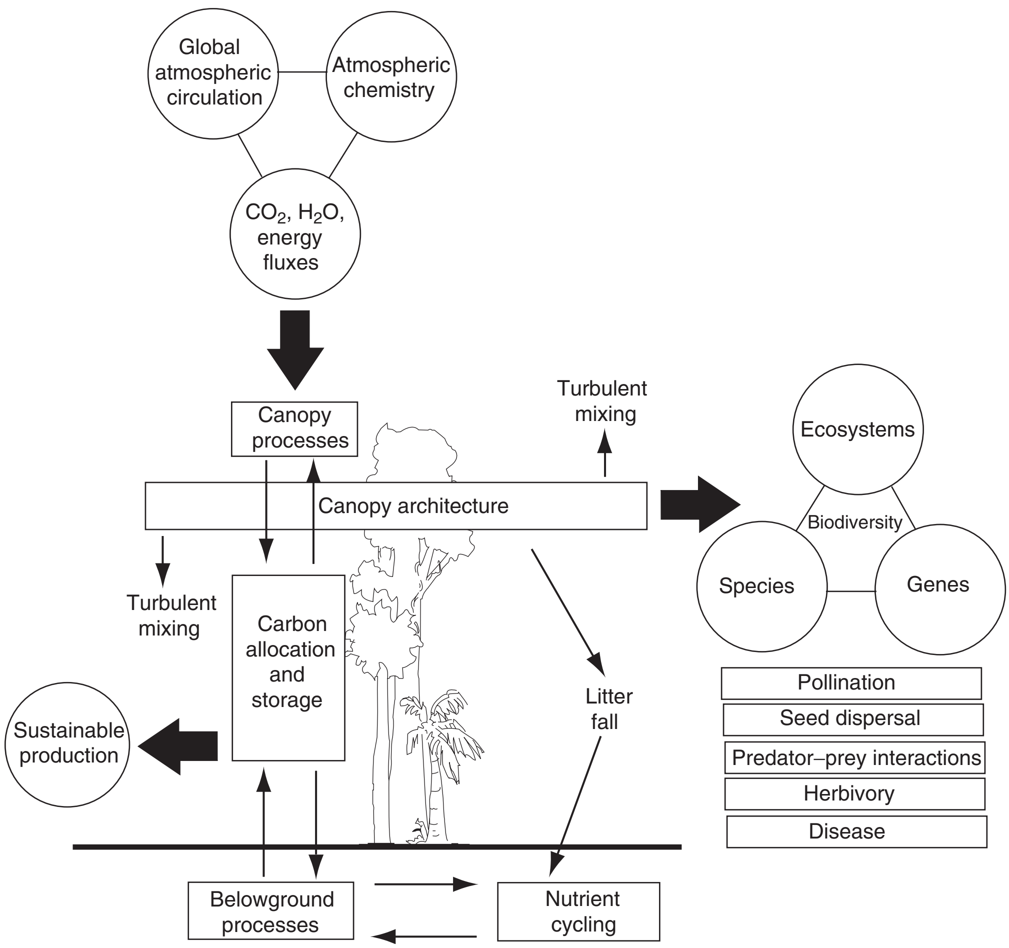

Figure 3 Conceptual diagram showing the key roles of forest canopies as the substrate, buffer, and catalyst for forest dynamics. The structural and functional attributes of forest canopies are central to the maintenance of global biodiversity, the sustainability of forest production, and the stability of global climate.

importance of canopy epiphyte communities is not trivial in terms of forest dynamics. Epiphyte biomass in some wet tropical forests is four times greater than that of host tree foliage, stored nutrients within epiphyte leaves may represent 50% of total canopy foliar nutrients, and dead leaves decay almost twice as fast in canopy soils than in ground soils. Incredibly, canopy soil biomass can be equivalent to the total biomass and available nutrient pools of terrestrial leaf litter in many forests. As a consequence, canopy epiphyte communities can have a large effect on primary production and nutrient cycling rates in forests.

The surface area, biomass, and productivity of tree crowns and associated epiphytic plants provide a diverse range of niches that are exploited by canopy organisms. Notable, in terms of their diversity and contribution to total global biodiversity, are the arthropods of tropical forest canopies. Large numbers of undescribed species in forest canopies have spurred intense speculation on the magnitude of total global biodiversity, with estimates ranging as high as 30–80 million species. With the availability of better data on species turnover rates between geographic regions, host specificity, species coexistence, and coevolutionary relationships among animals and plants in tropical forests, estimates have been revised downwards to 3–5 million species. This still represents a threefold increase in the total number of recognized species in the world – most of them thought to be in the canopies of tropical forests. However, there has been no rigorous assessment of whether a large proportion (42–66%) or a relatively small proportion (10–20%) of forest species are canopy specialists. It may well be that many forest canopy species utilize belowground habitats, or nonforest ecosystems, during larval life history stages of which we are not yet aware.

Nevertheless, it is the overwhelming superabundance and diversity of canopy organisms that perhaps best exemplifies the structural complexities of forest canopies, and is a cause for concern in the face of habitat modification. Variation in canopy architecture, changes in resource availability, and an increase in microclimatic extremes due to changing land use management all influence biodiversity in forest canopies. It is precisely the accelerating rates of forest loss and conversion since the 1950s, combined with recognition of the magnitude of forest canopy diversity in the 1980s, which have prompted fears of an extinction crisis. If even 10% of species in the world are solely restricted to forest canopies, and a further 50% of all forest species depend critically on the canopy for some aspect of their resource requirements, then preservation of intact forest canopy structure and function is clearly key to the long-term maintenance of global biodiversity.

Sustainability of Forest Production

Management of forests for fiber production uses conventional empirical, or statistical, approaches to estimating growth and yield based on accumulated experience of site quality, stand structure, or tree species traits in the area being harvested. However, the future of sustainable forest production lies in the application of process-based models for ecosystem management – models that define the actual mechanisms of net photosynthate assimilation, carbon allocation, and storage in aboveground structures, tree respiration, and long-term stand viability that is affected by processes such as nutrient recycling and maintenance of predator–prey interactions, pollination, and seed dispersal services. Forest canopies play a central role in all of these ecological and physiological processes and in the maintenance of ecosystem services in forests.

Process-based models have only recently begun to be implemented at an operational level in forest management. Not surprisingly, the initial focus has been on improving predictions of growth rates and enhancing total yield at the stand level. Several carbon balance models have been developed for this purpose, which treat the acquisition and distribution of photosynthetic products as central to understanding forest production. Gross primary productivity in this sense is driven almost entirely by canopy processes. Canopy architecture also affects the distribution of organisms and flux of abiotic variables that influence tree respiration. The dynamic balance between these effects of the canopy on assimilation and respiration of carbon determine the total amount and distribution of new growth. For example, Norway spruce trees with narrower geometrical crown shapes have a higher LAI, greater stemwood production per unit crown area and higher harvest index due to greater allocation of carbon to stems, rather than roots or foliage. This variation in allocation is determined both genetically and environmentally, but a radical new perspective on the importance of canopy architecture to forest production is that trees could be more intensively selected and 'domesticated' for improved carbon allocation performance. It should be recognized, however, that predictions of overall stand performance must incorporate not only the net carbon balance of individual trees, but also aboveground and belowground competition for resources between trees (whether of the same or different species) and the dynamics of stand structure in response to biotic and abiotic disturbances. For example, herbivory directly affects the amount of leaf material available for photosynthesis, carbon allocation to defensive chemicals, new foliage growth and stem increment, and ultimately forest production.

Other tree physiological processes, such as water balance or nutrient cycling, have received considerably less attention than carbon balance, but are nonetheless critical to forest production. For example, tree canopies on more fertile sites produce greater leaf biomass, which increases foliar litter inputs to the soil, reinforcing differences in site fertility, nutrient availability to roots and overall soil heterogeneity. This can be exacerbated in harvesting situations because forest removal eliminates the buffering influence of the forest canopy on soil microclimate and removes litter inputs. Without foliar litter inputs, it is thought that microbes become carbon-limited (instead of nitrogen-limited), leading to reduced assimilation rates of nitrates and contributing to a pulse of nitrogen availability in clearcut areas. This change in nutrient cycling even occurs in small gaps of just a few trees and in natural windfall gaps, but not following single-tree removals in which canopy cover is not greatly compromised.

Beyond physiological models of growth and yield, production can be limited by biological factors that limit growth (such as herbivory), increase mortality (such as disease), and reduce seed or seedling establishment (such as pollination limitation or seed predation). Many animals that live in forest canopies play important functional roles in the provision of ecosystem services, like pollination and predation, in forests. Maintenance of intact structure and functioning of forest canopies is likely to facilitate preservation of species that may have beneficial roles in the sustainability of future forest production. These roles may be as simple as pollinating flowers that ensure a continued seed supply for reforestation, or as important as dampening the oscillatory dynamics of pest insect populations.

Stability of Global Climate

Forest canopies account for at least 50% of global CO_2 exchange between terrestrial ecosystems and the atmosphere, as well as a significant proportion of global net primary productivity. Compelling evidence suggests that tropical forest canopies may be net carbon sinks, mitigating the rate of increase in atmospheric CO_2 concentration from anthropogenic sources. Increased deforestation and burning threatens to alter this balance by directly liberating vast amounts of carbon (and other elements) into the atmosphere, and indirectly limiting the net assimilation rate of carbon by disturbance to the remaining forest canopies. Synergistic interactions between deforestation, increased fire frequency, and drought in the Amazon Basin, the world's largest remaining expanse of tropical forest, are enhancing a positive feedback cycle in altered climatic circulation patterns and increased forest degradation. Experimental exclusion of rainfall from large areas of undisturbed tropical forest in eastern Amazonia has simulated the effects of increasing drought. A 40% reduction in precipitation throughfall to the soil significantly reduced tree growth and reproductive output, lowered net primary productivity and increased leaf loss and tree mortality, all of which resulted in the forest becoming a net source of CO_2 to the atmosphere rather than a net sink. Correlated drought and tree mortality effects have been detected at distances of up to 2–3 km inside 'intact' nature reserves, leading to concern over receding edges and the long-term viability of fragmented forest remnants. Because of the magnitude of change in disturbance regimes and climatic conditions in the wet tropics, vegetation dynamics in some areas are shifting away from high-diversity rainforest to low-diversity, fire-adapted sclerophyll vegetation.

The study of ecophysiological processes in forest canopies is not only critical for predicting forest responses to global change, but also for modeling how canopy structure and functioning mitigates future atmospheric CO_2 increase and climate change. Through diverse roles in carbon, water, and energy cycling, structural integrity of forest communities, nutrient cycling dynamics, and maintenance of forest productivity and biodiversity, forest canopies will shape the direction and magnitude of global change that human populations experience over the next millennium. We can either use this knowledge to advantage in conserving forests, or face a more extreme and more uncertain future.

Natural Disturbance in Forest Environments

D F R P Burslem, University of Aberdeen, Aberdeen, UK

Introduction

Disturbance in plant communities has been defined as consisting of ‘the mechanisms which limit the plant biomass by causing its partial or total destruction.’ In forests, disturbance arises from the agencies of tree damage or death. At small spatial scales, individual trees die standing or fall over, but in both cases a gap in the canopy is created and this initiates a successional process known as the forest growth cycle. The agencies of natural disturbance at larger spatial scales include windstorms, fire, and landslides and these factors vary in their impacts on forests and the ensuing mechanisms of forest recovery. Natural disturbance regimes in forests are important because they impact on tree population dynamics, the relative abundance of different species and functional groups, the biomass and carbon content of vegetation, and interactions with other components of the biotic community. Community ecologists have highlighted the importance of disturbance among mechanisms proposed for the maintenance of tree species richness, particularly in species-rich tropical forest communities.

Small-Scale Disturbance: Gap Phase Dynamics

Small-scale natural disturbances are an inherent component of all plant communities because plants have a finite lifespan. In forests, the size of the individual tree at the time of its death and the mode of death determine the scale of the disturbance created. The death of individual small understory trees and shrubs that live their entire life in the shade, and of the suppressed juveniles of canopy trees, may have limited impact on forest stand structure. However, the death of canopy-level or emergent trees has significant potential for localized modifications of canopy structure, resource availability, and microclimates. Some large trees die standing, perhaps following lightning strike or the synergistic effects of old age and wood decay fungi. Many trees lose large branches or parts of their crown long before the entire tree has died, and these events may lead to partial opening of the canopy and to some damage of surrounding smaller trees and other plants. However, the threshold for a natural disturbance event is usually regarded as the death of an individual large canopy or emergent tree, which results in the creation of a hole through all layers of the forest down to 2 m above the ground surface (a canopy gap). The size of a canopy gap varies according to the height of the tree that died, its architecture (height : canopy width), and its neighborhood. The fall of a large tree will inevitably lead to damage or death of surrounding trees, particularly if their crowns are connected by lianas. Thus canopy gaps arising from small-scale tree death can vary from a lower limit of 25–50 m^2 up to about 1000 m^2 for a large multiple tree-fall gap. Gaps can be further divided into zones influenced by the fallen crown (crown zone), the bole (bole zone), and the site where the fallen tree had been rooted (root zone). In addition, when trees fall over, particularly during severe windstorms, they frequently create an elevated mound of consolidated soil and roots known as a tip-up mound and an associated pit with exposed subsoil on its base and sides. Microclimatic conditions and availability of some resources for plant growth are known to vary between zones within a gap and on tip-up mounds. This variation within canopy gaps and between gaps of different size is thought to be one factor contributing to the maintenance of tree species richness in forests.

Changes in Microclimate and Resource Availability Following Gap Creation

Solar radiation reaching the forest floor increases following creation of a canopy gap because canopy leaves absorb a high proportion of radiation that falls within the range of wavelengths absorbed by photosynthetic pigments (440–770 nm) and reflect radiation of all wavelengths. Thus the proportion of total irradiance that reaches the forest floor increases from about 1% beneath a mature closed canopy site to 10–25% in the centers of large canopy gaps. Solar radiation is important because it affects directly other aspects of the aerial microclimate, it contributes to modifications to the belowground environment, and it impacts on plant growth and development in gaps both directly (via photosynthesis) and indirectly (for example via temperature-mediated effects).

Measurements have demonstrated that canopy gaps have higher mean and maximum air and ground surface temperatures, lower mean relative humidity, and greater wind speeds than sites beneath a closed forest canopy. This combination of conditions drives greater evaporation from exposed surface soils and thus a reduced water content at the top of the soil profile. Water availability lower down the soil profile, however, varies according to the density of live fine roots that survive gap creation, and can be either greater or no different to conditions beneath closed canopy forest.

After a tree dies its tissues decompose and contribute to fluxes of carbon and nutrients from plant biomass into microbial biomass and soil compartments. Leaves are the most readily decomposable aboveground plant tissues because they have the highest concentrations of nutrients and the lowest concentrations of lignin and fiber. Therefore the crown zone of canopy gaps receives the highest quantities of dead organic material and a transient increase in available nutrients in soil has been detected. Organic matter decomposition rates are enhanced by the relatively high temperatures in gaps, and the lower density of live roots in soil results in reduced competition for nutrients. Woody material decomposes much more slowly than leaves, particularly the bole and other material of large dimension. In tropical forests, termites and other components of the soil mesofauna initiate and hasten the process of wood decomposition, although it is common to observe large boles surviving semi-intact long after the gap created by the fall of the tree has closed over the fallen bole.

Forest Regeneration in Gaps

The changes in microclimate and resource availability that are induced by gap creation contribute to the mechanisms of forest regeneration, which describes the processes of recovery following disturbance. Regeneration proceeds via processes of both sexual and vegetative modes of reproduction. It is initiated by the germination of seeds, which either emerge from the buried soil seed bank or arrive in the gap after it has been created, or by the release of seedlings and saplings that were present at the time of gap creation (advanced regeneration). In addition, saplings and small trees of some species that are damaged during gap creation have the capacity to produce epicormic resprouts that grow rapidly in height and can contribute significantly to the regenerating tree community. Gap creation also stimulates enhanced growth of tree canopies surrounding the opening, which contributes to canopy closure and influences the development of vegetation growing up in the gap.

Some trees possess mechanisms that increase the likelihood that they germinate and grow rapidly in response to the environmental conditions that are stimulated by gap creation. Some of the species that adopt this strategy are termed 'pioneers' because they represent a distinctive functional group among all forest floras and share a suite of life-history characteristics that predisposes them to establish and grow in canopy gaps. Species of birch (*Betula* spp.) are characteristic pioneers of the cool temperate deciduous forests of Western Europe and North America, while *Cecropia* (neotropics), *Musanga* (tropical Africa), and *Macaranga* (tropical Southeast Asia) are the classic genera of pioneers in lowland tropical evergreen rainforests. All forest floras possess pioneer species, but their abundance and richness vary according to the characteristic disturbance regime manifested at a particular site.

Many (but not all) pioneer species possess seeds that are small and widely dispersed by animals or wind. Small seeds have few resources with which to grow a shoot and therefore cannot establish when deeply buried beneath soil or litter. For this reason, many species have evolved photoblastic germination, that is, they only germinate when the seeds are illuminated by light rich in wavelengths in the far-red range of the electromagnetic spectrum (centered on 720 nm) relative to wavelengths in the red light range (centered on 660 nm). Thus species with photoblastic germination are described as being responsive to the red to far-red ratio of light. The function of this response is to prevent germination when the seed is located in an inappropriate microsite for successful emergence (i.e., buried beneath a layer of soil or litter), or establishment (i.e., beneath a closed forest canopy).

Photoblastic germination in pioneers is concentrated among species with the smallest seeds (e.g., in neotropical pioneers, seeds with a fresh mass <1.5 mg). However, pioneer species with larger seeds have evolved alternative mechanisms to target germination in well-lit canopy gap sites, such as germination in response to an increased magnitude of diel temperature fluctuation. Surface soil temperature rises higher during the day in canopy gaps than beneath a closed forest canopy and at night falls either to the same or to a lower minimum value because of enhanced radiative cooling. Thus the magnitude of diel temperature fluctuation is an index of canopy gap size and a number of species have been shown to germinate poorly in the absence of a fluctuating temperature regime. One example from semideciduous tropical forest in Panama is provided by balsa (*Ochroma pyramidale*).

Germination in gaps is important for pioneer tree species because they lack an ability to survive and grow in the shaded conditions of the forest understory. For example, their photosynthetic physiology is adapted to rapid carbon assimilation at high light rather than persistence for long periods in the shade. To achieve this, they produce short-lived leaves containing high concentrations of nitrogen (required for the enzymes involved in photosynthesis) that tend to be poorly defended against herbivores and pathogens. In addition, the high respiration rates required to maintain the enzymatic machinery involved in photosynthesis and carbon assimilation precludes long-term survival of pioneers in the shade.

The trade-off between survival in shade and growth response at high light is resolved in different ways by different tree species, so that a continuum of response to heterogeneity in light conditions will exist among any group of coexisting species. This shade-tolerance continuum has important consequences for the changes in community structure that occur during tree regeneration in gaps. As described above, pioneer species are well represented among the community of seedlings that establish early following gap creation, particularly in large gaps or the centers of small gaps. However, over time species with more shade-tolerant seedlings will become established beneath the developing canopy of the early-colonizing pioneers. The shade-tolerant species grow more slowly in height than the pioneers, but they survive for longer. Therefore as the cohort of pioneers matures and dies their canopies begin to receive more light and their growth rates increase. Ultimately, the saplings and pole-sized trees of these attain dominance in the gap, and the forest growth cycle is said to be in the 'building phase.' The cycle is closed by the growth of poles to canopy trees and the recreation of forest understory light and microclimatic conditions in the former gap site.

Importance of Chance Effects

The description of forest regeneration provided above implies that the changes that take place after small-scale disturbance are entirely deterministic, such that disturbances of a similar scale in sites sharing the same species pool would proceed through a predictable sequence to an end point that is identical in terms of species composition and structure to its status prior to the death of the original canopy tree. However, it must be recognized that this description is an oversimplified caricature of many highly complex processes that collectively reduce the predictability of forest regeneration pathways in a particular site. For example, it is highly unlikely that all species that have the ecological potential for regeneration in any particular site will actually get there, because of constraints on dispersal.

Forest Growth Cycle

The processes of tree death and regeneration described above are intrinsic to all natural forest communities. They provide examples of internal secondary successions that arise because of the uneven-aged structure of most natural forest communities. The heterogeneous nature of forest composition and history creates a mosaic of patches at different stages in the forest growth cycle. Experienced foresters and ecologists have attempted to map the distribution of patches at different stages using species composition and forest structure as indicators of patch status, although these efforts are inherently limited by the low degree of spatial coverage relative to inherent spatial heterogeneity. However, in one well-replicated study of a semideciduous forest in Panama, approximately 0.1% of the ground surface area was covered by canopy gaps (defined as contiguous areas of at least 25 m^2 in which the height of the canopy is <5 m).

Large-Scale Disturbances

In addition to the small-scale internal dynamics inherent to all forests, most forests also show evidence of perturbation by agencies operating over larger spatial and temporal scales. These factors can be divided into those that destroy all vegetation and *in situ* sources of regeneration (such as landslides, volcanoes, and earthquakes), and those that do not (for example, windstorms, lightning strikes, drought, and fire). This distinction is important because loss or burial of seeds and stumps means that forest recovery can occur only via a primary succession. By contrast, those factors that leave components of the vegetation or a buried soil seed bank intact will undergo secondary succession and a more rapid recovery of structure and floristic composition. There is a third category of disturbance factor that arises from gradual processes occurring over longer timescales, such as climate change and plate tectonics. Although these processes might fall under some definitions of disturbance, their impacts extend over such long intervals that short-term effects on community biomass (as opposed to species composition) are likely to be minimal.

Disturbances that Result in Primary Succession

Landslides occur wherever steeply dissected terrain occurs in a wet climate. They occur most often after earthquakes or periods of very heavy rainfall, and are therefore most frequent in mountainous, tectonically active regions of the world. In New Guinea, for example, 8–16% of the land surface area is affected by landslides per century. Landslides often result in the exposure of nutrient-poor subsoils and parent rock at the surface and plant recolonization of these sites tends to be limited by the low nutrient status and instability of the soil. The plant community that re-establishes may differ in composition from the surrounding vegetation for a long period because of the slow pace of succession on these substrates. Studies of forest regeneration on landslides in the Caribbean have suggested that old landslides provide a habitat for some species that do not occur elsewhere in the surrounding forest matrix.

Active volcanoes have the potential to destroy forests over a large area by the direct effects of lava and ashfall and indirect effects caused by tsunamis and changes to atmospheric conditions. For example, the 1883 and subsequent eruptions of Krakatau, in the Sunda Straits between Java and Sumatra, are still evident in the contemporary flora of the Krakatau island group, which is dominated by a small group of well-dispersed tree species. Differences in the species composition of the islands in the Krakatau archipelago demonstrate the vagaries of chance colonization events and the patchy effects of historic and contemporary volcanic activity. The long-distance effects of the eruption of Krakatau are also illustrated by impacts on forest structure and composition on Ujong Kulon, west Java, located 70 km from the island group.

Rivers that migrate across the landscape on decadal timescales can cause disturbance to natural forest communities and stimulate primary successions on newly deposited substrates. In the Amazon floodplain of Peru, rivers can move by as much as 180 m during the annual floods, with resultant dramatic impacts on forest structure and composition. The communities that develop on land exposed by lateral river movement are initially species-poor and dominated by early-successional pioneers, but these forests are gradually replaced by richer communities that are more similar to the surrounding matrix of terra firme forest. It is sometimes possible to identify zonation in forest structure and composition that reflects species accumulation over time and the nature of the underlying substrate as the river moves across the landscape.

Disturbances that Result in Secondary Succession or Recovery

Cyclones and hurricanes impact forests in two belts between 10° and 20° either side of the equator, although their frequency and intensity vary greatly. Severe windstorms also occur occasionally at higher and lower latitudes. Typhoons also have localized impacts on forests in their path and occur over a broad range of latitudes. In the Caribbean, forests are impacted by hurricanes once every 15–20 years on average, and the forests are, therefore, permanently in a state of recovery. Severe windstorms cause trees to be snapped, uprooted, and defoliated, but only a minority is actually killed instantaneously. Studies in the Solomon Islands and the Caribbean have shown in both cases that about 7% of trees were killed outright by severe windstorms, although a larger number were damaged. Recovery occurs by a combination of resprouting of surviving damaged stems, release of seedlings that had been previously growing in the shaded forest understory, and germination of pioneer species in response to canopy opening. The pioneer trees soon grow up, reproduce, and die, so that within a relatively short period the species composition of the forest community may differ little from that of the forest that existed prior to the storm. There are three caveats that must be considered in response to this statement. First, if a second or subsequent disturbance intervenes before recovery is complete, the structure and composition of the forest may become permanently affected, particularly if the windstorm is followed by fire. Second, forests that contain a mixture of species or species groups that are differentially susceptible to wind (e.g., susceptible conifers vs. tolerant angiosperms) may exhibit a higher dominance of the tolerant group after a severe windstorm, particularly in areas where severe windstorms are relatively infrequent. Third, forests that are most frequently impacted by severe windstorms may develop a modified structure, such as a low and even stature (as in the forests of the eastern Sierra Madre mountains of Luzon, Philippines), or an open structure with a low density of large trees and many lianas (for example in east-facing slopes of the north Queensland rainforests).

Windstorms and volcanic activity may be associated with lightning strikes that can cause death of trees in large numbers. Even if only one tree is struck by lightning, others surrounding it can be damaged or killed if they are connected by lianas or roots. In New Guinea, mangrove forests may have patches of up to 50 m in diameter in which all trees have been killed by lightning strike, and *Nothofagus* forests may possess circular holes with a similar origin.

Lightning strike may also give rise to natural fires that impact much beyond the original source of ignition. Fires are a natural and inherent component of the disturbance regime in most natural forests, including those in the wet tropics that were formerly considered not to burn. However, recent evidence derived from dating of charcoal fragments extracted from soil profiles in tropical rainforest areas of South America and Africa have demonstrated a history of recurrent fires on millennial timescales even in sites that are currently very wet. Fires are an even more important feature of the disturbance regime for dry tropical forests and woodland, Mediterranean vegetation, and boreal forest, for which frequent and intense fires may be an important component of ecosystem functioning. The importance of fires in these forests is demonstrated by the occurrence of species that are either tolerant of fire, or possess mechanisms that facilitate their regeneration after fire. Fire tolerance is conferred by shielding living tissue beneath a thick bark or in underground storage organs, while regeneration after fire is enhanced by fruit or seed structures that are stimulated by high temperatures. Although fires have the potential to destroy living plant tissues, they can also have an important role in releasing nutrients from recalcitrant pools in the ecosystem and reducing species dominance. These effects depend on the intensity, timing, and frequency of fire and interactions with other disturbance agents.

Severe fires may be associated with periods of low rainfall, either naturally because they are concentrated in the dry season, or at supra-annual scales because they follow climatic droughts. Droughts may themselves directly increase rates of tree mortality, particularly when they occur in forests that are not normally associated with water shortage. For tropical rainforests, there is evidence that large trees are relatively more likely to be killed during a drought than small trees, and that droughts contribute to increased susceptibility to disturbance by fire. Both drought and fire are therefore more common in years when the El Niño-Southern Oscillation (ENSO) phenomenon is impacting global climates. In one or more regions of the world, severe ENSO events may be associated with increased rates of forest perturbation from either drought, fire, flooding, windstorms, lightning, landslides, or combinations of these factors. As a dramatic illustration of this phenomenon the 1982/83 ENSO caused a reduction to one-third of average rainfall across some parts of Southeast Asia and destruction of 3 millions ha of rainforest in Borneo by drought and fire. In Panama, the same ENSO event caused increased mortality rates of 70% of woody plant species represented as individuals ≥ 1 cm diameter at breast height on a large forest plot, from about 2% year^{-1} in a nondrought period to about 3% year^{-1} in the interval spanning the ENSO-related drought. This 50% increase in mortality rate has been associated with dramatic changes in species composition on the plot, because not all species were affected equally.

Conclusions

This discussion has demonstrated that disturbance to natural forests varies greatly in scale and effect in different forest types and for different disturbance agencies, such that robust generalizations are difficult to construct. A disturbance regime has components describing the intensity, frequency, and extent of its effects, although these are rarely quantified. These properties are important because they may influence emergent properties of the forest community, such as species composition and tree diversity. For example Connell's intermediate disturbance hypothesis, relates the intensity, frequency, or timing of disturbance to community diversity and has recently been tested in forests (*see* **Biodiversity**: Plant Diversity in Forests). Although disturbance and its impacts are difficult to quantify, the evidence from historical and ecological analyses of forest communities is highlighting the importance of natural disturbance regimes to forest community structure and ecosystem functioning. It is self-evident that all forests experience the small-scale disturbances associated with individual tree death and mortality. However, it is now clear that most well-studied forests also exhibit the imprint of one or more of the large-scale disturbance factors discussed above. This consideration highlights the importance of disturbance history in any attempt to understand contemporary forest ecology.

Biological Impacts of Deforestation and Fragmentation

E M Bruna, University of Florida, Gainesville, FL, USA

Introduction

In addition to housing the majority of the planet's biodiversity, forest ecosystems are the basis for trillions of dollars in global revenue. They are homes to indigenous groups, sources of food, medicines, and raw materials for industry, and they provide opportunities for recreation and tourism. They are also being logged, cleared, or otherwise altered by humans at alarming rates. Consequently, understanding the physical and biological consequences of deforestation has become one of the leading areas of research in forest ecology.

This review aims to describe the physical and biological consequences of deforestation on four levels of ecosystem organization: individuals, populations, communities, and ecosystems. In addition, I will also highlight some of the major gaps in our understanding of how fragmented forests function.

Physical Consequences of Deforestation

Habitat Loss and Insularization

The most dramatic and immediately obvious consequence of deforestation is the loss of native habitat in newly cleared areas. However not all deforestation results in the denuded landscapes one typically associates with clear-cut logging or industrial cattle ranching. In many cases deforestation proceeds unevenly, leaving behind a patchwork of forest fragments that are isolated at varying degrees from one another. These fragments of forest are embedded in an intervening habitat, referred to as the 'matrix habitat,' whose use varies in intensity from regenerating forest, to cattle pasture, to human settlements. The study of the physical and biological consequences of this now widespread phenomenon, known as habitat fragmentation, has become one of the principal areas of research in conservation biology. While these consequences can vary substantially by location and forest type, some general patterns have begun to emerge. As a result, we now have a greater understanding not only of how individual species are influenced by fragmentation, but also of what some of the consequences of fragmentation are at community and even continental scales.

Abiotic Changes in Forest Fragments

The abiotic conditions in forest fragments change dramatically once fragments are isolated, and these alterations are thought to drive many of the biological changes observed in fragmented landscapes. Sunlight penetrates forest fragments from above as well as laterally at the fragment's margins. Consequently, there is an increase in the amount of photosynthetically active radiation (PAR) at the forest understory. There is also an increase in understory air temperatures, frequently by as much as 8°C, and fragments become drier since the elevated temperatures and wind turbulence near fragment edges act synergistically to reduce relative humidity. Increased exposure of trees to wind results in wind throws and snapped crowns, leaving the canopy ragged and allowing additional sunlight to reach the understory. The temperature of the soil can increase markedly, and surface soil moisture can be diminished or even depleted.

These changes are not felt uniformly throughout the fragment. The intensity of these changes is spatially variable, and diminishes rapidly with increasing distance from the fragment's edge (**Figure 1**). As a result, these changes are frequently referred to as 'edge effects.' The extent to which fragments are influenced by edge effects will vary depending on fragment size, with small fragments more susceptible to environmental changes than large ones. It also depends on fragment shape, or more specifically the ratio of fragment perimeter to area. Fragments with high perimeter to area ratios, such as linear strips along roadsides, have much of their forest near edges and therefore have a greater amount exposed to harsh environmental conditions. In contrast fragments with lower ratios of perimeter to area have a greater amount of the fragment in the more buffered fragment interiors (**Figure 2**).

Abiotic changes in fragments can be ameliorated over time if vegetation outside the fragment regenerates and 'seals off' the fragment edge. Fragments surrounded by activities that maintain sharp fragment borders, such as cattle ranching or wheat farming, remain continually exposed to altered environmental conditions. Conditions in fragments can eventually return to levels similar to those found prior to fragment isolation, if cleared areas are allowed to regenerate or if agroforestry and other less intense forms of land use are adopted.

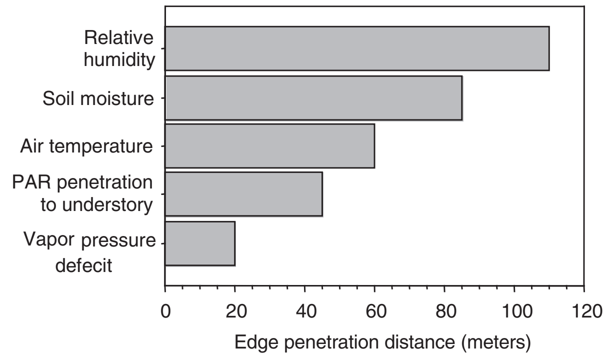

Figure 1 Edge penetration distances of abiotic changes in forest fragments. The *x*-axis indicates the distance (in meters) into forest fragments at which changes in abiotic parameters could be detected. PAR, photosynthetically active radiation. Adapted from Figure 32.1 in Laurance WF, Bierregaard RO (1997) *Tropical Forest Remnants: Ecology, Management, and Conservation of Fragmented Communities*. Chicago, IL: University of Chicago Press with permission from the University of Chicago Press.

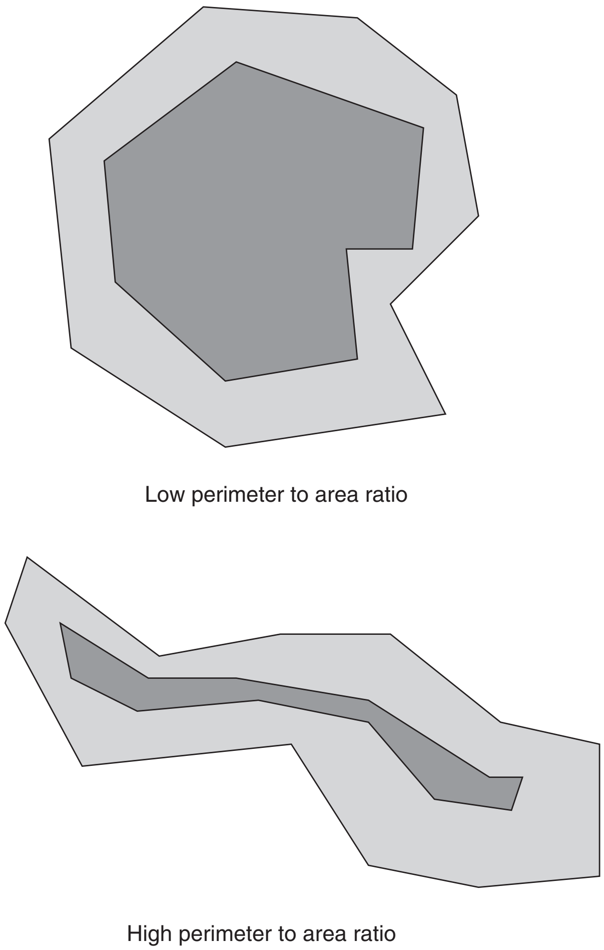

Figure 2 Influence of fragment shape on edge to perimeter ratio. The two fragments shown have approximately the same area, however the top one has a lower perimeter to area ratio. As a result, a greater proportion of the fragment is in the central core area that is buffered from edge effects (dark gray region).

Biological Consequences of Fragmentation

Changes in Individual Physiology and Behavior

As might be expected, the dramatic environmental changes in fragments can have serious consequences for the physiological condition of individuals that live there. For instance lizards in Australian rainforest fragments (*Gnypetoscincus queenslandiae*) have been found to be smaller than those in continuous forest, which could result from increased thermal variance during gestation or perhaps the reduced abundance of temperature-sensitive prey items. Similarly, temperature-related reductions in the abundance of insects could be responsible for the lower feather growth rates of the insectivorous birds *Glyphorynchus spirurus* and *Pipra pipra* in Amazonian forest fragments, though they could also have resulted from higher rates of evaporative water loss.

Plants surviving in fragments also appear susceptible to physiological changes. Some understory herbs, such as *Heliconia acuminata* (Heliconiaceae), shrink in response to the droughtlike conditions in fragments, and their leaves show signs of solar damage to the photosynthetic system. Their seeds also germinate less frequently in fragments than in continuous forest, which could be because they become buried under the leaf litter created by water-stressed trees or the light and temperature levels they use as cues to induce germination have changed. Plant mortality can also be sharply elevated in fragments, especially for the seedlings of shade-tolerant tropical trees such as *Pouteria caimito*, *Chrysophyllum pomiferum*, and *Micropholis venulosa*. Large adults of these species are also susceptible to increased mortality, since the inflexible trunks can be snapped by the gusts of wind that buffet fragment edges. Although the consequences of these changes for the long-term persistence of plant populations are unclear, they could be substantial – body size and physical condition are frequently correlated with reproductive success. It is worth noting, however, that the effects of fragmentation are not detrimental for individual physiology in all cases. For instance, individuals of *Pachira quinata*, an important timber species found in the dry forests of Central and South America, were found to develop crowns with more reproductive branches when isolated by fragmentation than when in continuous forest. This increased reproductive effort can probably be attributed to a lack of competitors in disturbed areas.

Perhaps less intuitive is the fact that forest fragmentation can also influence the behavior of individuals. An increasing number of studies have found that animals, even highly mobile ones such as migratory birds, are frequently averse to traversing roads, pastures, and the other types of clearings made by humans in forest landscapes. For example, mixed flocks of birds led by *Thamnomanes* antshrikes avoid crossing dirt roads through tropical rainforests if the vegetation along roadsides is regularly cleared. This aversion to clearing in the forest may lead to altered territory shapes and sizes, which can in turn increase the frequency of aggressive encounters between conspecifics. As might be expected, the birds will readily cross the roads again if the vegetation is allowed to regenerate.

Changes in Population Size and Genetic Structure

Ecological theory predicts that small or isolated populations are most likely to decline and become extinct, due in part to the effects of environmental and demographic stochasticity. It has therefore been hypothesized that populations in fragments will decline as well, particularly those that are in smaller or more isolated remnants. Empirical results partially support these conclusions, and the abundance of some organisms does decrease dramatically in forest fragments.

Species highly susceptible to population declines include large-bodied animals, which frequently require large areas in which to establish feeding or mating territories. Many of these species, such as the Florida panther (*Puma concolor coryi*) and black bear (*Ursus americanus floridanus*), can actually survive in a landscape that is only partially forested. However, the reduced amount of forest cover puts them in frequent contact with human populations, particularly when the cause of fragmentation is increased urbanization. As a result, they often have elevated rates of mortality due to poaching, collisions with automobiles, or exposure to pollutants and agricultural runoff.

Populations of species specializing on particular host-plants for oviposition or with highly specialized diets may also decline precipitously in fragmented landscapes. This is particularly true in tropical forests, where host plants and preferred food items are often patchily distributed and at extremely low densities. For example, the tropical butterfly *Hamadryas februa* utilizes the vine *Dalechampia scandens* for oviposition and larval development. Recent studies have found that butterfly populations in small fragments were not limited by their colonization ability or environmental conditions. Instead, it was the lack of host plants and high rates of emigration from fragments that constrained butterfly populations. While the 'fragments' in which these studies were conducted were a set of forested islands recently created by a hydroelectric project, they nonetheless demonstrate the importance of considering resource utilization in addition to habitat heterogeneity when evaluating the consequences of forest fragmentation.

Finally, populations of species with limited tolerance to abiotic changes may also be susceptible to declines in forest fragments. The increase in temperature and decrease in relative humidity that often accompany fragmentation are thought to be particularly detrimental to animals such as amphibians and invertebrates, which do not have the capacity to thermoregulate. One such example is of the Amazonian leaf-litter frog *Colostethus stepheni*, which has been found to have lower abundance in forest fragments than in continuous forest up to 19 years after fragment isolation. While a number of mechanisms could explain these reductions, one intriguing possibility is that altered abiotic conditions in fragments have delayed the sexual maturation of females. This delayed breeding would result in reduced per capita reproductive rates, ultimately driving the declines in growth rates of isolated populations.

As with individual physiology, however, the effects of fragmentation on population size are not uniformly negative. Populations of generalist invertebrates can increase dramatically in forest fragments, as can those of lianas, vines, rattans, and other pioneer plant species commonly found in natural forest gaps. The increased amount of edge habitat may also favor nest parasites such as cowbirds (*Molothrus ater*) or nest predators such as ravens (*Corvus corax*) and skunks (*Mephitis mephitis*), though the effects can vary considerably between species and locations. Still other populations show no change in density at all, although it is unclear if this is because the species under consideration are tolerant to fragmentation's consequences or because the studies have not continued long enough for changes in density to be detected.

The extent to which population size declines or increases in fragments may depend in part on how well individuals of each plant or animal species disperse across the intervening matrix habitat. This may be especially important for species that act as metapopulations, in which several subpopulations are linked to each other by dispersal. Unfortunately, detailed information regarding the movements of plants and animals between populations found in different forest fragments is rare, and the efficacy of habitat corridors connecting remnants of habitat to promote dispersal between isolated reserves remains the subject of ongoing debate. There is some indication that corridors may be useful in promoting the dispersal of at least some species, such as frogs, moths, small mammals, bush-crickets, and some birds. However there is little empirical evidence that dispersal alone will reduce the risk of population declines resulting from local changes in environmental conditions.

Isolated populations have been shown to suffer from increased rates of inbreeding depression, genetic drift, and reduced genetic diversity. These changes, which could result from reductions in population size following fragment isolation or because the movement of individuals between different forest fragments is limited, can have both short- and long-term consequences. In the short-term, populations of plants and animals may show an increase in fluctuating asymmetry (departures from bilateral symmetry) and other developmental problems due to reduced genetic diversity, as well have reduced fecundity. In the long term, genetic erosion could restrict evolutionary responses to changing environmental conditions and the potential for speciation, since genetic diversity provides the raw material upon which natural selection operates.

Changes in Community Composition and their Consequences

Using as a model MacArthur and Wilson's theory of island biogeography, researchers studying islands of forest have predicted that smaller fragments would support lower numbers of species than large fragments. This prediction has held true in a broad variety of temperate and tropical sites, with fragments often containing only a limited subset of a region's biota. These reductions in diversity have shown to affect disparate groups of plants and animals, including birds (e.g., insectivores, frugivores, cavity nesters), insects (e.g., beetles, fruit flies, ants), and plants (e.g., herbs, forbs, shade-tolerant trees).

Two different mechanisms have been invoked to explain this general pattern. First, populations in fragments could have become locally extinct following fragment isolation. Alternatively, lower diversity in fragments could also result from differences in the initial species composition of the patches that were isolated. This may be especially common in tropical forests, where regional species diversity is very high but many species are locally rare or patchily distributed. In this case a species may be missing from a fragment not because it went locally extinct, but because it was absent when the fragment was originally isolated.

Species diversity is not always lower in fragments, however, and there are numerous cases in which it has actually been found to increase following fragmentation. Many amphibians, insects, small mammals, and plants are habitat generalists tolerant of a broad range of habitat types. In some cases species diversity even increases despite the loss of forest-interior species, because their absence is compensated by an influx of generalists from the surrounding matrix. Perhaps one of the best examples of this phenomenon is tropical pool-breeding frogs, of which disturbed-habitat specialists (e.g., *Scinax rubra, Adenomera hylaedactyla*) can be found in recently isolated forest fragments and on the edges of continuous forest. Similar results have also been documented for small terrestrial mammals (e.g., *Oecomys* spp.), perhaps due to their preference for foraging in sites with abundant leaf litter and fallen branches.

Shifts in community structure may also depend on what trophic level a species occupies. Top predators such jaguars (*Panthera onca*) and gray wolves (*Canis lupus*) are hypothesized to be particularly vulnerable to extinction because they are found at lower population densities, forage in large territories, or are dependent on prey that can also be detrimentally affected by fragmentation. When these species become locally extinct, medium-sized predators (also known as mesopredators) such as coyotes (*Canis latrans*) and opossum (*Didelphis virginiana*) may increase in abundance. As a result, the abundance of the species preyed upon by the mesopredators will in turn decrease.

One of the defining features of forest habitats is the myriad interactions in which resident species are involved. Predation, herbivory, competition, and mutualisms all play an important role in structuring forest communities and promoting evolutionary change. As a result, it is widely believed that the disruption of these interactions in fragmented landscapes, particularly mutualistic ones related to plant reproductions and establishment, could have major repercussions for ecosystem functioning. In fact some authors have gone so far as to suggest that fragmentation-related reductions of these interactions will lead to 'ecological meltdown' or 'cascades' of further extinctions in forest fragments.

Some interactions relating to plant recruitment can be substantially modified in fragmented areas. For instance, the pollination of plants can decrease in fragments, either because pollinators are less abundant, they visit plants less frequently, or because they transfer less pollen per visit. Interestingly, a number of studies have also documented the opposite effect – dramatic increases in pollination in both fragments and the intervening matrix. The increase in these cases is usually due to a superabundance in the disturbed areas of exotic pollinators, such as the African honeybee (*Apis mellifera scutellata*). Seed dispersal and predation can be modified as well, although results to date have been somewhat contradictory. The quantity and composition of the seed rain has been shown to vary in disturbed habitats, due to changes in the abundance, diversity, or diet of dispersing animals such as monkeys, bats, birds, and dung beetles. Once these seeds are successfully dispersed, an influx of predators from the habitat surrounding fragments, particularly rodents and insects, can rapidly depress the seed numbers. This may be why the abundance of seedlings of understory plants is frequently much lower in fragments than in continuous forest. However, seedling numbers can also be lower if herbivory is higher in fragments and near edges, as might be expected given the larger populations of generalist browsers such as white-tailed deer (*Odocoileus virginianus*) or meadow voles (*Microtus pennsylvanicus*) in these areas.

Changes in Ecosystem Dynamics

Deforestation and fragmentation can also influence ecosystem processes at fragment, landscape, or continental scales. Within fragments, nutrient cycling can be substantially altered, since there is an increase in the amount of leaf litter on the forest floor and this litter often takes longer to decompose. At the regional scale, fragmentation can influence temperature and rainfall patterns. It is estimated that as much as 50% of rainfall in the parts of the Amazon is produced by the respiration of trees, and that by removing half the forest and replacing it with pastures total rainfall could be reduced by as much as 25%. Since forests are major reservoirs of the earth's terrestrial carbon, deforestation can also contribute significantly to global warming. As downed wood decomposes, it releases greenhouse gases such as carbon dioxide and methane. In fact it is hypothesized that as a result of this decomposition, deforestation alone contributes approximately one-fourth of all greenhouse gas emissions. Since tree mortality is elevated in fragments, this carbon is released by decomposing trees long after the original process of deforestation has been completed. These dead and downed trees, coupled with an increased accumulation of litter in fragments, also make fragments more susceptible to fires, which further alters the cycling of carbon and other nutrients. All of these changes in ecosystem processes can have major direct and indirect consequences for biodiversity. Increased fire frequency, for example, may directly cause the mortality of plants and animals in fragments. It may also indirectly drive reduced rates of individual growth and survivorship by altering the distribution of resources on which these individuals depend.

Future Directions

In this brief review I have attempted to summarize how deforestation and fragmentation can influence biological systems. However the field of fragmentation biology remains a dynamic and exciting one, and there is still much to learn regarding the structure and functioning of fragmented forests. For instance the precise ecological mechanisms responsible for most local extinctions from fragments are still unknown, as are the details regarding the dispersal of plants and animals between the remaining patches of forest. Finally, while the populations of plants and animals surviving in fragments continue to be the subject of considerable research, one cannot understate the importance of the matrix habitat in which these fragments are embedded. Some types of matrix habitat are better at mediating the impact of abiotic changes, while others have a higher diversity of species regenerating in them. Perhaps most importantly, matrix habitat influences the movement of plants and animals in fragmented landscapes. These movements are critical, since they may be sufficient to ameliorate population declines or inbreeding depression in fragments. All of these differences are dependent on how the land was managed immediately following forest clearing, therefore understanding the biological dynamics of forest fragments will require not only a greater understanding of what happens inside them, but also of what goes on in the habitat that surrounds them.

Human Influences on Tropical Forest Wildlife

C A Peres and J Barlow, University of East Anglia, Norwich, UK

Introduction

Different patterns of anthropogenic forest disturbance can affect forest wildlife in both tropical and temperate regions in many ways. The overall impact of different sources of structural and nonstructural disturbance may depend on: (1) the groups of organisms considered; (2) the evolutionary history of analogous forms of natural disturbance; and (3) whether forest ecosystems are left to recover over sufficiently long intervals following a disturbance event. The wide range of human-induced disturbance events are widely variable in intensity, duration and periodicity and are often mediated by numerous economic activities including timber and nontimber resource extraction, other causes of forest degradation, forest fragmentation, and forest conversion to other forms of land use. Examples of human enterprises that can severely affect wildlife may include hunting, selective logging at varying degrees of intensity, slash-and-burn agriculture, plantation forestry, selective removal of the understory to produce shade-tolerant crops, and outright deforestation for large-scale livestock operations. The resulting faunal assemblages can be drastically disfigured in highly modified forest landscapes compared to those in truly undisturbed forest lands containing a full complement of plant and animal species, which are being rapidly confined to the best-guarded strictly protected areas or the remote, roadless wildlands in the last remaining pristine forests.

In this article, we focus on tropical forests rather than their temperate counterparts because tropical forests arguably present the greatest challenge to global biodiversity conservation. We also focus on forest vertebrates because the effects of human disturbance on tropical forest invertebrates remain poorly known. Within the terrestrial vertebrates, most of our examples come from bird and mammal studies because effects of disturbance on reptile and amphibian assemblages remain poorly understood. We illustrate this discussion and review the evidence from the literature and our own field studies on the basis of three increasingly ubiquitous types of human disturbance in forest lands with severe consequences to the vertebrate fauna – hunting, selective logging, and wildfires.

Hunting

Hunting is perhaps the most geographically widespread form of human disturbance in tropical forests, although the total extent of this form of nontimber resource extraction cannot be easily mapped using conventional remote sensing techniques. Many parts of west Africa, Southeast Asia, and the neotropics are becoming chronically overhunted, partly as a result of burgeoning human populations that often escape to and become marginalized in frontier regions. Exploitation of wild meat (the meat from wild animals often referred to as bushmeat) by tropical forest-dwellers has also increased due to changes in hunting technology, scarcity of alternative protein sources, and because it is often a preferred food. Large-bodied game birds and mammals providing highly desirable meat packages and hunted for either subsistence or commercial purposes are particularly affected, because they are the main target species and tend to be associated with low reproductive rates, thus recovering slowly from persistent hunting pressure (**Figure 1**).

Estimates of Wild Meat Harvest

Studies of wild meat harvest tend to be approached at the level of subsistence communities, where wild animals can be intercepted, or market and restaurant surveys. These studies tend to severely underestimate the true mortality because many of the animals intentionally or incidentally killed in the forest are not retrieved, thus not translating into meat consumed at the level of villages, markets, or informal sales. The species most threatened by hunting may also be rarely seen in markets, because they were already at very low population densities.

Figure 1 A young Kaxinawa Indian hunter showing a recently killed howler monkey (*Alouatta seniculus*) and a white-faced capuchin (*Cebus albifrons*), which are unsustainably harvested at his indigenous reserve in western Acre, Brazilian Amazonia.

Subsistence Hunting

Subsistence game hunting can often have profound negative effects on the species diversity, standing biomass, and size structure of vertebrate assemblages in tropical forests that otherwise remain structurally undisturbed. This occurs mainly through local population declines, if not extirpation, of large-bodied vertebrate taxa which make a disproportionately large contribution to nonhunted forests in terms of their aggregate biomass and role in ecosystem functioning. Overharvested forest sites where large game species have been depleted thus tend to be dominated by small-bodied species that are either bypassed or ignored by hunters. Regardless of the nature of density compensation by small-bodied species following the local extinction of large vertebrates, important species interactions or ecosystem functions associated with large body size such as dispersal of large-seed plant species and herbivory of tree seedlings may no longer take place.

Overhunting

Overhunting of wildlife for meat consumption has reached an unprecedented scale across the humid tropics, causing local extinction of many vulnerable species. Yet productivity of tropical forests for wild meat is at least an order of magnitude lower than that of tropical savannas, and can only support fewer than 1 person per square kilometer if they depend entirely on wild meat for their protein. Reasons why the scale and spatial extent of hunting activities have increased so greatly in recent years include human population growth and migration; severe reduction in forest cover and nonhunted source areas; increased access via logging roads and paved highways into remote forest areas allowing hunters to harvest wild meat for subsistence or cash; the use of efficient modern hunting technologies especially firearms and wire snares; and, in some regions, greatly increased trade in wild meat. Forest defaunation driven by wild meat hunters has therefore become one of the most difficult challenges for tropical forest wildlife conservation.

In addition to drivers of the bushmeat harvest, wildlife depletion in tropical forests can be driven by extractive activities targeted to other desirable animal parts or products, including skins, feathers, ivory, horns, bones, fat deposits, eggs and nestlings, as well as live-captures of juveniles or adults for aviaries, aquaria, and the pet trade. These activities are often poorly regulated in the humid tropics, and have been responsible for wholesale extinctions of many target species.

Aggravating Effects

In frontier tropical forest regions, hunting and other forms of offtakes often co-occurs with different patterns of forest disturbance that can either aggravate or buffer the detrimental effects of faunal exploitation. For instance, effects of hunting are likely to be considerably aggravated by isolated forest fragmentation because fragments are more accessible to hunters, allow no (or very low rates of) recolonization from nonharvested source populations, and may provide a lower-quality resource base for the frugivore–granivore vertebrate fauna. On the other hand, selective logging may actually boost the local densities of large terrestrial browsers by puncturing and opening up the canopy, thus enhancing the understory productivity through a more favorable light environment. Likewise, slash-and-burn agriculture associated with long-term rotation of a successional mosaic can generate attractive foraging areas for populations of large herbivorous rodents and ungulates, as well as species preferring second-growth. We therefore turn to other important forms of anthropogenic disturbance involving structural changes to wildlife habitats in tropical forests.

Selective Logging

Selective logging is a major anthropogenic disturbance event in tropical forests, affecting around 15 000 km^2 a year of forest in the Brazilian Amazon alone. As only a small proportion of the remaining tropical forests is expected to be strictly protected within reserves, there is much debate over whether timber production can be reconciled with biodiversity conservation. For wildlife, the crucial issues are whether populations of species of conservation importance can be maintained within a matrix dominated by logged forests. However, despite the growing amount of literature documenting the effects of selective logging on the abundance and distribution of forest wildlife, the lack of agreement between studies means that few conclusions can be drawn. The disparity is highlighted by a recent review. In eight studies on the effects of logging on the forest avifauna, frugivorous birds were found to increase, decrease and to remain unaffected, whilst the same range of responses were demonstrated in different studies on forest chimpanzees (*Pan troglodytes*).

There are four major reasons why these studies have failed to find consistent results. Firstly, the effects of logging can be strongly influenced by the time elapsed since logging occurred, the number of recurrent logging events, the severity of the logging operation and extraction methods used, and the composition of the surrounding landscape. Secondly, sampling techniques are rarely standardized between studies. Effects may differ across different spatial and temporal scales, and by whether sampling focuses on understory species, canopy species, or species from all forest levels. Studies also differ depending on whether they examined tree fall gaps, or the entire logged forest matrix, in the latter case capturing many disturbance-intolerant species that are able to persist in unlogged refugia. Thirdly, some of the differences may be explained by geographic and historical factors. Production forests occur throughout the tropics, capturing many faunas that are unlikely to be equally adapted to disturbance. In the neotropics alone, logging appears to have greater impacts on the Amazonian avifauna than that in the Atlantic forest or in Belize, a difference that can be attributed to the more intensive history of natural disturbance events in those areas. Finally, few studies have incorporated the synergistic effects of other forms of disturbance that co-occurs with logging, including fires, edge effects, and area effects resulting from forest fragmentation (**Figure 2**).

Patterns of Adaptation

Despite these problems, some general patterns have become apparent. By opening up the canopy, and shifting much of the primary production to the understory, logging tends to simplify the vertical stratification of forest species. Both bird and butterflies typical of the canopy layer may begin to forage at lower levels, replacing many of the highly specialized shaded understory species that are adapted to foraging within the dark forest interior of undisturbed primary forest. This shift in productivity may also favor many large terrestrial browsers, and may boost the abundance of elephants, okapis, and duikers in African forests, or pacas, brocket-deer and tapirs in neotropical forests. The same may be true for highly folivorous arboreal mammals such as colobine primates and howler monkeys in African and neotropical forests, respectively. Across all taxa, specialists with narrow niches tend to decline whilst generalists that are able to switch between resources tend to increase. This is illustrated in primate populations; unripe seed and ripe fruit specialists such as bearded sakis (*Chiropotes* spp.) and spider monkeys (*Ateles* spp.), respectively, tend to decline in highly selectively logged forests, whilst generalists such as brown capuchins (*Cebus apella*) may increase.

Effect of Logging Method

One crucial factor in the overall impact of a logging operation is the method used for timber harvest and extraction, which will determine the proportion of the forest area affected by canopy gaps where the understory light environment is significantly different.

Figure 2 A roundlog loading bay and logging road in the Brazilian Amazon.

Selective logging operations targeting commercially valuable species accounting for considerably less than 1% of the forest basal area can result in as little as 5% and as much as 40% of collateral damage to nontarget species in the remaining stand. The level of collateral damage is context-dependent in terms of the size of trees, abundance of woody lianas spreading over adjacent tree crowns, terrain topography, and hydrology, but tends to increase with heavy mechanized machinery such as operations in which roundlogs are dragged out over long distance by bulldozers. Collateral damage is lowest where the extracted roundlogs can be floated out in the case of seasonally inundated forests, or removed by a system of steel cables or even cargo helicopters, or where the timber can be sawed *in situ* and removed by less destructive methods. Another important factor is whether the timber species targeted by loggers are important food sources for forest wildlife, and how crucial these are for a particular vertebrate assemblage when these food resources become available. For instance, the systematic offtake of important fruiting species may have a far greater impact on highly frugivorous species, particularly if these fruit crops would otherwise become available during annual periods of food scarcity.

Although changes in species abundance and distributions are common, the complete extirpation of species from logged forest has been rarely recorded. Most primary forest specialists merely exist at low population densities, utilizing small unlogged patches until the forest becomes suitable for recolonization. As a result, timber production has been promoted as a means of biodiversity conservation, as it is seen to provide an economic justification for large tracts of tropical forest outside protected areas. Management of the logging methods can substantially reduce their impact on forest structure (actually increasing long-term yields), whilst careful planning of unlogged refugia and corridors may ensure the survival and recolonization of disturbance-sensitive species. Despite these mitigation measures, timber production cannot be seen as a panacea to the problems of forest wildlife conservation in the tropics. Reduced impact methods are rarely used, and still account for a very small proportion of the logging concessions in the tropics. Furthermore, very little data exist on the effects of repeated timber harvests at variable intervals, a necessary component if production forests are to remain economically viable. Indeed, this may lead to structurally homogeneous forests unlikely to maintain the full array of biodiversity found in primary forest. Logging may also disrupt many of the complex interactions between species, the effects of which may not be noticeable in the short term.

Finally, logging cannot be examined in isolation from other forms of forest disturbance. The creation of logging camps, logging roads, and skidding trails generates greater demand for bushmeat and access to previously undisturbed forest, which greatly increases local hunting pressure. The logging access matrix also accelerates the rate of forest clearance for agriculture, and the associated effects of forest edges and fragmentation, which combined with the higher density of tree-fall gaps can greatly enhance both the risk and potential severity of wildfires in seasonally dry forest. These secondary effects are not restricted to conventional selective logging, but can also result from reduced-impact logging operations associated with lower levels of canopy damage. Without appropriate and enforceable postlogging restrictions, the role of timber production in conserving forest wildlife will be diminished well beyond the immediate impact of logging itself.

Forest Wildfires

Historically, fire events in tropical forests have been rare and largely associated with the mega El-Niño Southern Oscillation (ENSO) events of the past 7000 years. However, within recent years understory wildfires have become increasingly common events in tropical forests: in the 1997–1998 ENSO year fires burned around 17 million ha of lands in Indonesia and Latin America alone, much of which was tropical forest. Three factors explain this unprecedented increase of tropical forest fires, all of which can be related to anthropogenic activity:

1. Human-induced climate change exacerbates wildfire hazards by increasing the frequency and intensity of ENSO events, which cause abnormally long droughts in the dry season and allow normally fire-resistant forests to become flammable.
2. Selective logging lowers the flammability threshold of forests by reducing canopy cover and understory humidity, whilst increasing the amount and continuity of fine and coarse fuel loads on the forest floor.
3. Tropical agricultural practices are often heavily reliant on fire, ensuring that seasonally flammable forests are never far from ignition sources.

The consequences of these fires to forest structure and composition will depend on their severity, as well as the history of fires in a given forest ecosystem. Initially, low-intensity surface fires move slowly through the leaf litter, burning the fine and coarse fuel layer. Under normal fuel loads and humidity conditions, flame heights rarely exceed 10–30 cm. However, these fires serve to increase greatly the fuel load and open up the canopy, so that recurrent burns will become much more intense, scorching the canopy layer, and killing many of the surviving trees that remain after the first burn. Because of their recent historical rarity, very few studies have documented the effects of accidental fires on forest wildlife; the following is based on information from a small number of studies conducted in Amazonia and Southeast Asia, and outlines the effects of fires in their immediate aftermath, up to 1 month, and 1 to 3 years thereafter. However, considering that this is a recent phenomenon and the possible range of postburn responses, these conclusions cannot be generalized to all contexts.

Fire-Induced Mortality

Reports of the initial fire-induced mortality appear to be inconclusive. In Sumatra, the lack of animal carcasses following the fire was taken as evidence that most birds and mammals were able to escape the fire. However, in the Brazilian Amazon there is evidence of substantial mortality in several groups of terrestrial vertebrates including tortoises, tinamous, armadillos, and caviomorph rodents, whilst even more mobile arboreal species such as toucans, parrots, and some primate species can succumb to the fires, presumably through smoke asphyxiation. In high-intensity fires in forests burning for the second time, even large, highly mobile mammals, such as the collared peccary (*Tayassu tacaju*) and brocket deer (*Mazama* spp.), can be killed by the fires.

Many understory birds and forest lizards appear to be absent 1 month after the fires, perhaps reflecting the conspicuous lack of foraging opportunities in the scorched understory. Some canopy frugivores are also less abundant. In Sumatra, two hornbill and two primate species had either declined or become absent from burned forest, whilst in Amazonian forests many surviving canopy trees shed or aborted their fruit crops, leading to declines in the abundance of frugivorous primate species. These declines may have been exacerbated by hunting, as the open understory rendered many game species as easy targets for subsistence hunters.

Post-Burn Survival

Up to 1 to 3 years after the fires, many primary forest specialists appear able to persist in lightly burned forest, though most are found at much lower densities than in adjacent unburned forest. Considering the understory avifauna, highly specialized insectivores such as the dead-leaf gleaning and ant-following species, which often contain many regionally endemic species, appear to be the most vulnerable, and often disappear from burned forest. However, species richness at small spatial scales may actually increase in burned forest, as many gap specialists and edge species invade from more disturbed areas. As with logging, fires open up the canopy and shift primary productivity to the understory. This dense postburn regeneration, often spearheaded by bamboo and some pioneer tree and liana species, appears to cause an increase in the abundance of many terrestrial browsers in an Amazonian forest, most notably collared peccaries and both species of brocket deer. It also provides these species with a temporary refuge from hunting. Frugivorous primates appear to be far more susceptible than their folivorous counterparts, although most primates species manage to persist in forests succumbing to a single fire event, and may also benefit from reduced hunting pressure.

Where fire severity increases, either because of a recurrent fire, or a high level of preburn logging activity, the effects on wildlife is considerably greater. Most primary forest species, and even many gap and specialist species, are extirpated from the dense early-successional regeneration that follows these fires, and are replaced by species typical of young second-growth. The understory avifauna in twice-burned forest is almost entirely dissimilar with that found in the unburned forest, and becomes dominated by the second-growth specialists such as the wren *Thryothorus genibarbus*. Most primate species are also absent in this highly modified habitat, and only small-bodied species typical of young second-growth such as marmosets (*Callithrix* spp.) and titi monkeys (*Callicebus* spp.) are particularly abundant.

Overall, initial low-intensity fires appear to act in a similar manner to logging, puncturing the canopy, severely altering the understory light environment, and changing the abundance of many species. This, however, only rarely results in the local extinction of disturbance-intolerant species. In contrast, recurrent fire events from as early as a second burn appear to have a much greater effect in substantially disfiguring forest structure, and represent a serious threat to forest wildlife. While no information is available on the recovery of these forests it appears that the potential for the establishment of a recurrent burn regime in many tropical forests represents one of the largest contemporary threats to wildlife, as it can lead to the conversion of extensive closed-canopy forest lands into scrub savannas. This occurs concomitantly with the local extinction of almost all the forest wildlife typical of undisturbed forest. To a large degree wildfires in the humid tropics can represent an irreversible transition into replacement fire-climax ecosystems that provide considerably lower value both in terms of wildlife habitat and key ecosystem services.

Aquatic Habitats in Forest Ecosystems

K M Martin-Smith, University of Tasmania, Hobart, Tasmania, Australia

Introduction

There is a wide variety of aquatic habitats found in forested areas ranging from water-filled tree holes through to large rivers, lakes, and inundated forests. This article initially reviews the classification of aquatic habitats and some of their important geomorphological, physicochemical, and biological parameters. Following this, different classes of aquatic habitats in forests are presented in outline with consideration of their global distributions, defining abiotic characteristics and aquatic biota. A broad distinction has been made between aquatic habitats where the forest itself forms part of the habitat matrix (forested wetlands) and those where the forest is only on the periphery (water bodies in forests). Four subdivisions of forested wetlands are discussed: (1) peat bog forests, (2) swamp forests, (3) floodplain forests, and (4) mangrove forests, and three types of water bodies in forests: (1) container habitats (phytotelmata), (2) ponds and lakes, and (3) streams and rivers. For the latter groups, emphasis has been placed on the differences in characteristics when compared to nonforested ecosystems. Finally human interactions with aquatic systems are discussed, including both dependency on aquatic resources and anthropogenic threats.

There have been many attempts to classify aquatic habitat types based on combinations of geomorphological, physical, chemical, or biological characteristics. Some of the most important and frequently used classification variables are given in **Table 1**. Whilst providing an excellent framework for rationalizing our understanding of aquatic systems, there are inevitably exceptions to all classifications. Usually, this is because the habitat characteristics exist as continuous variables rather than distinct states and thus the criteria for inclusion in a particular category will be, to some extent, subjective. For example, some rivers will dry up to a series of pools, thus transforming a flowing water (lotic) habitat into a still water (lentic) one. Similarly, many of the habitat variables covary – nutrient levels are generally strongly correlated with organic production, for example. Despite these caveats, it is possible to identify a number of types of aquatic habitat in forested ecosystems.

At the highest hierarchical level, there is a broad distinction between aquatic habitats where the forest itself is an integral part of the habitat and those where the forest is only on the edges of the water body. There is no standard terminology for either group and there are a huge variety of local names for subdivisions within each. In this article, 'forested wetlands' is used for aquatic habitats where there are inundated live trees found throughout the water mass whereas 'water bodies in forests' is used where live trees surround or line the water and do not extend throughout the habitat.

Table 1 Some common continuous variables used to classify aquatic habitats

Type of variable[a]	*Example variables*	*End points of continuum*	
Geographical or geomorphological	Size of water body	Small	Large
	Depth of water	Shallow	Deep
	Permanence of water (hydroperiod)	Ephemeral	Permanent
	Stability	Fluctuating	Stable
	Degree of water flow	Lentic	Lotic
	Gradient	Steep	Shallow
	Latitude	Tropical	Temperate
Physicochemical	Temperature	Low	High
	Light	Fully shaded	Open
	Degree of mixing	Amictic	Polymictic
	pH	Acid	Alkaline
	Oxygen levels	Anoxic	Oxygenated
	Nutrient levels (N, P)	Low	High
	Suspended sediment	Clear	Turbid
Biological	Organic production	Oligotrophic	Eutrophic
	Source of production	Autochthonous	Allochthonous
	Organic debris	None	Plentiful
	Dominant trophic group	Shredders	Filter-feeders

[a] Some variables will only apply to a subset of aquatic habitats discussed in the text; for example, degree of mixing is generally only used for standing water bodies.

Forested Wetlands

The total extent of forested wetlands in the world has been estimated at 3.4 million km^2 but there are considerable uncertainties in this figure. Furthermore, there are very large variations in degree and period of inundation and thus the actual extent of forested wetlands at any point in time is difficult to determine. The local hydrological balance between inputs (rainfall, surface runoff, and groundwater seepage), storage, and outputs (evapotranspiration, infiltration, and runoff) determines the formation, maintenance, and hydroperiod (the amount of time that the forest is inundated) of forested wetlands.

Important characteristics shared by all forested wetlands are submerged physical habitat structure (tree trunks and branches) and wide distribution of terrestrially derived organic input over the entire water surface. Tree trunks and branches play a very important role in modifying hydrological parameters, including slowing of water flow and precipitation of suspended material. Furthermore, they provide surfaces for colonization by aquatic biota. Terrestrial input of material may be from the trees themselves (leaves, fruit, and seeds) or plants or animals living on the trees.

Four major categories of forested wetlands are described below, although the categories grade into one another, swamp forests often receiving river floodwater for example.

Peat Bog Forests

These are forests growing on peat-rich soils that are permanently waterlogged. They are formed where there are large inputs of fresh water and low levels of organic decomposition. Aquatic habitats in peat bog forests may be sporadic, seasonal, or permanent.

Distribution The vast majority of inundated forests on peat bogs are in boreal areas – extensively in Canada, Alaska, Scandinavia, Russia, and China. The coast of the southeast USA (Florida to North Carolina) also has considerable amounts, whilst in the tropics substantial peat bog forests are found in Borneo, Sumatra, and Papua New Guinea.

Physicochemical characteristics Peat bog forests that receive water input solely from rain (ombrotrophic) have a low pH and are low in inorganic nutrients. Where there are groundwater inputs in addition to rain, pH is near neutral and there are higher levels of nutrients. Water in all peat bog forests is often darkly colored from the presence of dissolved tannins which reduce light penetration. Water depth is shallow to moderate. Water movement is slight, thus turnover and flushing rates are low. Combined with high levels of organic materials, this leads to anoxic conditions particularly near the benthos.

Aquatic biota Few or no macrophytes are present because of low light levels and/or low pH. Similarly, algal production is low. Invertebrates appear to be specialists with adaptations to deal with low oxygen levels. Trophic food webs are based on detritus. In boreal areas fish are absent or restricted to a very few species. In the tropics there may be considerable fish diversity from families specialized to deal with low oxygen levels with adaptations including air-gulping and labyrinthine organs. There may be considerably greater fish diversity than is presently recognized because sampling effort has been low in these habitats. Other vertebrates such as turtles and snakes may spend time in these habitats but there are few or no obligate species.

Swamp Forests

Swamp forests are found on peat-poor soils that are permanently waterlogged. They may be created and maintained by land topography (basin swamps), hydrological barriers, and/or high water tables. Aquatic habitats in swamp forests may be sporadic, seasonal, or permanent. Palms are a prominent group in tropical swamp forests.

Distribution Swamp forests are distributed widely, but are more common in tropical rather than temperate zones. The largest areas of swamp forest are to be found throughout Central America, Brazil, Argentina, tropical Africa, and Southeast Asia (particularly Borneo, the island of New Guinea, Laos, and Cambodia). There are also substantial swamp forests in central Asia and the southern USA.

Physicochemical characteristics As there is a wide variety of mechanisms that create swamp forests physicochemical characteristics also vary widely. There is generally little or no water movement for most of the hydroperiod, particularly in basin swamp forests, and water depth is shallow to moderate. However, flushing may occur during seasonal or episodic flooding from rivers. Oxygen and nutrient concentration of the water varies considerably depending on source of input, soil, and vegetation type.

Aquatic biota Considerable diversity of aquatic biota may be found in swamp forests. Where there is not a closed canopy some development of rooted or floating macrophytes may occur. Invertebrates from a wide range of taxonomic groups (particularly insects, crustaceans, and gastropods) are present and trophic webs may be based on autochthonous production, terrestrial input from trees, or detritus. Vertebrates including fish, amphibians, and reptiles are present. Fish diversity may be moderately high with specialists on detritus and benthic or terrestrial invertebrates. Caimans, crocodiles, or alligators are often the top predators in the system.

Floodplain (Alluvial) Forests

These are forests that are seasonally or irregularly flooded by changes in river level. In temperate areas flooding is often associated with snowmelt in the upper reaches of catchments, whilst in the tropics monsoonal rainfall is the major contributor.

Distribution Floodplain forests are found throughout the world. The most extensive are associated with very large rivers such as the Amazon, Mississippi, Orinoco, Congo, and Mekong, although they are associated with almost all unregulated rivers. Estimates of the extent of floodplain forests have been generated by satellite imagery during periods of maximum inundation and include 300 000 km^2 for the central Amazon and 70 000 km^2 for the Mekong.

Physicochemical characteristics The predictability of flooding and hydroperiod depends on the gradient and water storage capacity of the rivers and streams. Forests associated with smaller, high-gradient streams and rivers have rapid changes in water level and irregular and short hydroperiods, whereas those through which large, lowland rivers flow have more predictable hydrological regimes. Water depth may be considerable (>12 m), although shallow depths are more common. Rising water levels transport sediment which is deposited in the floodplain and levels of inorganic nutrients are high. Waters are usually oxygen-rich during initial phases of inundation, although thermal stratification, anoxic conditions, and pH changes can develop over time. River regulation often changes the areas inundated and the hydroperiod substantially.

Aquatic biota Invertebrates, fish, amphibians, and other mobile riverine animals rapidly move into newly created floodplain habitats. This movement can be to escape high-flow conditions in the main stem of the river but is more often related to exploitation of the floodplain habitat for food, reproduction, or avoidance of predators. Where the hydroperiod is of sufficient duration, algae and aquatic macrophytes will become established and may add additional habitat and trophic complexity. Floating mats of vegetation may develop if the light environment is suitable. Aquatic insects, crustaceans, gastropods, and many other groups may reach high abundance levels and complex food webs based on autochthonous production, terrestrial input, detrital material and fruits and seeds develop. In the tropics, high diversity of fish, amphibians, and reptiles are found. These form the basis for well-known fisheries in the Amazon and Southeast Asia. The Amazon basin is home to more than 3000 species of fish, the majority of which spend at least some period of their life history in floodplain forests. It has been suggested that some of this extraordinary diversity is related to additional habitat and trophic interactions that occur during flooding of the forest. Similarly, there are at least 1200 species in the Mekong basin and 700 in the Congo basin, many of which are dependent on floodplain forests.

Mangrove Forests

Mangrove forests are found on the coastal fringes of land on sheltered shores. They are characterized by regular inundation by salt water during the tidal cycle and are composed of a specialized group of trees with adaptations to cope with this. Aquatic habitats in mangrove forests fluctuate in extent over short time periods.

Distribution Mangrove forests are exclusively coastal and predominantly found in the tropics. They are particularly abundant in Australia and Southeast Asia, the Indian subcontinent, Mexico, Central America and Brazil, and equatorial Africa.

Physicochemical characteristics The dominant abiotic factors in mangrove forests are tidal fluctuations in water level and salinity gradients related to proximity to the coast. Water levels change regularly on short timescales following tidal inundation with saline, marine water. Salinity decreases moving inland from the mangrove margin, dependent on levels of freshwater input. Soils are anoxic with large amounts of organic material present (primarily mangrove-derived).

Aquatic biota Plant and animal life in mangroves has to withstand large daily changes in abiotic conditions. Almost all species are of marine origin rather than freshwater origin and may undergo daily migrations or retreat to refugia in response to these variations. Distinct zonation in communities is seen with boundaries orientated parallel to the coast. There are few aquatic macrophytes although marine algae may be found on submerged parts of mangroves. Invertebrates (mostly gastropods and crustaceans) are abundant, with their production based on detritus. Marine fishes move into inundated mangrove areas on the rising tide to feed on invertebrates or detritus. However, there are few species that are restricted solely to mangrove areas, mudskippers being an exception. Crocodiles are characteristic top-level predators. Mangrove areas are very productive, exporting large amounts of carbon and contributing to substantial coastal fisheries through energy transfer or acting as 'nursery habitats' for exploited fishes.

Water Bodies in Forests

These aquatic habitats are found in virtually all forest ecosystems throughout the world, thus no distributional information is given. For ponds, lakes, rivers, and streams the forest is restricted to a fringe around or along the edges and the influence of the forest (shading, chemical, and biological inputs) is restricted to these areas. Obviously, the relative effect of the forest on the water body is dependent on the latter's size relative to the height and extent of the forest. Thus, smaller water bodies or those surrounded by large areas of forest may be profoundly influenced whereas large lakes and rivers may be similar to those in unforested areas. Three types of water bodies in forest are described on the basis of their origin and water movement.

Container Habitats (Phytotelmata)

Phytotelmata are water-retaining structures formed by hollows in plant materials. These containers may be holes in tree stems or branches, the leaf axils of plants (particularly epiphytic bromeliads), leaves of pitcher plants, or fruit husks. They are generally ephemeral although some 'tank' bromeliads may have water in them for their entire lives ($>$20 years).

Physicochemical characteristics The volumes of phytotelmata are small (up to 1300 cm^3) and the water contained within them shows no movement. Water quality is strongly influenced by the surrounding plant material. Most contain decaying plant material – leaves, wood, or fruit – and drowned animals. Leachates from this material and the forest canopy make the water acid and rich in organic nutrients. Oxygen concentrations are low because of decaying organic material.

Aquatic biota Algae may be found in phytotelmata that are in bromeliads located in the forest canopy. Aquatic insect larvae are often the dominant animal forms in phytotelmata, particularly flies and mosquitoes. Many of these are specific to particular phytotelm habitats and are not found elsewhere. Microcrustaceans (such as ostracods), gastropods, and aquatic mites are also found. In tropical areas, juvenile and/or adult frogs may be present. Food webs can be based on algae, detritus, or drowned animals.

Ponds and Lakes (Lentic Habitats)

Lakes and ponds are habitats that are enclosed by land with outflows small in comparison to their volume. They also have water movement that is not unidirectional. In the smallest ponds there may be little or no water movement, but in larger lakes wind and/or convection currents create water movement. Lentic habitats may be created by depressions in bedrock and sediment or by barriers and they are fed by a combination of one or more of the following water sources: streams and rivers, groundwater, and rain. Water depth in lakes in forested areas can be far greater than the other aquatic habitats considered in this article, reaching over 700 m for Lake Mjösen in Norway. There is a large range in surface area from tens of square meters to hundreds of square kilometers. Lentic habitats, particularly larger ones, share a number of similarities with marine habitats such as thermal stratification. Lakes can be sporadic, seasonal, or permanent.

Physicochemical characteristics The dominant abiotic factor in all but the shallowest lentic water bodies is stratification. Heating of the surface water (epilimnion) makes it less dense and it floats on top of cooler water underneath (hypolimnion). Mixing depth is dependent mainly on wind action. Stratification affects not only temperature but also oxygen and nutrient levels across the thermocline. Deep lakes are often anoxic below the thermocline. Turnover, where all of the water in the lake mixes, is strongly influenced by latitude. Cold temperate lakes may turn over twice a year, warm temperate lakes once, and tropical lakes daily or occasionally. In deeper lakes light may be rapidly absorbed. The influence of surrounding forests on ponds and lakes is greatest on the water quality entering through groundwater or rivers. Nutrient levels, pH, and organic input are dependent on the type of forest and soil. Effects on shading and temperature are minimal in comparison with streams and rivers.

Aquatic biota An important component of the flora of lakes is plankton. Autochthonous production by phytoplankton is the major source of organic material in large and/or deep lakes. Macrophytes may be found in shallow zones around the edge of the lake and occasionally may be an important source of organic material. There is a clear distinction in many lakes between benthic and pelagic animal communities. Benthic invertebrates include aquatic insects, crustaceans, and gastropods. These latter two groups may be of greater abundance, diversity, and importance than in lotic habitats. Where the hypolimnion is anoxic there are few benthic invertebrates. Benthic food webs are dependent on detrital input. Pelagic invertebrates include high abundance of zooplankton, particularly crustaceans (cladocerans and copepods) and rotifers, dependent on autochthonous phytoplankton. Aquatic insects – water beetles and water bugs – are also found in the pelagic zones. Fish are found in both the pelagic and benthic zones where there is sufficient oxygen. They may be specialized planktivores or generalist detritivores or omnivores. Reptiles, particularly turtles, are common in shallow areas. Wading and piscivorous birds are also conspicuous aspects of the fauna. There appear to be few generalizations possible about differences between lotic water bodies in forested and unforested ecosystems. Small ponds and the fringes of larger lakes may have faunal elements specialized to take advantage of terrestrial input (fruit, leaves, flowers, invertebrates), but these influences rapidly decrease in importance moving away from the shoreline.

Streams and Rivers (Lotic Habitats)

These aquatic habitats are characterized by an overall unidirectional movement of water. However, there is considerable heterogeneity within most rivers and streams with areas of fast unidirectional flow (such as cascades, riffles, and runs), slow unidirectional flow (glides and reaches), and multidirectional flow or gyres (eddies, slacks, and pools) (**Figure 1**). These latter habitats may behave as lentic environments. Streams may be ephemeral, only flowing at certain times of year or after heavy rains, or permanent. There is a large size range from a few centimeters in width to a few kilometers for the biggest rivers such as the Amazon. Patterns in physicochemical and biotic characteristics are strongly related to position along the river course (river continuum concept) as well as temperate–tropical differences.

Physicochemical characteristics These parameters vary widely between different types of river. Depending on the geology, morphology, and forest cover of the catchment, there can be large differences in levels of suspended sediment, dissolved nutrients, oxygen, and pH. However, when compared to rivers running through nonforested areas, there are a number of generalities that can be made. Forests intercept and store water so that flows are moderated. Light levels are lower and the spectral composition is different because the forest intercepts much of the incident light. This effect is more pronounced in smaller rivers which may have completely closed forest canopies. Water temperatures are lower for the same reason. Inputs of dissolved, particulate, and large organic matter are greater than in nonforested catchments and have a different elemental composition. In deciduous forests there is a pulse of organic input with leaf fall, either seasonally or related to drought conditions. Thick layers of leaf litter can build up in temperate and tropical rivers providing an additional habitat for animals. Large woody debris is a significant structural aspect of forested rivers with important effects on hydrology (debris dams), nutrient retention and cycling, and animal microhabitat. Large woody debris is introduced into rivers by physical disturbance such as storms or floods and activity of animals, particularly the actions of beavers in northern temperate areas. Forestry activities have pronounced effects on water quantity, quality, sediment, and debris input.

Aquatic biota The aquatic biota of forested streams has been well studied around the world, particularly in temperate areas. Algae and aquatic plants may be present where current velocity is sufficiently low and there is adequate light penetration. Autochthonous production may peak in intermediate-size rivers where there is open canopy and shallow water depth while larger rivers often have floating mats of vegetation. Invertebrates from a wide range of taxonomic groups (insects, crustaceans, molluscs, and annelids in particular) are present although diversity tends to increase with decreasing latitude. Mayflies, stoneflies, caddis flies, dragonflies, beetles, and true flies are the dominant invertebrates in terms of numbers and biomass in many systems. Invertebrate production is dependent on leaf litter input in small streams, although grazing on autochthonous production may contribute in larger streams and rivers. The fauna in the streambed (hyporheic zone) is also an important component of the ecosystem, responsible for nutrient processing among other functions.

Fish and amphibians are generally present in all but the smallest and most ephemeral streams, again exhibiting distinct longitudinal zonation. Diversity increases moving from headwaters downstream and taxonomic composition changes through both species additions and replacements. The trophic structure of the fish community also changes with greater dependence on invertebrates and herbivory in upland streams while omnivory and piscivory are more important in lowland rivers. Additional food sources are available to fishes in forested streams, particularly terrestrial insects and fruit and leaves from trees. In north temperate streams migratory salmonid fishes may provide a large additional trophic subsidy, transferring production from the marine to the freshwater environment.

Reptiles, birds, and mammals may also be present either obligately or facultatively. Many snakes and most turtles spend large amounts of time in watercourses while crocodiles, alligators, and caiman are important predators in subtropical and tropical areas. Beavers are a conspicuous feature of north temperature forested streams with a profound influence on the structure of water bodies through their dam-building activities while otters may be found in temperature and tropical areas. River dolphins are a feature of large tropical rivers as are manatees in Central and South America.

Human Interactions with Aquatic Habitats in Forested Ecosystems

In many parts of the world there are intimate connections between human populations and the aquatic habitats described above. A large proportion of the annual protein intake may be derived from aquatic organisms, mainly fish. In the Amazon and Southeast Asia, floodplain forests support very large artisanal fisheries and human activities are synchronized with particular phases of the hydrological cycle. Very sophisticated methods of capture and exploitation exist to ensure maximum use of resources. For example, in the flooded forest system of Danau Sentarum, Kalimantan, only two of more than two hundred recorded species of fish are not used in some way by the several thousand people dependent on the system (**Figure 2**). Dozens of different fishing gears are used from lift and cast nets through gill nets and seines to large, semipermanent fish traps. Fry of certain large species (catfish and snakeheads) are captured and raised in floating cages where they are fed on smaller species. Highest catches are taken during the falling phase of the hydrological cycle and these fishes are preserved for use during the remainder of the year. Similarly, in northern temperate areas, salmonids from streams and rivers in forests are a vital part of the diet of native peoples.

Figure 2 Human use of aquatic resources in flooded forest, Kalimantan, Indonesia. Photograph courtesy of Keith Martin-Smith.

Conversely, many human activities threaten the integrity of aquatic habitats in forested ecosystems and individual species within them. The most prominent of these are resource overexploitation, habitat degradation from land-based activities (primarily logging), and the introduction of exotic species. Overexploitation of fishes has been documented as human populations increase and/or greater access to water bodies is created. The giant Mekong catfish and the Asian bonytongue are both considered threatened from overfishing. Logging, both selective and clear-cut, alters water quantity, timing, physicochemical parameters, and the aquatic biota. Sedimentation increases dramatically following logging and profoundly alters the ecosystem. Exotic species can also cause major, irreversible changes, with infamous examples including the water hyacinth and Nile tilapia.

While these threats are serious and immediate, they can be overcome if appropriate, sustainable solutions are developed. This will require adequate funding, political will and the application of multidisciplinary approaches.

Population Dynamics of Forest Insects

S R Leather, Imperial College London, Ascot, UK

Population dynamics is the study of changes in the number of organisms in populations and the factors influencing these changes. It thus, by necessity, includes the study of the rates of loss and replacement of individuals and of those regulatory processes that can prevent excessive changes in those numbers.

A wide variety of factors can affect the population dynamics of a particular species. These can be divided roughly into two categories. First, the extrinsic or environmental influences on populations, such as temperature, weather, food supply, competitors, natural enemies, diseases, and all possible combinations of the preceding; and second, the interactions between members of the same populations, be these direct or indirect, e.g., intraspecific

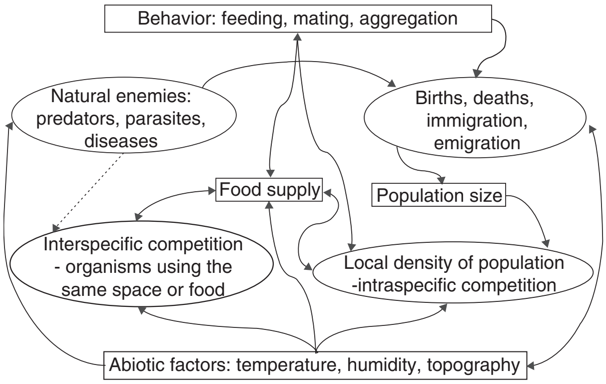

Figure 1 Factors influencing the population dynamics of a forest insect.

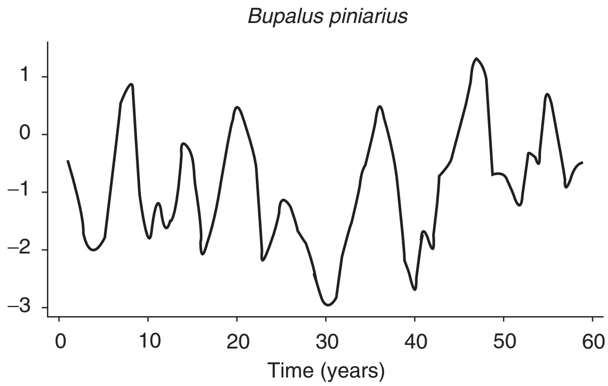

Figure 2 Populations of the pine looper moth, *Bupalus piniarius* (data from the Centre for Population Biology database).

competition, behavioral processes, and aggregation (**Figure 1**).

This article gives an overview of the main factors affecting the population dynamics of forest insects and explains how population cycles arise and are maintained.

Detecting Patterns and Identifying Processes

Perhaps the fundamental rationale behind the many published studies on population dynamics is the desire that population ecologists have for detecting and explaining patterns. The question that they are really trying to address, should they be honest, is why some species of insect are relatively scarce whilst others are extremely abundant and why some of the abundant species show cycles of abundance and relative scarcity. Cyclical fluctuations in population size are commonly seen in animal populations, with classic examples from mammals and birds, but the most dramatic examples are, without doubt, those shown by the invertebrates, and in particular, forest insects. The spectacular effects of defoliating forest Lepidoptera with their ability totally to defoliate hundreds of hectares of trees and their equally graphic population cycles have resulted in them becoming textbook examples (**Figure 2**). One of the most controversial debates of the past was whether population cycles were driven by abiotic factors or biotic interactions. At the moment the general consensus is that biotic factors, in particular density-dependent processes, are the major forces driving insect populations. The fact that the jury has voted for density-dependence does not, however, mean that the mechanisms that drive these population cycles are either fully understood or agreed upon.

As forest insects are of general and economic interest and generally occur in long-lived environments, there has been a tendency for field data to be collected over many years. The resulting time series (**Figure 2**) are often analyzed using sophisticated mathematical techniques. For example, autocorrelation analysis is used to describe the effects of a lagged population density and can also provide an indication of the periodicity of the time series. Partial autocorrelation, on the other hand, can provide an indication of the respective roles of direct and delayed density-dependent processes within a population. Whichever analysis is undertaken, the usual outcome is that the majority of forest insects, in particular the Lepidoptera, show periodic cyclical dynamics oscillating around a 6–11-year period, with delayed density-dependent effects being the most common driving variable. Although these mathematical and statistical approaches to exploring long-term data series are useful in providing an overview of the ecological processes and revealing hidden patterns, the mechanisms that drive the patterns are what most ecologists are really interested in discovering.

Although abiotic factors such as weather, plant stress, and site factors have all been implicated as contributing to, if not driving, the oscillatory behavior of forest insects, it is generally agreed that biotic factors, in particular natural enemies and the insect's host plants, are the major factors causing the population cycles. Weather and other abiotic factors undoubtedly play a major supporting role in modifying the peaks and troughs of the populations, if not in their timing and frequency.

Top-down versus Bottom-up

During the latter part of the twentieth century the acrimonious nature of debate over the factors enabling the regulation of herbivorous insect populations derived from the peculiar and partisan views of the importance of the host plant versus the natural enemies of the herbivore, i.e., whether the population was driven from the bottom up by the effects of the plant or from the top down by the impact of the natural enemies. These positions were at one time deeply entrenched and I remember as a postgraduate student being deeply sceptical about the relevance of natural enemies in agroecosystems and crop protection, despite the undoubted success of some biological control operations. Ecologists tended to study only one part of the system and ignore the other as being largely irrelevant – the emphasis was on ditrophic rather than on multitrophic interactions. Fortunately, most ecologists now agree that there is room for both top-down and bottom-up forces to act together to influence the populations of insect herbivores. There is, however, still much debate as to which is the most important and whether the relative importance of one over the other is fixed in a particular system or varies according to environmental conditions.

Insect population biologists working in forest ecosystems could perhaps be excused for espousing the top-down view, as it is well known that forest Lepidoptera are attacked by a large number of natural enemies, in particular Hymenopteran and Dipteran parasitoids. Parasitoids are distinguished from parasites in that their host usually dies as a result of their attack and that some parasitoids also directly predate their hosts as well as laying their eggs inside or next to them. Parasitoids do have an important role in the population dynamics of forest insects and, in many cases, as in small ermine moths, appear to be the major cause of the cyclical crashes in population seen in these insects.

The role of predators is less well supported. There is good evidence that predators have an effect on the population dynamics of forest insects, e.g., outbreaks of the pine beauty moth, *Panolis flammea*, in northern Scotland are associated with a lack of generalist predators such as carabid beetles and spiders; other forest Lepidoptera, notably the Douglas-fir tussock moth and the spruce budworm in North America, are subject to substantial predation by these agents. Evidence for the action of predators as a causal mechanism for cyclical population fluctuations is in shorter supply. The predation of pine sawfly cocoons by small mammals (*Sorex* spp.) has been postulated to influence the cyclical population dynamics of Diprionid sawflies in northern Europe and predators are claimed to be the driving mechanism causing the oscillatory behavior of southern pine beetle populations in the USA.

An important natural enemy complex that may be responsible for the maintenance of population cycles in forest insects are the insect pathogens: viruses, bacteria, protozoa, and fungi. For example, nuclear polyhedrosis viruses (NPVs) and the granulosis viruses have dramatic physical effects on forest Lepidoptera and Hymenoptera and appear to be responsible for sudden population crashes in these organisms. In addition, they have been used worldwide in attempts to control forest insect pests. Until recently, however, it was difficult to prove that they had a major role to play in the induction of population cycles. New developments supported by simulation modeling indicate that if pathogens act at the same time as resource competition then population cycles are more likely to be generated.

All of the preceding are so-called 'top-down agents.' What about those operating from the bottom up? It may appear that the plant can have little influence on the generation of population cycles. It seems intuitively obvious that plants are inherently more or less susceptible/suitable to attack by a particular herbivore species. Plant breeders have used this knowledge for a long time when seeking to breed insect- and disease-resistant crop plants as part of pest management systems. There are, however, ways in which the host plant can influence the development of population cycles in forest insects. First, even if the nutritional quality of the host plant remained unchanged, the build-up of the herbivore population on the host plant can result in competition for resources, either through depletion of the food source or by the increase in the number of larvae feeding on a finite host plant. Second, the physiological state of trees (and other plants) is not static, and their susceptibility/suitability as food plants both within and between years can be changed. Insect feeding, for example, can in some cases induce rapid changes in plant physiology and biochemistry (rapid induced responses). The biochemistry of the leaves can change detrimentally for the insect and leave the equivalent of a nasty taste in the insect's mouth, resulting in its either ceasing feeding altogether or moving to a new leaf or site on the same leaf. Although this phenomenon has been demonstrated on many occasions, it is not likely to influence cyclical population behavior. A more likely candidate is the so-called delayed induced responses where attacked trees become more resistant or less palatable to the insect herbivores the following year. The effect is mediated through the mother, in that the changes in food quality and an increase in the degree of larval crowding cause reductions in growth and developmental rates, resulting in smaller, less fecund adults. A reduction in the fitness of individual adults can markedly affect the population dynamics. In other words, the population cycles are driven by long time lags by the action of density-dependent factors, i.e., larval quality is impaired by insect-induced changes to the host plant, the insect population decreases, and the quality of the host plant slowly improves or returns to normal, at which point individuals within the insect population become fitter (faster-growing, larger and more fecund) and the cycle starts anew.

The classic example of this phenomenon is the larch bud moth, *Zeiraphera diniana*, the larvae of which defoliate *Larix decidua* and *Pinus cembrae* in the European Alps. Outbreaks of the larch bud moth occur at regular 9-year intervals in the Engadine valley. The cycles are hypothesized to be caused by host-induced changes in the quality of the larvae. When defoliated by the moth larvae, the raw fiber content of the new larch needles increases considerably; this has a strong negative effect on larval survival and female fecundity. It can take several years for the raw fiber content to return to normal and this in itself constitutes a delayed negative-feedback mechanism which in theory could be sufficient to generate regular population cycles. Mathematical modeling and many years of observation appear to support this hypothesis. Gypsy moth, western tent moth, and autumnal moth populations also show similar responses to the quality of their host plant in that host-mediated maternal effects affect the quality of their offspring and may generate cyclical population dynamics. There is, however, some debate as to the generality of these results and evidence of whether the maternal carry-over effects can generate the cycles on their own is equivocal.

Multitrophic Interactions

The situation becomes more complex when the top-down forces meet those operating from the bottom up: the tritrophic or multitrophic interactions, between the predators, parasites, and other natural enemies, the herbivores and their host plants. This can be expressed in a number of ways, but perhaps one of the best known is the sublethal plant defenses paradox. The paradox resides in the fact that the host plant gains more by being partially resistant to the insect herbivore than by being immune. To possess total immunity against an insect herbivore requires a large investment in defenses, be this through antibiosis, antixenosis, or architectural attributes such as spines, thick cuticles, and resin flow. Any resources invested in defense are of course not available for growth and reproduction and this imposes a fitness cost. If, on the other hand, the plant reduces its investment in defenses, it has more reproductive currency to spend. By being partially resistant (i.e., partially susceptible), however, the insect herbivore is able to consume it, thus reducing reserves available for growth and reproduction. On the face of it this is potentially reducing the fitness of the plant. If there was a simple trade-off between the plant's investment in defenses (carbon-based) and the amount likely to be eaten by the herbivore (nitrogen-based), there would be no paradox. Put simply, the insect herbivore requires x amount of nitrogen to complete development and any reduction in plant nutritional quality implies that the insect needs to eat more plant to obtain the required amount of nitrogen to complete its development. As the insect is not killed or repelled by the plant, it remains on the plant and continues to feed until it reaches adulthood or its own reproductive threshold. Hence the paradox. By being less suitable as a food source, the plant appears to be encouraging the insect to eat more of it. This does not appear to be the best form of defense. Bear in mind, however, that the general effect of sublethal plant defenses is either to slow down the growth of the insect or, for example as in the case of rapidly induced defenses, to cause the insect to change feeding site more often. These effects have the same net outcome. The insect herbivore becomes more vulnerable to its natural enemies. In the case of reduced insect growth rates, it remains in a vulnerable (less developed) stage for longer and thus has more chance of encountering a predator or parasitoid. In the case of the rapid-induced defense scenario, where the leaf becomes less palatable, the insect moves from one feeding site to another more often and spends more time exposed on the leaf (caterpillars often feed in bouts, coming out from sites within the inner parts of the plant foliage to feed, and then returning to the relative safety of the area near the main stem). The overall result is more journeys back and forth and thus more chance of encountering a predator or parasitoid. In addition, by changing feeding sites more often, the insect makes more holes in the leaves and this acts as a 'supercue' for vision-dependent predators such as birds.

Yet another effect of sublethal plant defenses is that the insect herbivore, feeding as it does on a suboptimal diet, is more likely to become stressed and more susceptible to infection by pathogens, e.g., fungal and viral diseases, although in some cases it is possible that the insect is able to sequester plant chemicals that inhibit virus infection.

Population Cycles

So how do these top-down and bottom-up forces interact with the insect herbivore to produce the population cycles seen in so many forest Lepidoptera? Populations that cycle are characterized by highs (peaks) and lows (troughs) in abundance. As foresters usually first become aware of defoliating insects when they outbreak, it is appropriate to start our consideration on a peak, when the population is at its maximum.

The herbivore population is at its peak, and the trees are likely to be showing marked signs of defoliation, either totally stripped or at least half their foliage removed. The nutritional quality of the plants for the insect is at its lowest, either because of a scarcity of foliage and/or because of induced defenses. Interspecific competition between the insects is markedly higher than before and the caterpillars are small and stressed. Their growth rates will be low and this will make them susceptible to natural enemies. Natural enemy populations are now increasing rapidly and parasitism and disease rates are now extremely high. Any caterpillars that survive to pupate will be small and, if they survive the winter, will produce even smaller and less fecund adults than before. The herbivore population now begins to decline steeply. The natural enemy populations are now at their highest levels and competing amongst themselves. The nutritional quality of the trees is still very low, although consumption of the foliage is lower than before as there are now fewer caterpillars. The caterpillars, although likely to be growing and developing slightly faster than the season before, are now greatly outnumbered by their natural enemies. The herbivore population crashes and they virtually disappear from the forest. The following season caterpillar numbers are extremely low indeed. New foliage will be available and the nutritional quality will be improving. Food is thus in relatively plentiful supply. Most of the natural enemies will fail to find suitable hosts or prey as the herbivore population is so low.

The natural enemy populations now crash. The following year, the few emerging herbivore adults are able to exploit an underutilized food resource and pick egg-laying sites likely to maximize offspring fitness. The emerging caterpillars thus find themselves with a plentiful and relatively defenseless source of nutrition. Their environment is relatively competition-free and consequently they are able to grow and develop rapidly, attaining relatively large sizes and hence, after pupation, producing large and fecund adults. Natural enemy populations are almost nonexistent and, as the herbivores are likely to be widely dispersed and uncommon, predation, parasitism, and disease are also likely to be very low. The herbivore population will thus start to increase. However, as the herbivore population increases, the nutritional quality of the host plant begins to decrease, first perhaps by the induction of plant resistance but also by depletion of the resource as more and more foliage is removed by the feeding caterpillars. Interspecific competition is also likely to influence the quality of the herbivore. As a result the larvae will be smaller and less well defended, and will grow and develop more slowly. After pupation, the emerging adults will be smaller and less fecund. The effects of the levels of natural enemies (predation, parasitism, and disease) will also be more marked. The herbivore population, although composed of poorer-quality individuals, will continue to increase, but at a slower rate and the herbivore population reaches its peak as the combined effects of natural enemies, host quality, and insect quality have their greatest effect and then the cycle starts again.

Foliage Feeders in Temperate and Boreal Forests

D Parry, State University of New York, Syracuse, NY, USA

D G McCullough, Michigan State University, East Lansing, MI, USA

Introduction

Insect consumers of tree foliage comprise one of the most abundant and diverse feeding guilds in forest ecosystems. Known as folivores, this guild is integral to the structure and functioning of forests. Folivores influence vital ecosystem processes in forests, including nutrient turnover, competition among plants, and stand structure. In addition, these insects are critical sources of food for many invertebrate and vertebrate predators. In this article, we will address foliage-feeding insects that affect trees in temperate and boreal forests. In these ecosystems, an estimated 10–30% of the total leaf area is annually removed by leaf-chewing forest insects. In some forest types, defoliating insects strongly influence productivity and the long-term dynamics of the ecosystem. Foliage-feeding insect species have little effect on tree health in most years. During outbreaks of some insect defoliators, however, the entire canopy can be consumed, sometimes for several years in succession. While outbreaks may cause significant economic harm by accelerating tree mortality, reducing productivity and increasing fire risk, they may also play an important long-term role in maintaining healthy forests.

Diversity

In this section, we focus on folivores with chewing mouthparts, which represent the vast majority of insects feeding on the leaves of hardwood trees (deciduous angiosperms) and the needles of conifers (gymnosperms). The forest defoliator guild is comprised of insects from several different orders. The greatest diversity of species is found within the order Lepidoptera. Nearly all larval Lepidoptera are herbivorous whereas the adults may imbibe fluids such as nectar or, as in many economically important species, may not feed at all. The sawflies (Symphyta), a relatively primitive group of Hymenoptera, are also important foliage feeders. Like the Lepidoptera, larval sawflies are herbivorous while adults generally do not feed. In addition to sawflies, leaf-cutting ants (family Formicidae) are another group of Hymenoptera that feed on foliage. While not important or diverse in temperate regions, leaf-cutter ants are the dominant herbivore in many tropical forests. Among the beetles (order Coleoptera), the diversity of leaf-feeders is richest in the large families Chrysomelidae and Curculionidae. Both adults and larvae in these families feed on foliage. Several other insect orders also contain species that can function as forest defoliators. These include grasshoppers, crickets, and walking-sticks from the order Orthoptera, and several families of flies (order Diptera). Other guilds of tree-feeding insects, such as sap-feeders and shoot borers, can also cause defoliation but will be described in other articles (*see* **Entomology**: Defoliators; Sapsuckers).

Feeding Ecology

Folivores with chewing mouthparts can be partitioned based on their general feeding type. Three types are generally recognized: free-feeding, shelter-feeding, and leaf-mining. Insects that free-feed consume leaf tissue openly. Species utilizing this type of feeding may consume all parts of the leaf (many caterpillars, sawflies, and orthopterans) or may avoid veins and other structural tissue (shot-hole, window-feeding, or skeletonizing). Skeletonizing is characteristic of chrysomelid beetles as well as some caterpillars and sawflies. Because free-feeding species are exposed to predators as they forage, many have adaptations, that may reduce their risk of mortality from these natural enemies. These include high mobility, nocturnal feeding, cryptic coloration, sequestration of toxins, physical defenses such as urticating or stinging hairs, or stereotyped defensive behaviors like regurgitation, head flicking, or dropping immediately to the ground upon sensing danger.

Another common feeding strategy is shelter-feeding. Shelter-feeding species may enclose and feed on foliage within a silk structure, or may use silk to roll leaves or to tie leaves or needles together. Enclosures are often used by gregarious species including fall webworm (*Hyphantria cunea*) and ugly-nest caterpillar (*Archips cerasivorana*). Many solitary species of Lepidoptera, as well as some sawflies, create tubes or shelters by leaf-rolling or tying. These structures provide a concealed place for the larva to rest and feed. Leaf-rollers and leaf-tiers tend to have lower mobility than free-feeders and fewer species have evolved physical or chemical defenses. Instead they rely on reduced visibility to escape natural enemies. Some species have evolved behaviors thought to lower the risk of detection by parasitoids that rely on chemical signals to find their hosts. For example, a number of lepidopteran leaf-rollers eject their frass (feces) from the feeding tube, often for considerable distances, which reduces the scent profile of the caterpillar.

Leaf-mining represents another type of folivory. Insects that mine leaves or needles are usually small and dorsoventrally compressed, an adaptation for feeding between the upper and lower layers of the leaf epidermis. Leaf-mining requires a more intimate association with the host plant and specific behaviors may be required to avoid host defensive responses such as leaf-shedding, withdrawal of nutrients, or increased concentrations of secondary chemicals. These behaviors can be critical as many leaf-miners utilize only a single leaf over their lifespan and cannot mitigate unfavorable conditions by moving. Several families of Lepidoptera, sawflies (Tenthredinidae), the dipteran families Agromyzidae and Anthomyiidae, and the beetle families Chrysomelidae, Buprestidae, and Curculionidae have all adopted this life-history strategy. Folivores may utilize one feeding method when small, while switching to another feeding strategy in later larval stages. For example, spruce budworm (*Choristoneura fumiferana*) larvae may mine needles in the early larval stages, but utilize a needle-tying feeding strategy as they become larger.

Population Dynamics

The population dynamics of forest-defoliating insects have long been of particular interest to ecologists. The vast majority of this research has focused on a relatively small group of species characterized by explosive changes in population density known as outbreaks. This bias is primarily due to the spectacular nature of outbreaks and the potential of these species to cause economic harm. Because factors important in the dynamics of outbreak species may not necessarily be the same for the vast majority of leaf-feeding forest insects that never outbreak, we must be cautious in generalizing from studies of outbreak species. In outbreaking species, populations increase from virtually undetectable levels to densities that defoliate entire forests, often in only a few generations. While outbreaks occur at irregular intervals in some species, there are a fascinating subset of species whose populations rise and fall at regular intervals, known as cycles. A number of our most economically damaging species fit this profile.

Life-History Traits

Several studies have attempted to assess whether or not outbreaks are a property of particular life-history attributes found in some forest insects. Among Lepidoptera, for example, gregariousness, flightlessness, egg-clustering, low host plant specificity, and nonfeeding adults are all found in greater frequency in species known to have outbreaks. However, there does not appear to be either a single trait or a suite of overarching traits that are uniformly associated with species that outbreak. All of the above traits can be found in species which do not outbreak. In addition, species such as the forest tent caterpillar (*Malacosoma disstria*), larch budmoth (*Zieraphera diniana*), autumnal moth (*Epirrita autumnata*), budworms (*Choristoneura* spp.), and gypsy moth (*Lymantria dispar*) outbreak in only portions of their ranges, suggesting that alone, life-history characteristics are insufficient to explain outbreak dynamics.

Population Regulation

Regardless of whether a species is prone to outbreak or not, there are three forces that influence the density and dynamics of populations: (1) top-down, driven by organisms in trophic (feeding) levels above the folivore; (2) bottom-up, the influence of species in trophic levels below the folivore; and (3) horizontal, competitive interactions with other herbivores. The relative importance of these factors is likely species-specific. Historically, top-down and bottom-up factors were considered separately, but there is increasing recognition that they function in tandem to influence population dynamics. Communities of leaf-feeding insects were also thought not to be structured by competition, a view that is less tenable when indirect competitive interactions such as those mediated through changes in host plant quality or through shared natural enemies are considered.

Top-down regulation of herbivorous insect populations is driven by a suite of organisms collectively called 'natural enemies.' Natural enemies of forest insects include invertebrate and vertebrate predators, parasitoids, and pathogens. Important invertebrate predators include pentatomid bugs (Hemiptera), ants and wasps (Hymenoptera), spiders (Arachnida), and carabid beetles (Coleoptera). Insectivorous birds and small mammals such as mice and shrews are examples of important groups of vertebrate predators. Foliage-feeding insects are susceptible to many pathogenic organisms, including viruses, bacteria, fungi, and protozoans. In addition, they are attacked by a staggering diversity of parasitoids. The vast majority of parasitoids are found within two superfamilies of Hymenoptera, the Ichneumonoidea and Chalcidoidea, and a large and diverse family of Diptera, the Tachinidae. In general, the larvae of parasitoids develop within or sometimes on the body of a host species. Parasitoids often possess remarkable adaptations for locating hosts and for circumventing the immune system of their insect victims. Once the developing parasitoid completes larval development, the host is usually killed.

The relative importance of natural enemies varies among folivores and may also vary within a species in different parts of its range, or at different population densities. For example, in the gypsy moth, vertebrate predation on pupae and large larvae by white-footed mice is important at low population densities whereas a nuclear polyhedrosis virus (NPV), a pathogen, dominates mortality in many outbreak populations. In other species, such as tent caterpillars and budworms, specialist parasitoids may play an integral role in the cyclical rise and fall of population densities.

For leaf-feeding insects, the host plant is the primary bottom-up factor influencing their populations. Trees are not passive recipients of herbivory. Indeed, millions of years of evolution have led to numerous physical and biochemical traits that confer some degree of resistance to folivores. Concentrations of primary compounds important to insects such as water and nitrogen, secondary compounds such as tannins and terpinoids, and physical properties such as toughness vary among leaves on an individual tree, among trees, and across entire forested landscapes. Foliage quality for herbivores also changes seasonally and is generally highest in the spring. As current-year needles or new leaves fully expand, the concentration of indigestible fiber and lignin increases. New growth on conifers is of much higher quality for many foliage-feeding insects than needles retained on the tree from previous years. Thus, folivorous insects encounter great temporal and spatial variation in the quality of leaves on which they feed. To counter this, insects have evolved detoxification mechanisms, feeding behaviors, and/or restrict their feeding to specific times of the season such as early spring.

Trees may respond actively or passively to insect feeding or may simply be tolerant to some level of leaf loss. Active responses occur rapidly following damage and these wounding responses often involve the production of compounds such as proteinase inhibitors or polyphenol oxidases that deter feeding or reduce the nutritional value of the leaf to subsequent herbivores. Such responses can be site-specific or can be rapidly propagated throughout the plant. The production of these compounds may involve complex biochemical signaling pathways that are only just beginning to be understood.

Trees also exhibit passive responses that result in deterioration of the nutritional value of a leaf following defoliation. While not as rapid as the wounding responses above, these effects may last for a year or more. Water and nitrogen are often reduced in damaged leaves or in trees that were severely defoliated in the previous year. In addition, levels of some carbon-based secondary compounds such as tannins may be elevated in the same trees. The combination of lower concentrations of primary nutrients and higher concentrations of secondary compounds may reduce the performance of folivorous insects on these trees. These long-term responses can reduce insect fecundity and growth for several years. These effects have been well documented for autumnal moth on mountain birch, forest tent caterpillar on aspen, and black-marked spear moth (*Rheumaptera hastata)* on paper birch.

Phenology is the seasonal timing of specific growth, developmental, and reproductive processes. In trees, the phenology of budbreak, flowering, or leaf drop, is recognized as being critical in determining the density of some foliage-feeding insect populations. For example, jack pine budworm (*Choristoneura pinus*) larvae survive by feeding in pollen cones in the spring until new needles, their preferred food, begin to expand. Many other spring-feeding folivores must time their hatch to coincide with budbreak, when primary nutrients such as water and nitrogen are high, many secondary compounds are low, and physical properties such as toughness are at their seasonal minima. Hatching earlier than budbreak may lead to starvation, whereas hatching late may lead to lowered fecundity, longer development times, and higher mortality.

Intra- and interspecific differences among trees in phenology and phytochemistry can shape foliage-feeding insect communities in both time and space. For example, the population density of folivores feeding on white and black oaks varies across the landscape with greater diversity and abundance on trees with lower tannin levels. Similarly, the phenology of individual trees can determine the density of a number of different folivores including winter moth (*Opherophtera brumata*) on oak and large aspen tortrix (*Choristoneura conflictana*) on aspen. For both species, trees whose buds break in synchrony with the emergence of larvae in spring support higher populations than trees that leaf out prior to larval emergence or after it has already occurred. Slow growth of insects stemming from poor phenological synchrony with the host tree may lead to increased mortality from parasitoids or predators if the insect remains in a vulnerable stage for longer periods of time, as has been shown for tent caterpillars and autumnal moth. Even extreme generalist folivores like gypsy moth have a hierarchy of preferences for different tree species, based primarily on phenology and phytochemistry.

In addition to the direct influences mentioned above, trees may indirectly influence the population dynamics of folivores. Alterations to relationships between a herbivore and its natural enemies mediated by the host tree are known as tritrophic interactions. For example, leaves damaged by feeding folivores may release volatile chemicals that predators or parasitoids can use as cues to locate the herbivore. There are both intraspecific and interspecific differences in the type and strength of volatiles released by trees, contributing to variability in the susceptibility of folivores to predators and parasitoids. Tree chemistry can also alter the susceptibility of folivores to pathogens. Gypsy moth larvae are less likely to succumb to NPV when feeding on oaks which are rich in hydrolyzable tannins than when feeding on other species with lower concentrations such as aspen. In some, but not all studies, increases in tannins following defoliation of oaks reduce susceptibility of gypsy moth to NPV.

Another indirect influence of trees on herbivore populations can occur through so-called 'maternal effects' where the foliage quality experienced by the parental generation can have significant effects on the performance of their offspring. The influence of the environmental quality experienced by the parental generation on offspring is well documented for many organisms, including some foliage-feeding insects. An example is the change in yolk provisioning of gypsy moth eggs after the parental generation has experienced defoliation-induced declines in tree quality. While these effects have been documented in some studies of gypsy moth, they were not evident in several other folivores and their importance in population dynamics continues to be debated.

Population Cycles

A fractious debate in ecology during the mid-twentieth century focused on the relative role of density-dependent and density-independent factors in population dynamics. Density-dependent factors have effects that are a function of the size of a population. Such factors can act immediately or with a lag time or delay in the response. It is now generally accepted that cycles can only occur if a density-dependent process has sufficient lag time. Any process that functions in a delayed density-dependent manner can drive population cycles. Mathematical models have suggested that natural enemies, maternal effects, and host plant quality can all cause population cycles, although it has proved difficult to show whether or not any one density-dependent factor is critical to population cycling.

A long-standing hypothesis for explaining forest insect outbreaks was that periods of favorable climate allow populations to increase. This was thought to occur because the herbivore population grows faster than its natural enemies during favorable periods or because plant quality changes in a way that is advantageous to the herbivore, either through reduced defenses or increases in nutritive value. Although it is possible that periods of favorable weather could be driving the dynamics of species which outbreak at irregular intervals, weather patterns are too random (stochastic) to be responsible for the regular cycles that characterize the dynamics of many important defoliators.

Forest insects such as jack pine and spruce budworms, forest tent caterpillar, larch budmoth, and large aspen tortrix are prone to region-wide, synchronous outbreaks, some spanning distances of several hundred kilometers or more. The Moran effect, originally used to describe the synchronization of lynx populations across large regions of Canada, may offer an explanation for the remarkable degree of synchrony among these widespread populations. It postulates that an extrinsic factor such as weather may act to synchronize populations across a region so that they fluctuate in unison. In this case, the cycling of individual insect populations is driven by intrinsic density-dependent factors, but is brought into regional synchrony through Moran-effect processes.

Some have also proposed that dispersal among populations could also be responsible for synchronization. Certainly, large dispersals of adults from outbreak populations have been documented for conifer-feeding budworms. However, while dispersal among populations may account for synchrony over a small scale, the outbreak areas that are affected greatly exceed the dispersal capabilities of individual insects. In addition species such as Douglas-fir tussock moth (*Orygia pseudotsugata)*, spring canker worm (*Paleacrita vernata*), and gypsy moth also exhibit strong regional synchrony despite very poor dispersal abilities.

Impacts of Foliage-Feeding Insects on Trees

Effects of insect defoliation on tree health vary considerably depending on the species of tree, how much foliage is consumed, and the general health or vigor of the tree. In addition, the timing of the defoliation and the age or location of the affected foliage can also influence the severity of impact.

Hardwood and conifer trees differ greatly in their ability to tolerate severe defoliation. Healthy hardwood trees can generally recover from defoliation, even if 100% of the foliage is consumed. Most hardwood trees are able to produce a second set of leaves a few weeks after the initial foliage is lost – a process referred to as 'reflush.' As a rule, hardwood trees do not reflush until roughly 60% or more of the canopy has been consumed or otherwise damaged. The second set of leaves is typically smaller and less photosynthetically active than the original leaves, but they enable the tree to produce an adequate amount of energy to survive the winter and leaf out the following spring. Of course, there is a cost when a tree has to reflush. Carbohydrates and other nutrients must be utilized to form the second set of leaves, depleting the stored energy available to the tree and substantially reducing its radial growth. While healthy hardwood trees can generally reflush for 2 or 3 consecutive years, the stress eventually becomes too great. Trees that have sustained heavy defoliation for more than 2 or 3 years often succumb to secondary pests such as bark beetles, phloem-borers or root rot pathogens. These secondary pests rarely affect healthy trees but are able to take advantage of stressed trees. Hardwood trees that experience other stresses such as extended drought, wounds, or poor growing conditions are less likely to tolerate and recover from insect defoliation.

Unlike hardwood trees, conifers produce only a single set of buds in mid to late summer and cannot reflush in response to defoliation. Conifer trees that sustain complete defoliation will die and moderate to heavy defoliation increases the vulnerability of conifers to bark beetles and other secondary pests. Conifer forests killed by defoliating insects or associated secondary pests can be highly susceptible to wildfire, especially when conditions are dry. Some conifer feeders, such as jack pine budworm and yellow-headed spruce sawfly (*Pikonema alaskensis*), feed more heavily on needles at the top of the tree than in the middle or lower portion of the canopy. This can result in top-kill – a condition in which the tree survives and continues to grow radially, but the leader and upper whorls of branches die.

Because foliage-feeding insects reduce leaf area, photosynthesis is reduced during defoliation. This, in turn, leads to a decrease in the rate of radial growth. Most people are familiar with the annual rings of spring and summer wood growth that are visible in cross-sections of the trunk and branches of trees. Healthy trees produce wider rings and grow at a faster rate than unhealthy trees. When a tree loses more than about 10–20% of its canopy, less energy will be available for wood production and growth rings will be narrow. When defoliation exceeds 50–60% of the canopy, little or no radial growth will occur that year. Radial growth rates of hardwood trees may recover the following year while growth rates of conifer may only recover after 2 years or more.

Insects that feed in the spring or early summer generally have more effect on tree vigor than insects that feed later in the summer. Early in the year, young, succulent leaves or needles function as a sink for stored carbohydrates and nutrients. When young foliage is consumed by insects, the tree effectively loses that investment before the tissue begins to produce energy through photosynthesis. In contrast, defoliation in the latter part of the summer, when trees are beginning to prepare for winter dormancy, generally has little effect on tree health. Fall webworm and orange-striped oakworm (*Anisota senatoria*) typically cause less harm to trees than species like gypsy moth or forest tent caterpillar simply because they feed later in the year. Insects that feed on current-year foliage of conifers such as jack pine budworm or red-headed pine sawfly (*Neodiprion lecontei*) are generally more harmful than are insects such as European pine sawfly (*N. sertifer*) that feed primarily on needles 1 year old or more.

While severe defoliation can reduce radial growth, cause top-kill or tree death, foliage-feeding insects can also increase the overall long-term health of a forest. Suppressed or diseased trees are usually more vulnerable to mortality during outbreaks of defoliators. When these trees succumb, space, water, light, and nutrients are freed up for the healthier trees that survive the outbreak. Forest entomologists sometimes refer to this pattern as a 'thinning from below,' because mortality of the less vigorous trees can lead to increased rates of growth and productivity for the forest as a whole. This regulation of productivity by foliage-feeding insects is an important part of the long-term dynamics of many forest ecosystems.

Defoliators

H F Evans, Forestry Commission, Farnham, UK

Published by Elsevier Ltd., 2004

Introduction

The dictionary definition of a defoliator is 'an insect that strips the leaves from plants.' This serves as a useful broad statement of both the nature of the biotic agent and of its overall impact on its primary target resource on trees. Its effects on tree growth and structure are manifested through removal of photosynthetic and transpiration tissues from trees, thus compromising the ability of the tree to grow, respire, control moisture loss, etc. Defoliation, therefore, is rightly regarded as detrimental to the plant but the severity of effects depends very much on both the timing and nature of defoliation. In the brief description in this article, defoliation is taken to mean the damage or removal of leaves by direct feeding, rather than the indirect defoliation that can occur from damage to other parts of the plant leading to browning of leaves and indirect loss.

Defoliating Species

Leaf feeders are found in a number of insect orders, particularly in the moths (Lepidoptera) (**Figure 1**), sawflies (Hymenoptera), grasshoppers (Orthoptera), and beetles (Coleoptera). Some feed on tree foliage exclusively in the larval stage, while others can include adult only or both adult and larval feeding. In all cases, however, timing of insect activity to coincide with the most suitable stage of leaf development and tree growth is critical. Some species, such as the winter moth (*Operophtera brumata*) overwinter as an egg and require close synchrony between egg hatch and bud burst to ensure maximum survival of the newly hatched larvae as they feed on the expanding leaves. It is fascinating to note, as an

Figure 1 A larval teak defoliator moth.

example of the potential effects of climate change, that oak bud burst in the southern part of Great Britain has advanced by an average of 20 days during the final 50 years of the twentieth century. This might be thought to give the tree an advantage in that bud burst could be too early for the young winter moth larvae. However, showing the high adaptability of many insect species, winter moth egg hatch has also advanced by around 20 days, thus retaining synchronization with its primary host tree. By contrast, a new association between winter moth and the exotic Sitka spruce (*Picea stichensis*) has not retained synchronization because bud burst in this tree species is not so dependent on temperature.

Impacts

As a general rule, suitability of leaves for feeding by the most vulnerable life stages of an insect is a strong determinant of the degree of defoliation and, ultimately of breeding success by the insect. Broadleaved tree species tend to tolerate episodes of defoliation without a high risk of tree mortality. This is mainly because the trees tend to be able to refoliate during the growing season and will develop adequate buds for shoot extension in the following year. This is not to say that the effects on tree growth are negligible. Attacks by teak defoliator moth (*Hyblaea puera*) during the early stages of development of teak trees (*Tectona grandis*) can result in up to 44% loss of growth increment during the first 9 years and up to 13% loss of total volume over the rotation of the crop. Losses of up to 30% in stem growth have also been recorded for defoliators of temperate broadleaved trees (e.g., 7–13% loss of beech growth arising from 90% defoliation by pale tussock moth (*Dasychira pudibunda*) in continental Europe).

The degree of tolerance to defoliation by conifers depends on whether either or both current and older foliage is consumed. Although known to have a significant effect on growth increment, European pine sawfly (*Neodiprion sertifer*) does not kill pine trees because it feeds exclusively on older foliage. By contrast, pine beauty moth (*Panolis flammea*) feeds on both young foliage and, later, on older foliage and can completely defoliate trees leading to heavy mortality. Similar specialization in feeding sites is apparent in the major lepidopterous pests of conifer forests in North America so that, for example, although spruce budworm (*Choristoneura fumiferana*) is regarded as highly damaging and occasionally renders trees vulnerable to mortality from actions of other biotic and abiotic factors, it does not lead directly to tree mortality, unless there are several consecutive years of heavy defoliation. This arises from larval feeding specialization on expanding young foliage in the spring which, although damaging, still allows the plant to photosynthesize through older foliage and to develop buds for the following year.

Management Approaches

The above examples illustrate the diversity of feeding habits for those defoliators that totally consume leaves or needles. This external feeding habit means that they can be vulnerable to natural enemies and to direct intervention in management programs. Thus, use of chemical or, particularly, microbial control agents can be contemplated when the economic or environmental case requires intervention. Integrated pest management approaches to control of defoliator populations are discussed elsewhere in this volume (*see* **Health and Protection**: Integrated Pest Management Practices. **Tree Breeding, Practices**: Biological Improvement of Wood Properties). Other defoliators have more cryptic habits, including leaf mining where larval feeding takes place entirely within the leaf, leaving the outer surfaces intact. An interesting example in this category is the horse chestnut leafminer (*Cameraria ohridella*) which was only described for the first time in 1985 in Macedonia. This micromoth has, from a slow start, now spread across most of Western Europe and is giving rise to heavy cosmetic damage and premature leaf fall in urban horse chestnut (*Aesculus hippocastanum*) trees. The rapid spread of the moth from its original restricted range has been attributed to human movement, particularly of leaves accidentally falling onto vehicles and being carried long distances before emergence of the next generation of moths. It was found for the first time in Britain in 2002 in the Wimbledon area of London. By mid 2003 it had spread to Kingston and Oxford and is likely to colonize horse chestnut trees in most towns in the south of England and possibly elsewhere in Britain. At this stage there are no effective longer-term control measures, although collection and burning of fallen leaves in the autumn is known to reduce populations significantly.

Defoliators and Biodiversity

Defoliators are, therefore, significant biotic agents affecting tree health and growth and can even lead to tree mortality. Fortunately, the number of species resulting in these extreme impacts on trees is relatively rare. Indeed, it is a fortunate ecological fact that trees support a wide range of defoliators without showing undue signs of ill health and thus act as a valuable resource for enhancing invertebrate biodiversity at both local and landscape scales. In general, broadleaved trees with wide distributions tend to support more species than conifers or broadleaved tree species with restricted distributions. This has been well studied in Britain and it is known that oak (*Quercus* spp.) and willow (*Salix* spp.) support the greatest biodiversities of insects. Some of these, such as winter moth and oak leaf roller moth (*Tortrix viridana*) on oak occasionally reach damaging population densities, but these subside under the actions of natural enemies and resource limitation without causing tree mortality.

International Movements and Pest Risk Analysis

Greater diversity of defoliators on trees also tends to be accompanied by greater diversity of natural enemies, again contributing to the maintenance of a balance between resource utilization, in terms of leaves consumed, and effects on tree growth and health. This natural balance will have evolved over very long time periods and can be compromised through the introduction of exotic elements into the ecosystem. These can be in the form of exotic host trees or of exotic defoliator species or a combination of the two. Pine beauty moth is a good example of the former category. This species of moth is innocuous on Scots pine (*Pinus sylvestris*) in Britain but became a lethal pest when North American lodgepole pine (*P. contorta*) was planted in the north of Scotland from the 1960s. International movement of insect pests is increasing with the expansion and increased speed of global trade and there have been a number of instances of defoliators establishing and causing damage in new geographical locations. The horse chestnut leafminer described above is one example. Others include white marked tussock moth (*Orgyia thyellina*) in Auckland, New Zealand which was the subject of an intensive and successful eradication campaign involving repeated aerial application of the microbial control agent *Bacillus thuringiensis*. The authorities in Auckland are currently grappling with an outbreak of painted apple moth (*Teia anartoides*), a pest from Australia. Prevention of international movement of defoliators is an important task for national and regional Plant Protection Organizations and, internationally, legislation is already in place to raise awareness and to prohibit or manage the main pathways for movement of these pests in trade. In particular, international movement of plants is controlled very carefully, which tends to reduce the likelihood of egg or larval stages of defoliators being transported. However, life stages that could survive transit are not always associated directly with plants, making it extremely difficult to both inspect and to legislate against such incursions. For example, gypsy moth egg masses can be found on virtually any substrate, including the undersides of vehicles, etc., thus making inspection a very onerous task. Detailed pest risk analysis helps to identify the high-risk pathways and can aid risk management protocols, but it is also important that pioneer populations of a new pest are detected early and, where appropriate, action taken to eradicate or manage the problem. Unfortunately, it is often the case that by the time a population of an exotic pest is discovered it is already well established, thus making eradication a difficult prospect. However, the eradication of white marked tussock moth in New Zealand does indicate that a concerted campaign carried out in a determined manner can be successful.

Conclusion

In conclusion, insect defoliators can compromise tree growth and even lead to tree mortality. However, in relation to total diversity of insects on trees, heavy defoliations tend to be the exceptions and are often caused by a single pest species, thus pointing to the possibility of developing monitoring and management regimes for detection and for direct or indirect action. Effects can be serious when volume increment is an important component, for example in the growing of a commercial crop of trees. When trees are not grown for direct commercial reasons, their relatively high tolerance to attack means that occasional episodes of defoliation, although temporarily impairing visual and amenity values, do not significantly affect the long-term contributions of trees to the landscape (**Figure 1**).

Sapsuckers

A F G Dixon, University of East Anglia, Norwich, UK

Introduction

Insects of the order Hemiptera have mouthparts specialized for piercing and sucking, and within the suborder Homoptera of this order two groups, the Auchenorhyncha and Sternorhyncha, specifically feed on plants. As their general name implies these insects feed on the sap of plants. This can be the sap of individual mesophyll or palisade cells of leaves or the translocating elements of plants, in particular phloem. In feeding on phloem sap not only have these insects access to a more continuous supply of food but they can inject disease-causing organisms and saliva containing physiologically active chemicals, which are then translocated throughout a plant. In addition by telescoping generations aphids have overcome the developmental constraint and for their size achieved prodigious rates of increase. As a consequence aphids often become very abundant and so in addition to any indirect damage they can be extremely damaging because of the nutrient drain they impose on plants. That is, many phloem feeders in particular are such serious pests of trees that they threaten their survival, e.g., the scale insects *Carulaspis minima* and *Lepidosaphes newsteadi* attacking Bermuda cedar on Bermuda and *Orthezia insignis* attacking the native gumwood on St Helena. However, as they often do not apparently affect the leaf area or distort the leaves the damage goes largely unnoticed. The damage done by those sapsuckers that feed on mesophyll and palisade cells is often very conspicuous but possibly less damaging to the plant than that inflicted by the phloem feeders.

Mode of Feeding and Nitrogen Metabolism

As indicated above the mouthparts of the Hemiptera are adapted for piercing and sucking rather than chewing. The mandibles and maxillae are modified to form slender bristlelike stylets, which rest in the grooved labium. Both pairs of stylets are hollow and capable of limited protrusion and retraction by means of muscles. In the coccids and psyllids the stylets may be extremely long and greatly exceed the length of the insect, being looped and coiled upon themselves within its body. The mandibular and maxillary stylets together form a needlelike structure. Cross-sections through the stylets reveal that the maxillary stylets have two parallel channels on their inner aspects and are interlocked. The approximation of the two stylets results in the formation of two extremely fine tubes. The dorsal one functions as a food canal and the finer ventral one as a salivary duct (**Figure 1**).

Of the two groups of Homoptera that specifically feed on plants it is the Sternorhyncha that have specialized on feeding on phloem elements of plants and produce large quantities of honeydew (**Figure 2**), which is often the first indication of their presence. The reason for the abundance of honeydew is that phloem sap is rich in sugars but contains relatively little amino-nitrogen. To overcome this problem the insects process very large quantities of phloem sap removing most of the amino-nitrogen and excreting the sugars as honeydew. Because phloem sap is rich in simple sugars it creates an osmotic problem for the insects, which is overcome by converting the simple sugars into complex sugars, which effectively reduces the osmolality of the phloem sap as it passes through the insect. In addition, these insects are very effective at assimilating and utilizing the low levels of amino-nitrogen in their food. First, they are able to process rapidly relatively large volumes of phloem sap and so fuel their total requirements for amino-nitrogen. Second, they generally have symbiotic bacteria in bacteriosomes within their haemocoel, which increase the efficiency of their nitrogen metabolism by converting the nonessential amino acids in phloem sap into the essential amino acids the insects need to sustain their growth. In addition the symbionts may also recycle some of the insect's nitrogenous waste. In this way the aphids in particular are able to sustain a prodigious rate of growth on what is a very poor quality diet. That is, they are able to process quickly very large quantities of phloem sap and upgrade the quality of the amino-nitrogen component of their diet.

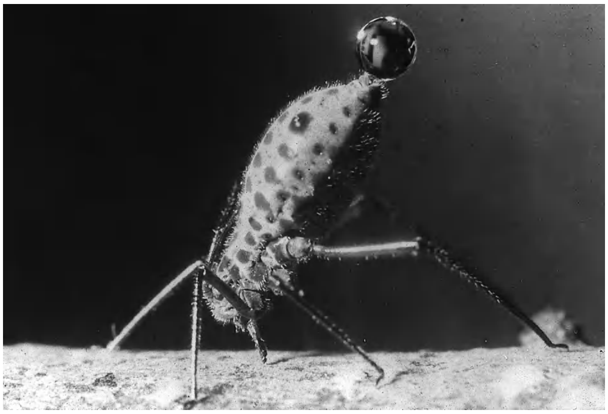

Figure 2 A giant willow aphid excreting a droplet of honeydew. In this case the aphid has its stylets inserted into a large willow twig.

Regional Distribution and Abundance

Correlation between the number of species of plants in an area is much better with the number of species of the least host-specific sapsuckers, the aleyrodids and coccids, than with the most specific, aphids and psyllids. In temperate regions sapsuckers, in particular aphids, are often an important and central component of the insect fauna of the canopies of trees. However, associated with the increase in plant diversity as one approaches the tropics is a decrease in aphid diversity, the reverse of what is seen in many other groups of animals and plants. This has been attributed to the lack of a marked seasonality in the growth of plants in the tropics or to a constraint imposed by the high host specificity and short period of time aphids can spend off their host plants searching for hosts. Although there are many species of plants in the tropics, all potential hosts of aphids, few of these plants are abundant enough to sustain a specific aphid. That is, for aphids to be able to survive its host plant has to be relatively abundant. However, other sapsuckers are more diverse, some considerably so, in the tropics. For example, there are 1000 species of Auchenorhyncha in the Panama Canal Zone, whereas there are only 350 species in the whole of Britain.

Ecology

Sapsuckers feeding on the leaves of trees that make up the forest canopy live in 'one of the least explored zones on land.' Obtaining estimates of the abundance of sapsuckers in the canopies of trees, which in the tropics can be very tall, presents considerable technical difficulties. Fogging the canopy with pesticides is often used to obtain such estimates but the accuracy of such estimates depends on the ease with which the insects are dislodged and whether they are likely to be intercepted by other leaves in falling through the canopy. Cranes have also been used to access the canopy and the estimates so obtained are likely to be more realistic and are only limited by the area that can be sampled from the crane.

Such samples show that ants can dominate the biomass of the arboreal fauna of tropical lowland forests. Since ants are largely regarded as predominantly predacious, this pattern challenges the usually accepted pattern of energy flow, in which the biomass of predators should only constitute a proportion of their prey. This has led authors to hypothesize that the availability of homopteran (Coccidae and Membracidae) honeydew provides a key resource for ants. As in temperate regions the homoptera on a particular tree are mostly monopolized by a single ant colony.

In summary, the few data that are available tend to indicate that there are more species of sapsucker in the tropics but they are less abundant than aphids such as the lime or sycamore aphids in temperate regions (**Table 1**). However, until projects with similar objectives and using similar methodologies are undertaken in the tropics and temperate regions these conclusions need to be treated with caution.

Direct Effects of Sapsucker Infestation

As phloem sap contains high concentrations of sugar and very little amino-nitrogen aphids have to process very large quantities of sap in order to obtain sufficient amino-nitrogen to sustain their very high rates of growth. In the case of the giant willow aphid (*Tuberolachnus salignus*), a single aphid consumes the photosynthetic product of 5–20 cm^2 of leaf per day. The annual energy drain imposed on a 14-m tall lime tree by a natural population of the lime aphid (*Eucallipterus tiliae*) is considerable (**Figure 3**). During the course of a year, the population turns over its own standing crop 482 times, or 3.4 times day^{-1}. This is considerably greater than that achieved by oribatid soil mites (38 times $year^{-1}$) and grasshopper populations (10 times $year^{-1}$). Thus although the lime aphid is not particularly effective at utilizing its energy intake, it turns over energy at a massive rate, much of which falls to the ground as honeydew. The annual production of honeydew by the lime aphid is equivalent in energy terms to 0.8 of

Table 1 Estimates of the standing crops of sapsuckers on trees in tropical and temperate forests

Forest	*Country*	*Method of sampling*	*Standing crop/unit weight or area of leaf*		*Reference*
			Number	*Weight*	
Tropical	Panama	Direct	3.4 m^{-2}		Basset (2001)
Tropical	Panama	Direct	3.5–11.8 m^{-2}	5.7–20 mg m^{-2}	Wolda (1979)
Tropical	Puerto Rica	Direct	6–500 kg^{-1}		Schowalter and Ganio (1999)
Temperate	UK	Direct	**Sycamore aphid**		Author's data
			115–742 m^{-2}	85–520 mg m^{-2}	
			508–7364 kg^{-1}	374 mg–5.15 g kg^{-1}	
			Lime aphid		
			150–801 m^{-2}	27.5–143 mg m^{-2}	
			955–7864 kg^{-1}	175 mg–1.39 g kg^{-1}	

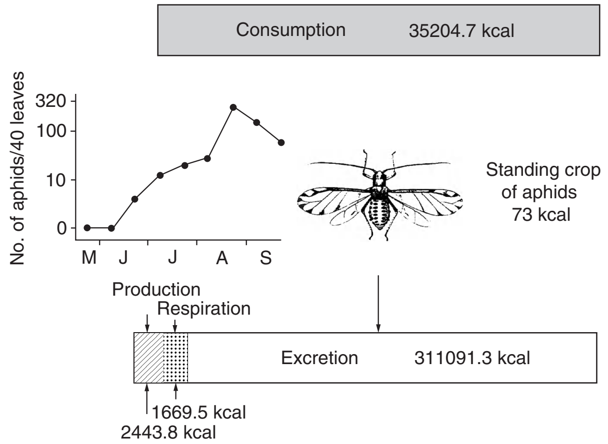

Figure 3 The annual consumption, production, respiration, and excretion, and average standing crop of a population of lime aphids on a 14-m tree, expressed in terms of energy. Inset is a graph of the lime aphid population trend for which this energy budget was computed.

that locked up in the leaves at leaf fall. In the case of the sycamore (*Acer pseudoplatanus*) it is on average equal to the energy in the leaves at leaf fall.

In the presence of the wood ant (*Formica rufa*) the energy drain imposed on sycamore can change dramatically. This ant preys on the sycamore aphid and tends another aphid found on sycamore, *Periphyllus testudinaceus*. In the absence of the ant the sycamore aphid removes approximately three times as much sap from trees than in its presence, whereas the ant-tended species removes 50 times more sap from ant-foraged trees than from unforaged trees. However, the ant-tended aphid on average only removes one-fifth of that removed by the sycamore aphid each year.

Aphid-infested sycamore saplings clearly grow markedly less than uninfested saplings. Although aphids do not affect the number of leaves borne by lime (*Tilia* spp.), oak (*Quercus* spp.), or sycamore, sycamore produces smaller leaves, which contain more nitrogen, when heavily infested in spring. However, the leaf area equivalent to the energy removed by sycamore aphids only accounts for a small proportion of the observed diminution in leaf area. If the drain imposed is expressed in terms of nitrogen rather than energy then aphids again remove far less nitrogen than expected from the reduced size of the leaves. This implies that the effect aphids have on tree growth is not a direct consequence of the energy and/or nutrient drain. Other factors, e.g., the saliva aphids inject into plants, contain physiologically active components that might also adversely affect tree growth.

The width of the annual rings of sycamore is positively correlated with the average size of the leaves, and negatively with the numbers of aphids on the tree throughout a year. This is possibly associated with the fact that each annual ring is composed of two types of vessel, which make up the spring and summer wood. The springwood is mainly laid down when the leaves are developing in spring, whereas the summerwood is mainly laid down after the leaves stop growing. In the absence of aphids some sycamore trees could produce as much as 280% more stem wood. Lime and oak aphids hatch later, relative to the time of bud burst of their host trees, than the sycamore aphid, and as a consequence rarely become abundant before the leaves are fully grown. This is reflected in the fact that the aphids on these trees do not affect the aboveground growth in girth and stem length of their respective hosts. However, infested saplings of lime and oak often weigh less at the end of a year than they did at the start, mainly due to a reduction in the mass of their roots.

Aphid infestation causes early leaf fall in all three species and, in oak and sycamore, results in the leaves becoming a darker green. In oak this is a consequence of a 25% increase in the quantity of both chlorophyll A and B. Associated with this is an increase in dry matter production per unit area of leaf, which in sycamore can be 1.7 times greater in infested than in uninfested saplings. Following years of heavy aphid infestations lime and sycamore break their buds later than usual, and in the case of lime the leaves are smaller and a darker green, and have a net production 1.6 times greater than the leaves of previously uninfested saplings.

Indirect Effects of Sapsucker Infestation

As indicated above, aphids produce large quantities of honeydew, which contains a high percentage of the trisaccharide sugar melezitose. Much of this honeydew reaches ground level, which can result in there being as much as 10 g of sugar per 100 g of soil. This has led to the proposal that trees release surplus sugars by enlisting the help of aphids. This sugar is utilized by free-living nitrogen-fixing bacteria in the soil, which increase in number beneath aphid-infested trees and make more nitrogen available to these trees. Melezitose, or a particular mixture of sugars characteristic of honeydew, is thought to have an optimal affect on nitrogen fixation. The aphids are seen as a necessary ‘part’ of a tree, releasing surplus sugars that promote a better supply of nitrogen.

The addition of the four sugars commonly found in honeydew – fructose, glucose, melezitose, and sucrose – to soil at rates equivalent to those found beneath lime trees infested with aphids causes an increase in the abundance of bacteria in woodland soils. In the laboratory fructose is more effective at promoting nitrogen fixation than melezitose. However, as a single sugar was used rather than a mixture this result does not refute the original hypothesis. In a more rigorous test of the mutualism hypothesis, in which alder aphids (*Pterocallis alni*) were removed from red alder (*Alnus rubra*) by spraying with malathion, aphid infestation resulted in a decrease in ammonification and nitrification in the soil, and a decrease in aboveground primary production. Although this does not rule out the possibility that melezitose may stimulate nitrogen fixation by soil bacteria, nevertheless, contrary to the prediction of the hypothesis, nitrogen availability in the soil is markedly reduced by large quantities of aphid honeydew and there is no positive effect on tree growth.

Much of the honeydew excreted by aphids feeding on the leaves and needles of trees falls on to the upper surface of other leaves where it promotes the growth of sooty molds. In some years these sooty molds blacken the upper surface of the leaves. On pecan (*Carya illinoensis*) these molds can reduce light penetration and photosynthesis by factors of from 25% to 98%. In addition, the darkening of the leaf surface can result in an increase in leaf temperature of 4°C. Epiphytic microorganisms, which include the sooty molds, are one of the most abundant groups of organisms. In areas where there is a lot of industrial pollution rich in nitrogen the limiting resource for epiphytic microorganisms is energy. Increasing the availability of energy in forest canopies in such areas results in a dramatic increase in the abundance of microorganisms (bacteria, yeasts, and filamentous fungi) of two to three orders of magnitude on the needles and leaves of aphid-infested trees. In addition to the changes in abundance there are also changes in species composition, more so on the leaves of beech (*Fagus sylvaticus*) than on oak, probably due to differences in the surface micromorphology of the leaves. In nonpolluted areas the nitrogen and sugar in honeydew are sufficient to stimulate an abundant growth of microorganisms when aphids are abundant on sycamore.

Less well understood are the effects of these microorganisms on throughfall chemistry, which is important because it determines the input of nutrients and ions into forest soils. For example, in June when aphids are most abundant on Sitka spruce (*Picea sitchensis*), the concentration of dissolved organic carbon (DOC) in throughfall collected beneath infested spruce trees is high and declines with the subsequent decline in aphid numbers. There is a very high correlation between DOC concentrations in throughfall and aphid abundance. The concentration of dissolved organic nitrogen (DON) in throughfall increases after the aphid population peaks and starts to decline in abundance. Concentrations of inorganic nitrogen are lower in throughfall collected beneath spruce heavily infested with aphids compared with uninfested trees but it becomes similar as the aphid numbers decline.

Field experiments show that following a high input of DOC from the canopy there is an increase in the DOC concentration in forest soil solutions, which is slightly delayed and longer-lasting than the aboveground aphid infestation. Similarly, there is an increase in the concentrations of DON and NO_3-N in the forest floor solution beneath aphid-infested trees. Laboratory experiments, in which simulated artificial honeydew is applied to cores of forest soil, reveal that low to medium inputs of honeydew increase base respiration within 1 h and cause a decline in NH_4-N fluxes. Large inputs of honeydew increased the immobilization of both NH_4-N and NO_3-N and slightly reduced DON fluxes. The DOC fluxes increase considerably but decline to base level within 72 h of applying the honeydew. That is, inorganic carbon from aphids in throughfall affects the mineralization, mobilization, and transport of organic matter in forest soils.

In conclusion, we are only just beginning to record the species and abundance of sapsuckers present in the canopy of forests, especially in the tropics. Nevertheless, they appear to be more species-diverse in this habitat in the tropics than in temperate regions but in terms of total biomass they are possibly more abundant in the temperate regions.

In temperate regions sapsuckers, in particular aphids, greatly reduce the growth of trees, whereas their honeydew encourages the growth/activity of epiphytic and soil microorganisms. This is in addition to their being an abundant source of food for insectivorous birds and the hosts and prey of various insect parasitoids and predators. That is, in spite of being relatively inconspicuous, sapsuckers possibly have a 'keystone' role in determining the community structure of temperate forests.

Bark Beetles

M L Reid, University of Calgary, Calgary, AB, Canada

Bark beetles are small, dark, cylindrical beetles, usually less than 7 mm long. As their name implies, they are usually associated with woody plants. Despite their small size and modest appearance, they have an intriguing assemblage of feeding and breeding habits, some of which result in significant economic losses to forest and agricultural industries. This article reviews the taxonomy, life cycle, host–plant interactions, and ecosystem consequences of bark beetles, concluding with management options.

Taxonomy

Bark beetles have commonly been considered a family, Scolytidae, but recent taxonomy places them as a subfamily, Scolytinae, within the weevil family Curculionidae. Major characteristics that are shared with weevils include elbowed, clubbed antennae, larvae that feed within plant tissues, and the loss of the development of legs in larvae (**Figure 1**). The Scolytinae and closely related Platypodinae differ from typical weevils in their oviposition behavior: adults bore deeply into plant tissues to oviposit, while typical weevils use their elongated rostrum to create egg niches from the surface of the plant. Many of the Scolytinae do not actually breed in bark, as discussed below, but the common name 'bark beetle' is applied to this whole taxonomic group.

Bark beetles comprise approximately 6000 species, found worldwide. Their origin was in the Cretaceous, with an early association with the ancient conifer *Araucaria* distributed across Gondwana. Subsequent diversification into tribes and subtribes has occurred in North America, South America, Eurasia, and Africa. About 30% of extant genera are temperate in distribution.

Life Cycle

Upon arrival at a host plant, adults quickly begin to burrow into the plant to breed. Several species are known to histolyze their wing muscles upon arriving at breeding habitat. The sex that initiates a breeding site, the pioneer sex, differs among species. In many species, the beetle initially constructs a nuptial chamber where mating will occur (**Figure 2**). Many species emit pheromones at this stage that attract the opposite sex but also others of the same sex. When both sexes are attracted, the pheromones are called aggregation pheromones, and they result in a rapid colonization of the surrounding plant tissues. Such aggregation is a notable feature of bark beetles. Many pheromones are derived from precursors in the plant tissues, especially defensive compounds such as monoterpenes. However, the same pheromones can sometimes be synthesized *de novo*, or be produced by associated microbes. The link between plant defenses and pheromones means that pheromones can indicate the state of the tree to other beetles, which is especially important for those beetle species that

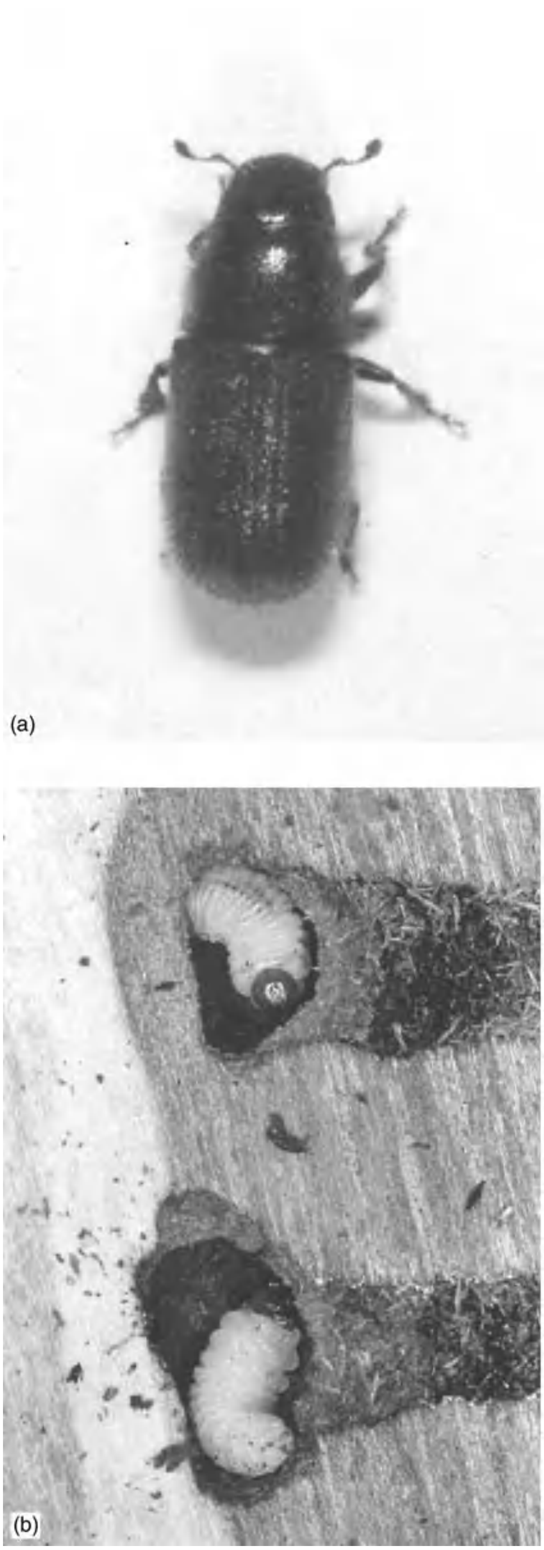

Figure 1 Douglas-fir beetle, *Dendroctonus pseudotsugae* (Hopkins): (A) adult; (B) Larvae. Courtesy of MM Furniss.

breed in live trees that they must kill. Aggregation pheromones diminish once an individual is established and mated. In some species, antiaggregation

Figure 2 Exposed egg galleries of pine engravers, *Ips pini* (Say), within the phloem of lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann. Typical of a polygynous species, several egg galleries radiate from a central nuptial chamber. Some larval galleries are visible extending perpendicularly from egg galleries. Courtesy of ML Reid.

pheromones are subsequently produced by one or both sexes.

Bark beetles have a fascinating diversity of breeding systems, including monogamy, polygyny, inbreeding polygyny (often associated with haplo-diploidy), and parthenogenesis. Monogamy and polygyny are clearest when males initiate breeding sites, with a species-typical number of females sharing the same nuptial chamber. Males contribute by removing debris produced by tunneling females and guarding the entrance against predators. Males may remain for some or all of the oviposition and larval development periods. When females initiate the breeding site, there is generally only a single female per nuptial chamber (monogyny), but males generally depart early in oviposition and may mate again elsewhere. In these outbred systems, mating generally occurs after dispersal at the new breeding site. In inbreeding polygyny, mating occurs between brothers and sisters at the natal site. Here the sex ratio is female-biased, usually achieved with haplo-diploidy, and males are dwarfed and flightless. These species commonly breed in xylem or seeds rather than phloem. Another variant of breeding system in bark beetles is pseudogamy, in which triploid females mate but only produce daughter clones.

Females tunnel through the tissue, and create orderly, characteristic egg galleries that generally extend linearly from the initial entry point, either parallel or perpendicular to the grain of the wood (**Figure 2**). In many genera, eggs are laid in individual niches along the sides of the egg galleries. Phloem-feeding larvae tunnel perpendicular to the egg galleries, while fungal-feeding larvae feed communally in chambers. Larvae progress through three to four instars before pupating, all within the host tissue.

Generation times depend largely on temperature, though also on feeding substrate and body size. For example, within North America, the southern pine beetle, *Dendroctonus frontalis*, a 3-mm beetle that breeds in the southeastern USA, may have eight generations a year. In contrast, the spruce beetle *D. rufipennis*, a 7-mm-long beetle breeding in northwestern Canada and Alaska, may take 2 or 4 years to complete a generation. Because the quality of the breeding substrate generally declines substantially over the course of offspring development, in part due to larval feeding, each generation typically disperses to a new breeding site. Parental adults may reemerge within a breeding season, after regenerating their wing muscles, and disperse to a new breeding site. The extent to which parent beetles successfully overwinter after breeding is unclear.

Host Plants

Evolutionarily, bark beetles appear to have originated in conifers, and many of the most conspicuous and economically important species breed in conifers. However, most bark beetle species (approximately 80%) breed in angiosperms.

As their name suggests, many bark beetles breed within the inner bark (phloem) of tree boles or branches. While these species are often the most important economically, phloem-feeding is characteristic of fewer than half of all bark beetle species. More commonly, bark beetles develop within tree xylem where they feed upon symbiotic fungi (xylomycetophagy). Such species are termed ambrosia beetles. Phloem-feeding species are characteristic of temperate environments (over 80% of temperate species), while ambrosia beetle species are numerically dominant in the humid tropics. Less common feeding and breeding substrates include the roots or stems of herbaceous plants, the pith of small stems, and seeds.

For species that breed within bark, host tree species are usually within a single genus. Ambrosia beetles often have a broader host range, likely because xylem is not as chemically distinctive as phloem, and because the beetles feed primarily on fungi rather than the tree itself.

Colonizing Host Plants

Bark beetles find their host trees primarily by chemical cues. These cues may come from trees themselves (tree kairomones), and may include both host volatiles to which beetles are attracted (primary attraction) and nonhost volatiles that deter beetles. The scale at which these cues operate is unclear. The proportion of host and nonhost volatiles may influence the distribution of bark beetles across the landscape (i.e., among stands). The problem of detecting an individual host tree that is suitable is more difficult, requiring finer chemical and spatial resolution. Conifers of different genera share many volatiles, and odor plumes from individual trees may be readily mixed depending in part on stand density and wind. The visual acuity of bark beetles is relatively poor. As a consequence, the range of detection of an unoccupied, suitable tree may be at the scale of centimeters. While one species of bark beetle has been shown to recognize tree suitability in flight, it appears that beetles of other species must actually land on a tree, and even consume part of it, to determine its suitability. Such a search process may be very time- and energy-consuming, and many species of bark beetles also respond positively to volatiles produced by breeding conspecifics (pheromones). This is true for species that colonize either dead or living host trees.

Bark beetles have several strategies for coping with plant defenses against herbivory and disease. The most common strategy is to colonize trees that are poorly defended, often because the tree is dying or severed from its roots. Such beetles are termed secondary species, since they are not the primary cause of tree death (e.g., *Ips* spp. in North America). Population sizes of secondary species correspond to the availability of poorly defended trees, sometimes increasing to significant numbers following extensive drought or large windfall events. At high numbers, these species may attack healthy trees, but even here there is evidence that trees that are attacked have been growing more slowly than average.

Of greater economic significance are those bark beetle species, termed primary species, that regularly attack healthy trees. The best known of these feed on phloem in conifers. Two attributes are key to the success of primary feeders against a defended tree: mass attack and symbiotic fungi. Mass attack is the arrival of large numbers of beetles at a tree over a few days. The synchrony of attack is important because trees not only have constitutive defenses, present before any attack, but also induced defenses where additional monoterpenes and oleoresin are synthesized around the site of an attack to kill or deter a pioneer attacker. To overwhelm the tree's capacity for defense, high attack densities are required. Thus the optimal attack density (maximizing an individual's reproductive success) may range from 20 to over 240 attacks per square meter, depending on beetle species and presumably on the vigor of the host tree. In contrast, the optimal density for beetles breeding in undefended hosts may be one individual in an entire tree.

Symbiotic fungi may be important to successful colonization of live trees, especially conifers, but their role is not entirely clear. Their evolutionary significance is indicated by special invaginations on the integument of adult beetles, called mycangia, in which particular species of fungi are carried. Among phloem-feeding beetle species, mycangia are most commonly found in species that kill trees. Interestingly, these mycangia occur at different places on different beetle species, including near the mandibles and in the thoracic pleural area. (Not surprisingly, many ambrosia beetles that feed on fungi also have mycangia.) In the temperate phloem-feeding bark beetles, the symbiotic fungi are usually ascomycetes within the genus *Ophiostoma*. Many, but not all, of these fungi stain the xylem blue, which diminishes the value of wood esthetically, though not structurally.

Mycangial fungi in tree-killing beetles species have been held responsible for early tree death that allows the beetles to breed, but this view has been disputed. The fungi penetrate and plug the vascular tissue, and their toxins may also adversely affect water relations and resin flow. However, mycangial fungi are found to be weakly pathogenic, and may spread into the vascular tissue after beetles are already established and breeding. Moreover, trees have been killed by primary bark beetles in the absence of these fungi. Thus it appears that the fungi may contribute to tree death, but high-density beetle attacks are also required. Additional benefits of fungi may be improved food quality, limitation of less beneficial fungi, and chemical communication. These latter benefits would also apply to secondary bark beetle species, but these species generally do not have mycangia.

Factors Limiting Population Growth

Although many bark beetles aggregate at breeding sites, individual reproductive success declines exponentially with breeding density in the absence of initial tree defenses. Part of this reduction can be attributed to changes in the oviposition behavior of females in response to density, such as by reducing egg density or the length of egg galleries. However, there is also competition where resources per larva are reduced by consumption of phloem or faster deterioration of heavily mined phloem. Cannibalism has also been reported. Offspring that do survive are usually smaller and have less fat when density is higher.

Mortality of bark beetles within their natal tree is often remarkably high, with fewer than 5% of eggs resulting in adult offspring (**Table 1**). As just mentioned, part of this mortality may be attributed to competition, but this is often difficult to identify directly. Host quality may significantly affect the survival of offspring from egg through to emergence.

Natural enemies are also an important source of mortality within the natal tree. Woodpeckers are an obvious predator of bark beetles, but usually have a minor impact on bark beetle survival (**Table 1**). Insect predators and parasites can cause substantial mortality, based on studies using exclusion cages (**Table 1**). Parasitism, a distinguishable source of mortality, varies widely in intensity (**Table 1**). Predation by insects generally leaves a poorer record. Some species of clerid beetles (Cleridae) are bark beetle specialists that detect bark beetle pheromones, arriving in large numbers, along with bark beetle colonizing trees. Adult clerids consume adult bark beetles on the surface of the bark while their larvae consume larval bark beetles. Consumption by adults reduces the number of beetles successfully colonizing by as much as 50% under realistic experimental conditions. Clerid larvae consumed about 10% of *Ips pini* larvae in one experiment. Clerids may determine the dynamics as well as the size of beetle populations (**Figure 3**). For example, clerids have longer development times than their bark beetle hosts, potentially resulting in a lag effect that can result in cyclic population dynamics (*see* **Entomology**: Population Dynamics of Forest Insects). They may also disperse differently than their hosts, causing patchy spatial distributions of bark beetles.

Dispersal between natal trees and breeding sites is also a significant source of bark beetle mortality. As mentioned, the breeding habitat of many bark beetles is no longer suitable after one generation, requiring dispersal every generation. Suitable hosts are typically rare, particularly for those bark beetles species relying on trees lacking defenses but with undeteriorated tissues, such as windfalls. While dispersal mortality cannot be observed directly, estimates from equilibrium population models and changes in sex ratio between emerging and breeding beetles suggest that more than half of beetles die during dispersal (**Table 1**). This is despite the ability of many species to fly 40 km or more.

Abiotic factors can also severely affect the success of small ectotherms such as bark beetles. Of these, temperature is fundamentally important. At higher latitudes and altitudes, temperatures may drop to lethal values over winter despite the cold-hardiness of bark beetles in these environments. For example, protracted temperatures of *c.* −40°C at unseasonable times of the year are an important contributor to the collapse of mountain pine beetle (*D. ponderosae*) populations (**Figure 3**). Cold-hardened larvae experienced 80% mortality at −34°C, compared to 27% mortality at −12°C. Temperature also influences reproductive rates in many ways. Dispersal in many temperate species is limited to temperatures above 16°C and below 40°C. Oviposition and larval development are also temperature-dependent processes. The

size and fat content of adults are negatively related to temperature during development, presumably influencing future dispersal and reproductive success. Temperature also determines the rate of phloem desiccation and perhaps fungal growth, indirectly influencing bark beetles through food quality.

Ecosystem Processes

The contributions of bark beetles to community and ecosystem processes, such as succession, fire, and decomposition, have not been well quantified. Bark beetle species that kill large numbers of mature trees are likely to have the largest effects on many of these processes.

Fire

While a high density of dead trees, caused by bark beetles, would seem to increase the risk of forest fire, this relationship has not been well established empirically. One study in Yellowstone National Park (Wyoming, USA) observed that severe pre-fire bark beetle damage was correlated with increased risk of crown fire, but the reverse was true when damage was moderate. Risk of fire will likely change with time after a beetle outbreak, because of changes in tree moisture, abundance of fine fuels, and responses of the understory plant community. It is possible that stands with large numbers of beetle-killed trees may actually have a reduced risk of fire. Once a fire has started, fallen trees killed by bark beetles may increase heat intensity around them, increasing consumption of organic matter in soil.

The effects of fire on bark beetles are better studied. For beetles already breeding in trees that are subsequently burned, reproductive success is reduced. However, because of the insulative properties of bark and the mass of the tree bole, and the occurrence of beetles over most of the tree bole, fires need to be intense to cause significant mortality. After a fire, burned trees may attract bark beetles both to the area and to particular trees, although the reverse has also been observed. The difference in response may be related to whether the bark beetle species are primary or secondary species. Successful attack of individual burned trees varies with tree species and the severity of burn. Resin response may either increase or decrease in burned pine trees, depending on species. Some species avoid scorched bark while others are limited to these areas.

Forest Succession

Because tree-killing bark beetle species attack dominant trees within one host genus, they have the potential of altering forest composition and the rate and routes of succession to the canopy. Not surprisingly, subcanopy trees show increased growth rates following a bark beetle outbreak. Whether this results in a change in the species composition in the canopy depends on the species composition in the subcanopy and their relative responses. In one outbreak where half of the spruce trees were killed by bark beetles, there was no significant change in tree species composition.

Decomposition

Bark beetles are expected to hasten decomposition because they penetrate the wood material and are vectors for many species of fungi, but few studies have tested this. Douglas-fir beetles, *D. pseudotsugae*, had a small effect on log decomposition after 10 years, with wood borers contributing much more. Decomposition of spruce in Finland, as measured by percentage mass loss over 30 months, was positively correlated with the number of beetle attacks, although the difference in mass loss between logs with and without exposure to beetles was not large.

Management Options

Bark beetles that kill mature trees have many negative economic impacts. If the tree had been intended for timber, it remains usable for only a year or two after death before it becomes fractured. Discoloration by blue-stain fungi reduces the value of the wood for esthetic purposes. Penetration into sapwood by ambrosia beetles can reduce the structural and esthetic value of the affected area of wood. When outbreaks result in millions of trees being killed simultaneously, increased salvage harvesting may depress prices, and disrupt harvesting plans and expected future yield. The potential loss of individual trees valued by people also prompts management actions.

Management of bark beetles affecting trees includes three approaches. These are: (1) killing beetles directly; (2) manipulating beetle movement using semiochemicals (pheromones and kairomones); and (3) stand and landscape management to prevent increases in beetle populations.

Killing bark beetles is difficult because most of their life cycle is spent within plant tissue. For individual beetle-infected trees, it is possible to kill beetle broods by applying insecticides that are conducted through the tree's vascular system to the developing broods (e.g., monosodium methanearsenate). An interesting biological approach is to attract less aggressive but faster-developing bark beetle competitors into trees colonized by pest species. However, these individual tree treatments are not practical on a large scale. Small groups of trees may be felled and either debarked or burned. Infested stands may be harvested or burned with prescribed fire although, as noted above, fire may not kill most beetles. When stand removal is prescribed, beetles can be lured into the stand using semiochemicals to maximize the number of beetles removed. A difficulty with any plan to remove beetles in trees is that the presence of beetles may be hard to detect, as trees may not show obvious signs of attack until broods are well developed or already emerged. Consequently, experienced surveyors are required on the ground to assess beetle populations.

For some species of bark beetle, large numbers of beetles can be removed by using traps baited with semiochemicals, especially pheromones. To minimize the number of predators that are also captured, small discrepancies in the chemicals that are maximally attractive to bark beetles and their predators can be exploited. Mass-trapping is simple and inexpensive to implement once the baits have been developed, but it is difficult to assess how much the population is reduced, since many dispersing beetles fail to establish in trees anyway. In addition, the baits may attract high densities of beetles into a local area, increasing the risk that trees around the baited traps will be successfully attacked (spillover). Consequently, it is often recommended that the baited traps be placed far from host trees. An alternative approach is to use baited trees as traps (trap trees); these tend to be more attractive than baited traps initially, but then become unattractive once saturated with beetles, minimizing the risk of spillover. More effort is required to dispose of the trap tree to prevent beetle emergence than for pheromone traps.

Manipulation of beetle search behavior is an approach that takes advantage of bark beetles' reliance on chemical cues for host selection and mate finding. Beetles can be deterred from settling on trees, or even in stands, by conspecific antiaggregation pheromones, pheromones of competitor bark beetle species, or nonhost volatiles. For species that require high densities of beetles to overcome tree defenses, even some deterrence might allow trees to defend against beetle attacks.

A preventive approach to bark beetle control is to manage stands and landscapes to prevent the development of large beetle populations. However, by definition, pest species use trees that people want, so any plan to make host trees difficult for beetles to find will usually compromise the economy of harvest. Indeed, many bark beetle species have become pests because their host plants have been planted in monocultures, reducing dispersal mortality. It is possible to manage the risk of beetle attack by predicting when a stand is likely to be at risk, and taking action at that time. Risk and hazard rating systems are based on stand conditions (e.g., tree size, age, density, physiography) and on current beetle population size. Beetle population size can be assessed by surveying the number of trees recently killed in the area, by assessing the success of broods, and by monitoring baited traps.

A preventive method widely used to control mountain pine beetles (*D. ponderosae*) is stand-thinning. The mechanisms by which this method works are unclear, but may include increased vigor of remaining trees and a less favorable microclimate of thinned stands (warmer and windier). Some studies of thinning, focusing on other bark beetle species, have found no effect or a positive effect of thinning on beetle populations. If thinning is conducted on mature stands, costs of this approach include increased tree damage due to wind sway and wind throw, as well as the requirement to enter the stand multiple times. Thinning is therefore not an approach to be implemented indiscriminately.

Environmental Impacts

P Maclaren, Rangiora, New Zealand

Introduction and Definitions

There is considerable debate over definitions for the word ‘forest’ and even for ‘tree.’ Most vegetation types fall clearly into the categories of forest or nonforest, but there is dispute at the margins. The following are contentious questions:

- Does ‘forest’ apply to a type of land cover, or to a type of land use? (An apple orchard, for example, may consist of a high density of trees but is not normally considered to be forest, whereas areas of bare land in the phase between clearfelling and replanting are normally included as forest.)
- At what height is a woody species classified as a tree? Does this vary with the age of the plant?
- At what proportion of ground cover do trees collectively form forests? (For example, do widely spaced trees in the African savannah or Australian outback constitute a forest? Do heavily tree-lined cities constitute forests?)

A similar debate rages over the classification of forests into natural and artificial types. On the one hand, we could say that totally natural forests do not exist. There is probably not a single hectare of the earth's surface that has not been modified to some extent by human activity. In some parts of the world, hominids have been a part of the ecosystem for perhaps a million years, often using fire or browsing mammals. Peoples have introduced new species or eliminated species from every land mass, and have even modified the air (which provides a tree with its most important nutrient by weight – carbon). On the other hand, even a 'monocultural' and monoclonal plantation contains a surprising variety of adventitious species and cannot be said to be entirely artificial.

There is widespread public enthusiasm for natural forests, with ever-increasing pressure for their protection and enhancement. The environmental benefits of such forests are well recognized. This contrasts with the opprobrium that is often directed towards commercial plantations. Whereas 'natural' forests tend to be as complex as the climate and soils allow, the profit motive forces managers of plantations into greatly simplified forest systems. In order to minimize costs, and to maximize timber revenues, single commercial timber species are favored. These are best grown in large stands of homogeneous age, and managed in a way that provides a uniform and consistent industrial feedstock. In many nations, it is acceptable to grow horticultural or agricultural crops in large monocultural blocks, but – strangely – public attitudes change where the harvest product is stemwood rather than fruit.

The awe of the natural forest, and the emotional opposition to the artificial version, have spawned a set of beliefs about the negative environmental impacts of the latter, which are often based on prejudice, rather than on demonstrable fact. That said, even groundless fears have a political reality that foresters ignore at their peril.

Effect on Soil

The sustainable productive potential of a soil often cannot be discussed without specifying the intended land use. Thus 'soil quality' is a subjective term. It seems likely that persistent plant species modify the soil to a condition that ensures their long-term survival. Certain species of tree are said to be 'soil improvers' because subsequent agricultural crops grow better, and because the deep topsoil consists of well-mixed organic matter (mull), as in typical agricultural soils. Other tree species are said to be 'soil deteriorators' because they result in – or are found on – soils with a clear separation of surface organic matter from the underlying mineral substrate (mor). The latter appears to be an evolutionary mechanism for the forest to minimize nutrient loss, by controlling (by means of mycorrhizal associations) the decomposition of organic matter.

Given that a mor-type forest contains most of its nutrients in the biomass and relatively undecomposed forest floor, if it is subjected to persistent fire or removal of the forest duff (for fuel, fertilizer, or animal bedding), then it will certainly become less productive over time. It is very often the case that certain forest types gained the reputation for being soil deteriorators because of human extraction of such nutrients.

It is possible (although not satisfactorily proven) that trees can extract nutrients from deep roots and bring these to the surface via litterfall. This could be one reason for the observed boost in agricultural production following a forest cover. Such a boost can even be noted in much-maligned plantations, including those with eucalyptus and conifers. A common criticism of coniferous plantations is that they acidify the soil and create an environment unsuitable for earthworms. Charles Darwin did some excellent work establishing the worth of earthworms in agriculture, but his observations are not necessarily relevant to forestry. Forests develop their own soil fauna that is more appropriate to forest conditions. The slight acidification noted for conifers could be a device to prevent nutrient leaching and ensure controlled nutrient recycling. It is not a permanent effect, as the pH seems to bounce back after removal of the trees. By means of acidification and mycorrhizal action, anions (nitrogen, phosphorus, sulfur) under such trees can be more plant-available than in similar soils that have not experienced a forest cover.

Sustainability of the soil resource is largely determined by the balance of inputs and outputs of key elements. There are losses into the groundwater (i.e., leaching, under the action of rain or irrigation), and losses to the air (i.e., volatilization, often by burning). There are also losses via human removal of agricultural or forestry products. Inputs can come from: biological nitrogen fixation; aerial deposition; and breakdown of the mineral substrate by weathering, possibly stimulated by plant or mycorrhizal exudates. They can also come from deliberate fertilization.

The huge quantities of wood often extracted from a forest may provoke the comment that the land is being 'mined' of significant amounts of essential elements. This ignores the fact that wood differs from many other rural products. Wood consists predominantly of carbohydrates (cellulose, hemicellulose, and lignin), which are predominantly made up of carbon, hydrogen, and oxygen – these elements comprise more than 99.7% of the oven-dry weight of stemwood. They come from rainwater and carbon dioxide, with minimum contribution from the mineral soil. In contrast, products that contain foliage or fruit, or derive from an animal, can be rich in nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium. If such elements are not replaced with fertilizers (organic or mineral), excessive exploitation of the land can easily 'mine' the soil.

To summarize: it is incorrect to state categorically that afforestation – even with monocultural conifer plantations – will cause soil deterioration, without defining what is meant. Soil from such plantations can produce higher yields of subsequent crops than adjacent, unplanted land. Nutrient levels, even in a highly exploited forest, need not decline provided that nutrients are replaced. Furthermore, the debate over soil deterioration can be somewhat academic if the main regional concern is the massive removal of topsoil via soil erosion. If soils are stripped down to the parent rock, this must be ultimate form of soil degradation.

Forests play a vital role in mitigating erosion in most of its dozen forms. Soil erosion is a major global problem, which occurs naturally but has been exacerbated by human actions. It is caused by wind, rain, or mechanical damage (e.g., plowing or livestock pugging (compaction and loss of soil structure in a clay soil)). Trees reduce wind speeds at ground level and thereby reduce wind erosion. They maintain the soil in a drier state, thus minimizing its mobility. Critically, they bind the soil together with their strong, interlocking and relatively deep roots. Erosion rates from mass wasting are typically 10 times lower in forest compared to, for example, pasture.

Effect on Water

There are more misconceptions related to the interaction of trees and water than to any other aspect of forestry. These myths are so widespread that they seem to have formed a self-sustaining body of belief, without recourse to empirical evidence. It is not true, for example, that – in some mysterious way – trees attract or even cause rain, resulting in abundant river flows. Rain is the result of the sun warming the planet and evaporating water, mainly from the oceans. Moisture-laden air masses are driven across the land by winds that would occur even if the earth were devoid of trees. Rain falls when the air cools, for example by rising over a mountain range. Trees affect the albedo (reflectivity) of the earth's surface, but this is not believed to be a major influence in planetary circulation patterns. Having said that, the presence of trees does maintain atmospheric humidity (by means of evapotranspiration). In other words, part of the rain that would have fallen to the ground and entered the groundwater is returned to the atmosphere by trees, and is available to enhance rainfall elsewhere. So, although forests do not greatly influence the total quantity of atmospheric water moved from the ocean to the land, they may well affect the quantity and distribution of rainfall on that land.

The effect of trees in a particular catchment is to reduce the yield of water, not to enhance it! Two effects cause this: interception and transpiration. Interception is where the rain wets the canopy and does not reach the ground. Readers will remember when they have stood under trees in a light shower and remained dry. Short vegetation (e.g., grass) also intercepts rainfall, but there is a critical difference: tree canopies readily evaporate the water, even during rain. Grass stays wet. This means that the trees are constantly intercepting and reexporting rain, whereas the first shower wets the grass and the second can penetrate to the ground. The reason why grass evaporates less water than trees is because it is shorter, and there is less wind at ground level. It is not a coincidence that people hang out their washing to dry on lines high above the ground!

Transpiration is the second way that trees reduce the water in a catchment. Plants have holes (stomata) beneath their leaves that allow the absorption of carbon dioxide from the air. These also permit the escape of moisture, which has been conducted upwards from the roots. When conditions are dry, plants close their stomata and moisture loss is minimized. This applies to both trees and to short vegetation, but the difference is that trees usually have deeper roots. Long after grass has closed its stomata and stopped transpiring, trees will continue to pump water from deep soil horizons. A light rain will recharge the water in the grass-covered soil, but it will require heavy or persistent rain to do the same for the forested soil.

The myth goes that 'forests act like a sponge, soaking up water during wet periods and releasing it slowly during dry periods.' A home experiment can soon confirm that even sponges do not work in this way: large pores release their water within minutes, under the influence of gravity. In smaller pores, capillary action is stronger than gravity and the water is not released. In soil, water in such micropores can be removed only by movement towards, and evaporation from, the surface or by active uptake by roots. Very small pores contain water that is inaccessible even to roots. Decreased water flow as a result of afforestation can be expected at all times of the year. So can forests act as a buffer, smoothing out flood peaks? That depends.

It is easy to observe that a bucket of water poured on to the forest floor usually penetrates quickly. Holes left by dead roots and gaps around living roots may provide the mechanism for rapid and deep infiltration. In contrast, water poured on to a bare or grass-covered soil may run along the surface for a considerable distance. Often, the soil may have been baked hard by the sun or compacted by grazing animals. Therefore we would expect that it would take longer for rain to reach the river in a forest, where it has to filter through the soil, than it would in a pasture, where much of the water flows overland. This has often been observed experimentally, but it is not always the case. In a heavy and prolonged downpour, the interception capacity of a tree canopy is quickly overwhelmed. The soil becomes saturated and instant penetration of water under the forest merely results in instant discharge along the riverbank – if a hosepipe is full, turning on the tap results in immediate release of water from the nozzle.

Another complication is that, while improved infiltration rates under trees may smooth flood peaks in small storms and small catchments, this does not usually occur in large river systems where the worst flooding damage takes place. As a storm passes over a large catchment, the rainfall peaks at different times in each tributary. Moreover, it can take many hours or days for the flood peaks from the mountainous headwaters to pass down the river and coalesce in the main channel. By this time, the smoothing effects attributable to the forest have all but disappeared. In short, the direct benefits of forestry for flood control have been grossly exaggerated. It is important to remember, however, that a major cause of flooding is the restriction in the cross-sectional area of river channels caused by upstream soil erosion. Forestry is highly important in this regard.

The lowering of water tables following from afforestation has at least one desirable side-effect: it can prevent and even (in nonchronic cases) reverse salinization. Salt is common in deeper horizons of soils that have not evolved under conditions of high rainfall. Irrigation has enabled crops to be grown in many drier parts of the world, but poor irrigation practices can allow this salt to migrate to the surface, by means of persistent soaking which dissolves the salt and distributes it throughout the soil profile. When the water evaporates from the surface the salt crystallizes out of solution, eventually creating conditions unsuitable for cropping and – in extreme situations – salt pans. Even in the absence of irrigation, salinization is a common result of deforestation and establishment of pasture. It may take many years of flushing by rainfall to lower the topsoil salt levels to a stage where trees can successfully be reestablished and the water table can be lowered by such means.

There is no doubt that freshwater is a scarce and underrated resource in many parts of the world, and that individual catchments will generate more usable water if they do not have a forest cover. But water quality is also important. Water that is polluted by salt, sediment, pathogens, or nutrient run-off is not as useful as clean water. Planning authorities, in a difficult balancing act, must ensure that river flow is maximized but water pollution is minimized. One way to do this is to afforest only the riparian areas. Water reduction from a forest cover depends on the proportion of the catchment that is forested, whereas water pollution is caused mainly by humans and animals having direct contact with the waterway.

The reason why human pathogens (viruses, bacteria, plasmodia, etc.) are more likely to be found in agricultural – as opposed to forestry – catchments is that many domestic mammals share the same intestinal diseases. The reason why polluted water normally has low transparency is that it is either filled with sediment from erosion, or with microorganisms fertilized by nutrient runoff. Enhancement of aquatic growth at first glance may be seen as beneficial to the environment, but there are usually negative impacts. Algae commonly excrete toxins, and when they decay they extract oxygen from the water (eutrophication), making it unsuitable for fish. The major plant nutrients are nitrogen and phosphorus, and while it is sometimes possible to keep the less-soluble phosphorus away from waterways, nitrogen is a more intractable problem. Nitrate salts are highly soluble and once they find their way into groundwater they can quickly bypass or overwhelm any barrier, such as riparian strips. To counteract the nitrogen via natural means usually requires filtration through a high-carbon medium, such as peat swamp. Nitrates and nitrites are often considered a health hazard in drinking water, although the evidence for this is not convincing.

Arguably, pollution of rivers is not as serious as pollution of lakes and aquifers. Whereas, if the source of pollution is removed, rivers can flush themselves clean within weeks, pollutants can persist in lakes for decades. Aquifers may contain water that fell as rainfall thousands of years ago, and it is most important to ensure that activity at ground level (including livestock farming) does not contaminate this valuable heirloom.

A major source of river pollution is siltation, often caused by deforestation in steep headwaters. As well as blocking the river channels and causing flooding, the sediment can cause major problems when it enters hydroelectric dams or the ocean. Siltation limits the useful life of many dams to a few decades, and silt particles rapidly erode the turbines. Deforestation can be the direct cause of siltation of harbors and decline in certain fisheries.

Effect on Air

It is now common knowledge that there is a connection between forestry and the enhanced greenhouse effect, but there is still considerable public confusion on the details. The concentration of atmospheric carbon dioxide (CO_2) has been rising for the last century, leading to the concern that it will cause global warming. The evidence is overwhelming that the increase in CO_2 is human-induced: the cause is both combustion of fossil fuels and deforestation (historically, one-third, but becoming less important). It is easy to imagine how burning coal – or burning a forest – could increase the atmospheric levels of the main combustion product, carbon dioxide. Why then is it so difficult to comprehend that establishing a forest is merely the reverse of this process? Deforestation puts carbon into the air, afforestation removes it from the air, but the mere maintenance of an existing forest usually has no net effect.

The process of photosynthesis has been understood for a long time. Plants use the energy of sunlight to combine water and carbon dioxide (obtained only from the air, via the stomata) into sugars. Oxygen is released as a byproduct. Half the dry weight of wood or other biomass is carbon, and therefore a forest represents a considerable amount of carbon that is not available to cause global warming. Whereas all green plants photosynthesize, only forests and swamps accumulate carbon to any great extent. It is conceptually simple to examine an ecosystem such as pasture or forest, and to observe the quantity of carbon it contains. Above knee-height, anyway, it is undeniable that a forest contains more carbon than a pasture, and that conversion of the pasture to the forest will result in extraction of atmospheric carbon. Because CO_2 is present in such small concentrations (0.036% of the atmosphere), the removal of approximately 100 tonnes of carbon per hectare by means of forest establishment has a major influence. Such afforestation could strip the air of all its carbon in an area six times the size. In contrast, the effect on oxygen is insignificant. It is often said that 'forests are the lungs of the planet' and provide us with our oxygen, but this is a gross exaggeration. If all the atmospheric carbon were removed by trees (an impossibility), this would increase the concentration of oxygen by only 0.036% from its existing 21%.

Once the forest has been established, it is not obvious whether this ecosystem is a sink (has more inputs than outputs), a source (the opposite) or merely a carbon reservoir (contains carbon but is not necessarily a sink or source). Forests consist of trees of all ages and sizes, and while all growing trees are individually sinks, the whole forest may not be a sink. Carbon is lost by the decomposition of biomass or by extraction of woody material. Over the long term, we can say that forests are not carbon sinks, because if they were to gain (say) only 1 t per hectare per year of carbon, then after 1000 years there would be an extra 1000 t. This would be clearly visible to the naked eye, and would not need sophisticated measurement.

The role of wood products in the global carbon cycle is also a cause for confusion. Wood products are carbon sinks only if the stock of such carbon is increasing every year. This may be the case, but it would be a trivial quantity. More important is the role of wood as a substitute for materials, such as steel, aluminum, concrete, and plastics that require large quantities of fossil fuels to manufacture. CO_2 emitted from burning wood is considered 'carbon-neutral' because it is merely recycled atmospheric carbon rather than additional carbon from beneath the earth's surface.

Effect on Wildlife and People

The main difference between forests and other terrestrial ecosystems is that trees have a more pronounced vertical component. In terms of the volume of space bounded by the ground and the top of the canopy, forests contain considerably more volume than all other terrestrial ecosystems combined. Within this space, there are many biological niches and an abundance of plant and animal wildlife can develop. These species are interesting because they add variety to the world, and because some of them can be useful to humans.

Just as in that other three-dimensional biospace – the oceans – the base of the biological pyramid is photosynthetic plant life. The primary productivity of the forest understory or the deeper ocean is often constrained by the sunlight that can penetrate – which is one reason why greater biodiversity is found in tropical forests. The high productivity of a natural forest (where little sunlight is wasted) can often support more human inhabitants than the degraded landscape that so often replaces it. Tropical forces often contain most of their nutrients in the trees and associated litter, and their removal (by repeated burning and browsing) can cause a long-term impoverishment of the soil and the people who live on it. Forests are often cleared to make way for food crops, but it is worth remembering that, while food is vital, so are shelter and fuel provided by wood. People can starve because they have not grown sufficient food, but they can also starve because there is no means to store that food or to cook it. Many staple foods (corn, cassava, potatoes, wheat, rice) must be cooked to be digestible.

There is often outrage when a timber plantation replaces a natural forest. Undoubtedly, such conversion reduces biodiversity – unlike the situation where plantations displace agriculture. But the high productivity of useful timber from plantations can take the pressure off overexploitation of natural forests. Most commonly, the opposition to plantation forestry is not because of the change in vegetation so much as the change in land ownership and control. Large plantations are associated with large companies, often transnational, whose prime interest is said to be profit rather than the well-being of local inhabitants. Locals who have traditional foraging rights in the forest may find themselves excluded by the plantation owners, and the wide range of useful products from a natural forests is reduced to a narrow range. Instead of the multipurpose role of natural forests (medicines, honey, game, fruits, rattans, slow-burning charcoal), locals must participate in the money economy to satisfy their various needs.

The comparison between natural forests and plantation forests is unfortunate, as the world needs more forests of any sort. Conversion of natural forest to plantations can be prohibited by legislation, as in most countries there is adequate degraded agricultural land than could be used for the latter purpose.

Summary

For environmental reasons, the world needs more forests and it needs more wood. Forests of all kinds protect the soil, water, and air – which are the basic life-sustaining resources of the planet. Wood is a benign product because it is biodegradable, and because it has been created by the combination of water and a greenhouse gas under the action of sunlight. Trees are a natural biological solar panel.

Plantation forests should not be seen as an alternative to natural forests. They are additional to natural forests, and there is sufficient degraded agricultural land to enable the area of plantations to increase without threatening natural forests.

Impacts of Air Pollution on Forest Ecosystems

P E Padgett, USDA Forest Service, Riverside, CA, USA
S N Kee, University of California, Riverside, CA, USA

Introduction

Air pollution problems are international in scale. All forests worldwide experience some degree of air pollution exposure above preindustrial levels. Atmospheric transport processes do not recognize geographic borders, but sources of pollutants, the pollutants of concern, and the specific effects of pollutants vary greatly depending on human cultural activities and natural climate patterns. For example, heavy-metal contamination is a result of poorly controlled mining and industrial emissions; when coupled with frequent rainfall, dispersion is minimized and local deposition is maximized. Deposition of suspended particles is most frequently a problem in forests in dry climates adjacent to agricultural areas where atmospheric conditions allow suspended particles to remain airborne for long periods of time. Ozone is a secondary pollutant formed from automobile exhaust (nitrogen oxides) and volatile organic carbon from a variety of chemical, combustion, and natural processes. The reaction requires ample sunlight, thus ozone is a serious problem in urbanized areas in sunny climates.

Air pollution effects on forests can, therefore, best be understood by looking at climate zone and the human cultural activities of agriculture, urbanization, and industrialization. Although there are many natural sources of air pollutants, such as vegetation fires, windstorms, and volcanic eruptions, for the purposes of this article we shall focus on human-caused, or anthropogenic, sources of air pollutants and their effects on forest ecosystems. The effects of elevated carbon dioxide, global climate change, and other abiotic stressors are covered elsewhere in this *Encyclopedia* (*see* **Environment**: Impacts of Elevated CO_2 and Climate Change).

There is still much to be learned regarding air pollution and forest health. For example, nitrogen deposition from agricultural and urban sources is recognized both in Europe and the American continents as having a large potential for changing existing ecological processes and species composition. However, understanding the mechanisms driving changes and the extent of the threat to existing ecosystems is subject to ongoing debate.

Air pollutants can have acute effects arising from very high pollutant loads such as the destruction of forests due to unregulated heavy industrial activities such as in the 'black triangle' of Czechoslovakia, East Germany, and Poland. Alternatively, pollutants can have chronic effects from long-term exposures at lower concentrations such as ozone damage found in southern Californian forests adjacent to the Los Angeles basin. Many of the chronic effects are difficult to identify and catalog. Plant species vary widely in their sensitivity to pollutants and the display of recognizable symptoms. The yellow pines of North America have been a key indicator species for identification of ozone toxicity because of a display of 'chlorotic mottle' (a stippling of the needles) and premature loss of annual whorls. However, the converse is not necessarily true; the lack of a specific suite of symptoms does not necessarily indicate a lack of pollutant effects. Many nonvascular mosses and symbiotic lichens simply disappear from the forests under polluted conditions.

Finally, many air pollutant effects are synergistic with other biotic or abiotic stressors. Heavy metal contamination may weaken a tree, but an insect or pathogen infestation may be the actual cause of death. Drought is part of the natural climatic cycle in semiarid forests, but forests that have experienced extended years of ozone toxicity may be more susceptible to drought-induced mortality.

In the sections that follow, air -pollution effects are described by major climatic zone (**Table 1**). A brief description of the primary environmental factors and human activities that affect pollution loads and distribution within each of the major climate zones is included. It is recognized that for the purposes of this article generalizations are made and many exceptions exist. The reader is referred to other sections in this series and the list of recommended reading for more detailed information.

Subarctic Boreal Forests

Air Pollution Causes

Subarctic forests occur across Asia, North America, and northern Europe; about 70% of the world's boreal forests are in Russia. The subarctic zones

Table 1 Pollutants described within the individual sections

Forest type by climate zone	*Pollutants of concern*
Subarctic	Heavy metals, sulfur dioxide
Wet tropic	Smoke
Semiarid	Ozone, dry deposition, particulates
Temperate	Acid rain

contain rich mineral deposits and extensive timber and coal resources for industrial processing and energy production. Resource extraction is the primary activity in these forests, creating intensely focused, localized sources of industrial pollutants. Little agricultural or urban activity occurs here. Coal mining and logging provide energy resources for local uses and export. Timber resources are also used for paper and wood products, creating air pollutants in the industrial processing of wood fiber. Most of the pollutants in boreal forests are generated from smoke stacks. However, since the human populations are low outside the immediate industrial site, regulations and restrictions based on human health concerns have, historically, been limited and concern regarding forest sustainability has only recently occurred. The climate plays a critical role in air pollution effects on boreal forests. The growing season is, at most, 3 months, with long hours of sunlight available during the summer for gas exchange and photosynthetic activity. During the winter not only does cold inhibit metabolic activity but also daylight hours are short. Boreal forests are slow-growing and slow to recover after disturbances.

Air Pollution Concerns

The effects of air pollutants on boreal forests are acute. The industries of the subarctic generate two primary pollutants of concern: sulfur dioxide and the generalized category of 'metals.' These two pollutants have very different dispersal patterns and modes of action (that is, how they affect trees and forest ecosystems).

Sulfur dioxide is a well-known byproduct of coal combustion, but it is also found in many minerals and is released during smelting. Once aloft, sulfur dioxide can be transported for hundreds of kilometers before depositing on foliage, soil, water, or other substrates. Deposition can occur in rainfall, snowfall, or fog. It is also absorbed by plants as a vapor, and can collect on surfaces in a dry form. Furthermore, sulfur dioxide reacts with a number of other atmospheric compounds to form sulfuric acid, ammonium sulfate, and other vapors or aerosols. Because of its wide dispersal patterns, sulfur dioxide emissions can result in damage to forests over a large geographical area.

Metals, on the other hand, are generally deposited within 10–15 km of the source. Although there are many potential metal contaminants, such as cadmium, uranium, or lead, most of the concerns regarding boreal ecosystems are focused on copper, nickel, and zinc. The tendency for metals to collect relatively close to the source limits their geographic impact, but increases the concentrations and thus the intensity of the effects.

Air Pollution Effect

Mining and forestry operations in Russia have resulted in about 1 million hectares of 'seriously damaged' forest and another 7 million hectares of 'affected' forests. The Noril'sk mining complex is one of the best examples of the catastrophic effects of unregulated mining and smelting on boreal forests. Tree mortality due to sulfur dioxide extends for 200 km downwind of the complex and copper, cobalt, and nickel concentrations in soils are 10–1000 times higher than background levels up to 30 km downwind.

In addition to differences in distribution, the effects of these two primary pollutants differ in several important ways. Sulfur dioxide is phytotoxic as an airborne pollutant while metals are generally most toxic when incorporated into soil systems. Acute exposure to sulfur dioxide results in necrosis (cellular death) of leaf tissue. Often the effects are first displayed as chlorotic spots and later as bleached-white or brown necrotic spots on leaves and needles or along the margins of leaves. As acute exposures progress, the entire foliar surface turns brown and the leaf or needle is abscised from the tree. Acute sulfur dioxide symptoms may begin to occur at ambient concentrations of 50 parts per billion (ppb). Emission episodes resulting in concentrations of 1 part per million (1000 ppb) have been measured around unregulated smelting plants and coal-burning facilities. Chronic exposures to lower concentrations of atmospheric sulfur dioxide cause interveinal chlorosis of leaves and tip burn on needles. Continued exposure at lower concentrations can result in premature shedding of foliage and reduced net primary productivity. Deposition of sulfur dioxide on foliage can cause erosion of the surface cuticle boundary, but more often the uptake through stomata is the primary mechanism for damage. Once in the foliage interior, sulfur dioxide is converted to HSO_3 – bisulfite – a free radical, $SO4_2^-$, or SO_3^-, all of which disrupt metabolic activity or alter plant nutrient balances. In the subarctic boreal forests, the long summer days provide extended periods of gas exchange and this extended period of foliar uptake can result in greater injury symptoms compared to regions closer to the equator. Conversely, during the winter, when days are much shorter and the cold temperatures limit water availability, stomata may not open at all for extended periods. During these times atmospheric sulfur dioxide interactions with the canopy of trees become less important, but deposition to, and accumulation in, soils can have adverse effects, which will be addressed in later paragraphs.

Metals generally do not attack foliage directly. Their effects are most pronounced on roots. Although lumping metals into a single category is scientifically inaccurate, as each element exhibits independent effects ranging from biochemical competition with nutrient ions (for example, zinc and phosphate) to direct inhibition of root tip growth (aluminum), for the purposes of this discussion they will be considered together. Most metals are not easily translocated to the shoots of plants but can have profound effects on root function and the healthy functioning of many soil organisms upon which plants rely for nutrient cycling. Studies of metal-contaminated soils have shown that the microbial communities are frequently altered. In addition, some metal-contaminated soils have reduced rates of litter decomposition, thus lowering nutrient availability. In particular, nitrogen and phosphorus can become growth-limiting. When metal concentrations reach a level such that they seriously inhibit root functions, the trees are no longer able to acquire enough water or nutrients, resulting in stunting of growth and ultimately death. Unlike sulfur dioxide, which may be metabolized and at least temporarily removed from the environment, the lack of uptake, assimilation, or translocation means that metals remain in the environment. Therefore, even relatively low levels of ambient air concentrations can result in metal accumulation in soils. Once a critical load has been achieved, tree mortality occurs.

The presence of both sulfur dioxide and metals is often synergistic, meaning that the effects together are more destructive than the individual effects. The second effect of sulfur dioxide emissions is 'acid rain,' although deposition occurs in any precipitation form. Acid rain has been greatly publicized and is probably the best recognized effect of air pollution. The significance of acid rain effects depends upon many other environmental factors, particularly those related to soil physical and chemical structure. Therefore a universal statement regarding acid rain effects in boreal forest is inappropriate. However, one of the more important chemical aspects of acidification of the soil is an increased mobilization of metals. When metals accumulate on the forest floor, many are bound up in organic compounds, or chemically bonded to the soil mineral fractions. In these forms metals are largely unavailable and will have little effect on plant roots. However, as the pH of soil decreases (becomes more acid) many metals lose their affinity for the organic ligands or minerals and become suspended in soil solutions. In these forms they are available to biological organisms, including tree roots, and begin to inhibit metabolic function.

Wet Tropics

The forests in the wet tropics vary from evergreen rain forests where growth occurs all year long, to deciduous rainforest with annual wet–dry cycles where growth is curtailed during part of the year. The seasonality of growth affects the extent of air pollution damage and the type of damage likely to occur. Many publications have highlighted the enormous diversity found in tropical forests, both within individual forest types, and globally when comparing rainforests of the world. One of the initial effects of acute air pollution toxicity is a loss of diversity. A few plant species are capable of tolerating the assault and ultimately prosper at the expense of less tolerant species. Whether this loss of diversity is a permanent or transient condition is subject to debate.

Air Pollution Causes

The tropics are generally defined as those areas between the tropic of Cancer (20° N) and the tropic of Capricorn (20° S). This climate zone covers most of South America, Africa, and parts of Southeast Asia and Oceania; thus many developing nations are found in the wet tropics. This section focuses on forest ecosystems where precipitation far exceeds evapotranspiration. Inland areas and landscapes along the western coasts of large continents, which tend to be arid or semiarid, will be discussed under that category. The wet tropics have relatively low industrial activity and traditional agricultural practices are small compared to many European nations. However, this is changing in many regions, and several examples of industrial pollution as well as effects of agricultural practices are beginning to be recognized. Urbanization and air quality problems associated with overcrowding and poor sanitation have created serious human health problems, but little research on ecological effects has been conducted. The use of fire as a land management tool and the prevalence of open fires for cooking, sanitation, and industry are the best-documented pollution concerns.

Air Pollution Concerns

Perhaps the most serious concern for the wet tropical regions is the potential for developing nations to repeat the environmental mistakes made by the developed world. At the same time developing nations are concerned that global air pollution problems of industrialized nations should not hinder their own efforts to improve the standard of living associated with industrialization. As has historically occurred in North America and Europe, when nations move from agrarian-dominated societies to urban manufacturing-based societies rapid influxes of people into cities causes crowding and sanitation problems. Until the necessary infrastructures are built, human and domestic animal wastes create nitrogenous pollutants and open fires remain the primary source for cooking and heating. Individually, small residential and entrepreneurial enterprises have little effect on the environment but, collectively, uncontrolled emissions from these sources generate the same air pollutants seen in larger industrial and urban complexes. These enterprises can produce sulfur dioxide, nitrogen oxide, and organic carbon compounds as primary pollutants. Secondary pollutants, nitric and sulfuric acids, aerosols and ozone generated by atmospheric processes are transported into adjacent forests or become part of the global circulation of anthropogenic atmospheric contaminants. Ammonia and other gases from poor sanitation, cropping systems, and animal husbandry resulting in nitrogen deposition and aerosol formation are typical of urban pollution problems anywhere in the world. The common use of managed fire, and the suggestion that wild fires have increased due to global climate change, are among the more serious concerns for sustainability of the unique forest structures in the wet tropics.

Air Pollution Effects

Clearly, burning to remove vegetation alters the immediate landscape but the effects of smoke on ecosystems downwind have only recently been addressed. The huge fires in Southeast Asia during the late 1990s and the annual burning of the cerrado grasslands in central Brazil offer examples of intentional and unintentional fire effects on native forests. Serious increases in tropospheric ozone have been documented as a result of cerrado fires. Concentrations measured are equivalent to those measured outside large urban centers (100–200 ppb). Data that document greatly increased atmospheric concentrations of volatile organic carbon and other pollutants due to the fires in Borneo have been published, but the long-term effects of these fires are not known. Few studies have been published relating the increase in ozone (and presumably other fire emissions such as organic carbon, nitrogen, and NO), to responses of native tropical forest trees, but experience from western North America would suggest that fire-generated ozone and its precursors are capable of being transported hundreds of kilometers, affecting native ecosystems far removed from the original burn site. Because the growing season is nearly year-round, foliar gas exchange would be expected to occur year-round as well, providing sites of entry for any number of airborne pollutants. The effect of anthropogenic emissions on the unique plant species of tropical rainforests is unknown. However, extrapolating from temperate forests where the nonvascular mosses and lichens appear to be the sentinel species, composition and structural changes are most likely occurring.

Semiarid Forests

Typically, forests found in semiarid regions are sparsely vegetated with trees and understory species well adapted to low, or seasonal water availability. Precipitation patterns vary from distinctly seasonal such as the wet winter/dry summer patterns of the Mediterranean climate, to bimodal rainfall patterns of wet winters and monsoon summer rains. On average, precipitation amounts equal evapotranspiration demands of the vegetation, but periodic drought is a normal feature. Forested landscapes are often at higher elevations where heat loads are not as intense and orographic processes increase total precipitation as moist air moves upslope. Many of these forests are found in coastal Mediterranean regions of the world where coastal influences modify the intense aridity found inland; southwestern North America, parts of the western coast of Africa and South America and of course, around the Mediterranean sea itself contain semiarid forests. Semiarid forests can be found inland as well, particularly at higher elevations where monsoonal rains provide enough moisture to survive the summers. Because metabolic activity is dependent on water and water availability is highly seasonal, direct interactions with the canopy and uptake of atmospheric pollutants are thought to be seasonal. However, deposited pollutants that accumulate in the terrestrial environment may result in unpredicted ecological responses.

Air Pollution Causes

These regions often contain extensive irrigation agriculture and large urban centers along shorelines focused on trade. Where logging has occurred it is not unusual for the forests to be extremely slow in returning, and total conversion of vegetation type to shrublands has been historically documented throughout the world. Although exceptions exist, for the most part semiarid regions do not contain large industrial complexes. Therefore both urban (primarily transportation sources) and agricultural pollutants are the most serious pollution causes in adjacent forested lands.

Air Pollution Concerns

The warm sunny climates, copious exhaust from roadways, and both natural and anthropogenic sources of volatile organic carbon provide the perfect combination for synthesis of the secondary pollutants ozone and nitric acid and primary and secondary aerosols. Nitrogen oxide and nitrogen dioxide from automobile exhaust can be taken up through leaf stomata but, except in the most extreme conditions, have only minor effects on plants. Because photochemical reactions that create ozone and nitric acid require sunlight, distinct diurnal patterns of atmospheric concentrations are typical. In coastal communities ozone concentrations may be near zero at night, increasing during the daylight hours to highs in the 100–400 ppb range. Since both ozone and the precursors are subject to transport aloft, similar ambient concentrations may be measured many kilometers away. This has been well documented in coastal southern California and southern Spain. Nitric acid is a byproduct of ozone synthesis. Currently there are no instruments that can measure nitric acid exclusive of other nitrogenous pollutants on an hourly basis. This has limited the ability to establish patterns of ambient concentrations and distribution. Denuder systems and passive collectors currently provide the best ambient concentration information, but they are labor-intensive and require longer exposure times. Therefore, the results are an integrated value over a 12-hour to 1-week period. Twenty-four-hour average concentrations above 1 ppb are considered high pollutant episodes. Daytime concentrations in the 10–12 ppb range have been recorded in southern California. Nitric acid is highly reactive. Once formed it can solubilize in water vapor, and readily deposit on exposed surfaces, combining with volatile ammonia products from cropping and animal production facilities to form ammonium nitrate aerosols.

Anthropogenic sulfur emissions are generally low in these regions largely due to the lack of significant coal-burning and metal-smelting operations but, along the coast and in saline valleys, natural sources of sulfate can provide the counterion for ammonium sulfate particles. Fugitive dust from roadways and land-disturbing operations such as construction and cropping practices are serious issues in these climates because the arid environment permits longer suspension times and therefore longer travel distances before the dust is deposited.

Air Pollution Effects

Ozone effects on semiarid forests are well documented in the Mediterranean climates of south-western North America, southern Spain, and Italy. Short-term exposures to ozone concentrations greater than 150 ppb can cause acute damage symptoms on many plant species. Long-term, chronic exposures to 50 ppb result in reduced growth of sensitive species and foliar mottling of many forest tree species. The primary sites of uptake and injury are the stomata of actively photosynthesizing leaves. When the stomata are open for gas exchange, ozone readily gains access to the stomatal cavity and mesophyll of foliage. Once inside the plant leaf, damage to cell and organelle membranes occurs, although the exact mode of attack is not well understood. Symptoms first appear as chlorotic spots on leaves and needles. As the damage progresses, cells in the chlorotic areas die, leaving necrotic spots. Although this kind of damage can be confused with other biotic and abiotic effects, the patterns of ozone damage and the distribution patterns of damage are often quite specific within a particular plant species. However, the lack of visible symptoms is not always an accurate indicator for tolerance to high ambient ozone concentrations. Ozone toxicity by itself is rarely the cause of death in mature trees, but weakens trees so that they are susceptible to insect, pathogen, or environmental assaults.

Much of the nitrogen deposition in semiarid forests occurs in the dry form, unlike nitrogen deposition in temperate regions. Dry deposition is very difficult to measure using current techniques. Among the many difficulties in understanding the effects of dry deposition is that nitrogen is a normal part of the ecosystem, unlike ozone or heavy-metal pollutants. For this reason establishing nitrogen deposition as a causal agent for changes in forests has been difficult. Deposited nitrogen accumulates during the dry season and becomes available when precipitation returns, in effect behaving as a fertilizer. Changes in nitrogen fertility have been shown to change ecological structure and function. Although forests are slow to respond to changes in fertility, monitoring nitrogen-impacted forests has indicated changes in species composition, beginning with the shorter-lived species, such as annuals and herbaceous perennials. Nitric acid and ozone are formed through the same photochemical processes in the atmosphere. Therefore, the presence of one is usually indicative of the other. Studies suggest that there is an interaction between the two air pollutants, but the nature of that interaction is poorly understood. Under some conditions it appears that nitrogen deposition may ameliorate ozone effects while under other conditions dry deposition of nitric acid to foliage may exacerbate ozone damage. The study of multiple pollutant effects is an emerging topic that will ultimately improve our understanding of air pollution effects on natural ecosystems.

Particulate pollutants occur in all parts of the world, but the low humidity and seasonal rainfall make suspended particulates a serious issue in semiarid ecosystems. The sizes of these pollutants can range from a few angstroms to several micrometers in diameter. The size affects physical behaviors such as travel distance and deposition as well as the pollutants' effects on biological organisms. Very small particles (less than 0.2 μm in diameter) are a serious public health concern. When breathed, they become lodged in the lung tissue and are not easily removed. It is not known whether similar phenomena occur in the plant kingdom. The effects of particulate pollutants in forests fall into two categories: physical abrasion/coatings and chemical effects. Blowing dust scratches leaf surfaces and damages the cuticles of leaves, increasing opportunities for pathogen infection. In addition, when dust lands and collects on foliage it blocks penetration of sunlight, reducing photosynthetic capacity. From a chemical standpoint, particulates serve as nutrient sources. Small ammonium nitrate or sulfate particles are capable of traveling hundreds of kilometers within a few days. Particles greater than 10 μm are restricted from rapid long-distance transport due to gravitational forces, but studies in Southwest North America have shown that multiple transport events over the course of a season can make a substantial contribution to the nutrient load at many kilometers distance from the particle source.

Temperate Forests

Most of the world's industrialized nations are partially or entirely in temperate climate regimes. Forests in the temperate climates experience all the air pollution insults and effects enumerated under other climate regimes. Ozone, particulates, nitrogen deposition, smoke, heavy-metal, and sulfur effects are well documented and in many ways best understood in these ecosystems. Europe and Central Asia have long histories of human settlement and industry. North America and Australia are more recently urbanized, but all participated in the industrial revolution that initiated large-scale air pollution effects in natural ecosystems.

Modern agricultural practices have improved crop yield and increased animal production by improving efficiency of land use. In many cases modern practices have led to highly concentrated animal husbandry operations where hundreds or thousands of animals are confined to small spaces and to the heavy use of synthetic fertilizers and pesticides. At the same time, urbanization concentrated humans into crowded cities where sanitation, fuel combustion for heating and cooking, and the need for transportation generates concentrated pollutants.

During the early expansion of industry and production agriculture, the ability of natural ecosystems to absorb the byproducts of human activities was either ignored or thought to be limitless. However, in the last several decades, many nations have recognized the serious effects of air pollution on forests and have taken steps to reduce or eliminate many of the pollutants through legislation and technology. Reduction in sulfur emission in the industrialized mid-west and northeastern parts of North America has resulted in measurable reductions in ambient concentrations and deposition to adjacent forests. Improved metal-smelting technologies have greatly curtailed atmospheric deposition of heavy metals in Canada, Europe, and parts of Asia. Improvements in energy production efficiency for heating, cooking, and transportation have reduced urban smoke emissions when compared to the air quality at the turn of the century. However, the problems of air pollution effects in temperate forests are far from solved.

Air Pollution Causes

The temperate forests are found in the most heavily populated climate zones on earth. All the known causes of air pollution are here. Intense animal production in western Europe, southeastern USA, and the UK produces enormous quantities of ammonia vapor that are then transported into native forests. Pesticide applications in valleys drift into the slopes of adjacent forests, and automobile exhaust continues to be one of the most serious causes of air pollution. Although reduction in sulfur emissions is a partial success story, nitrogen oxide emissions remain steady in the USA and are rising dramatically in western Europe and Asia as increased wealth allows increased numbers of automobiles and reliance on internal combustion engines for transport and energy production. Many of the most destructive smoke stack sources in Eastern Europe have been eliminated or reduced due to economic and outside pressure; however, these sources continue to impair forests seriously in developing Asian nations.

Air Pollution Concerns

The air pollution concerns of temperate regions are complex and intertwined. Frequently, it is difficult to isolate independent pollutant sources in an effort to control emissions and reduce impacts. Generation of the precursors for ozone synthesis, nitrogen oxide, and volatile organic carbon is a good example. Any combustion process – agricultural, urban, or industrial – can generate nitrogen oxide, although automobiles are the most frequently noted sources. Volatile organic carbon compounds can come from restaurants or dry cleaners, smoke stacks or motors, and fires or production of volatile compound by native vegetation. Once these compounds are aloft and the photochemical process initiated, the ozone created can impact forests tens or hundreds of kilometers away. This is clearly the case in the checkerboard pattern of land uses in the eastern half of the USA, much of Europe, and increasingly in Asia.

Pollution concerns in temperate agricultural systems are similar to those found in semiarid systems: particulates, nitrogen deposition, and pesticides. Unlike the semiarid systems, wet deposition plays a much more significant role. While wet deposition helps reduce high ambient particulate loads, it is the major source of nitrogen deposition in forests. The eutrophication effects of ammonia deposition are particularly acute in forests adjacent to large feedlots, dairy operations, and confined poultry and pig farms. Urban pollutant sources are generally associated with combustion processes, automobiles, and energy generation and its use. Although sanitation continues to be a problem in regions experiencing rapid population growth, many established urban centers have developed the necessary septic and sewer systems so that human waste is not generally an issue. Industrial waste does continue to impact local and global air quality. For many of the traditional smoke stack pollutants, sulfur, metals, and smoke particles, technology is available to reduce atmospheric loading; however, as new industries are being developed, new pollutants, particularly organic solvents, are emerging as serious health and ecological concerns. These new pollutants will continue to require new methods for detection and research into long-term impacts.

Air Pollution Effects

Acid rain and wet deposition are not unique to temperate forests but, because of milder temperatures, wet deposition, including fog and mists, can have pronounced effects on temperate ecosystems. Any substance that will solubilize in water will deposit as wet deposition. Acid rain studies have focused primarily on sulfuric and nitric acids but ammonia, metals, and pesticides – among other compounds – can be found in rain. One exception is ozone. Rainfall and very high humidity found in fog tend to ameliorate ozone, and without sunlight the chain reactions that form ozone are broken. The acidity in rain is caused by the presence of positively charged hydrogen ions (protons), which is why nitric and sulfuric acids have the most pronounced effect on pH; both are strong acids, releasing protons when solubilized in water. Normal rainfall tends to be slightly acidic, generally in the 6.2–6.5 pH range (neutral pH is 7). Acid rains have been measured as low as 3.5 and rainfall in the 4.5–5.0 ranges are not unusual in heavily industrialized or urban areas. How acid rain affects the forest is dependent upon many factors. In forest soils that are weakly buffered, wet deposition can reduce the soil pH, substantially changing below-ground processes, including mobilizing metals. Aluminum is an element that is found in large quantities in soils, but it is generally not toxic at higher pHs. When the pH is lowered, the availability of aluminum is increased, causing stunting of roots. Where soils are richer and better buffered, the percolation of rainwater through the soil profile leaches base cations (plant nutrients with positive charges) out of the rooting zone, causing impoverishment of the soil. The ability of forest soils to repair the damage once acid rain ceases is also highly dependent on the forest. Highly productive landscapes may reverse decline within a few years; however, many examples exist where the atmospheric inputs are no longer present, but the effects continue.

Wet deposition to foliar surfaces can result in erosion of the leaf surface. This is less of a problem in deciduous forests than in the evergreen conifer forests where excessive damage to needles results in premature abscission. Wet deposition of nitrogenous pollutants may not necessarily result in pH shifts, but long-term studies of nitrogen-affected forests indicate shifts in forest function and composition. The tendency of pollution-impacted forests to suffer 'winter kill,' for example, has been attributed to increases in nitrogen to those forests.

Remediation

Forests are slow to respond to management activities, and remediation measures are designed to shift the trajectories of forest ecological processes rather than completely change ecological patterns. Prescribed fire is being used as a remediation tool for several desired outcomes. Fire reduces the biomass of smaller trees and understory vegetation reducing the competition for water in semi-arid, ozone-impacted forests. Fire also reduces nitrogen loading in forests approaching nitrogen saturation and eutrophication. Selective harvesting and replanting of resistant varieties can also help shift pollution-impacted, declining forests into more productive forests. However, in recent years forests have demonstrated a surprising ability to recover all by themselves once the pollutant source is eliminated.

In recent years forests have demonstrated a surprising ability to recover once the pollutant source is eliminated. What was once thought to result in total destruction of forests in highly polluted regions is now understood to be yet another disturbance similar to fires or floods from which forests will recover over time. There are exceptions, such as sites heavily contaminated by metals; these areas will require more active remedial action. However, the annihilation of native forests due to air pollution, predicted during the 1970s and 1980s, has for the most part not occurred. Are these recovering forests the same before and after high pollution events? Probably not, but all landscapes are constantly responding to environmental conditions in ways that are difficult to quantify. It becomes the job of the forester and society to determine how air pollution effects are moderated so that all the resources that forests have to offer remain intact.

Carbon Cycle

J L Innes, University of British Columbia, Vancouver, BC, Canada

Introduction

The forest environment carbon cycle can be viewed at a number of scales. Measurements can be made at the scale of an individual leaf or tree, stand-scale measurements can be made, and models can be developed that examine forest-level, regional, and global carbon cycles. The role of the forest in the global carbon cycle has become increasingly important as it is realized that forests and forestry have a role to play in mitigating the so-called greenhouse effect. This article examines the sources, sinks, and fluxes of carbon as they relate to forests and then places this information within the context of global change. Finally, the potential contribution of forests to the mitigation of climate change is assessed.

The Global Carbon Cycle

The main components of the natural global carbon cycle are the sources, sinks, and fluxes between the land, oceans, atmosphere, and geological reservoirs. Current estimates suggest that the atmosphere contains about 730 Pg C, the land 2000 Pg C, the oceans 38 000 Pg C, and that an unknown amount remains in geological reservoirs. The greatest natural flux (120 Pg C per year) is between the land and the atmosphere, with a smaller flux occurring between the atmosphere and the oceans (90 Pg C per year). Estimates of the sizes of the different carbon pools are given in **Table 1**. In terms of fluxes, the carbon cycle can be seen as an approximate balance between the processes of photosynthesis by plants and respiration by plants, animals, and microbes. It is the variations on either side of an exact balance between photosynthesis and respiration that cause natural variations in the global carbon pools, supplemented by anthropogenic activities, such as the clearing of forests and the burning of fossil fuels,

Table 1 Estimates of terrestrial carbon stocks and net primary productivity published by the Intergovernmental Panel on Climate Change

Biome	*Area (10^9 hectare)*	*Global carbon stocks (Pg C)*		
		Plants	*Soil*	*Total*
Tropical forests	1.76	212	216	428
Temperate forests	1.04	59	100	159
Boreal forests	1.37	88	471	559
Tropical savannas and grasslands	2.25	66	264	330
Temperate grasslands and shrublands	1.25	9	295	304
Deserts and semideserts	4.55	8	191	199
Tundra	0.95	3	121	127
Croplands	1.60	6	128	131
Wetlands	0.35	15	225	240
Total	15.12	466	2011	2477

which cause further changes (both in the balance between photosynthesis and respiration and in the total carbon fluxes).

The Forest Carbon Cycle

All higher plants take up carbon dioxide. Globally, the amount of CO_2 that is dissolved in leaf water has been estimated to be 270 Pg C per year, representing more than one-third of all the CO_2 stored in the atmosphere. Most of this carbon leaves the plants without being involved in photosynthesis. The fraction that remains and which is converted from CO_2 to carbohydrate is known as the gross primary production (GPP). The total amount of terrestrial GPP has been estimated at 120 Pg C per year. Approximately one-half of this is converted back to CO_2 by autotrophic respiration. Autotrophic respiration (often abbreviated to R_A) can be divided into two distinct processes: maintenance respiration (R_M), which is the respiration that is required for a plant to maintain its basic physiological processes and thus to survive, and construction respiration (R_C), which is the respiration that is needed for the plant to build new structures such as leaves, roots, the stem, flowers, and other organs. Autotrophic respiration therefore refers only to plants.

Scaling up to the ecosystem level, the difference between GPP and autotrophic respiration is termed net primary production (NPP). There are many measurements available for NPP, and the total amount of NPP globally has been estimated to be about 60 Pg C per year. Almost all of this carbon is returned to the atmosphere through heterotrophic respiration (R_H), which is the respiration of organisms that break down the products of net primary production, including both herbivores and decomposers, and through fires. Within forest ecosystems, fires can be a particularly important mechanism for the return of carbon to the atmosphere, with a global estimate of 936 Tg C being released annually by forest fires. However, the reliability of the data used to derive this estimate is very questionable. Where data are available, the figures suggest that fire is of major importance. For example, the 1987 fires in Indonesia, which burnt both above-ground biomass and below-ground peat, are estimated to have released between 0.81 and 2.57 Pg C, equivalent to 13–40% of the global annual emissions of fossil fuels. This figure is higher than the global estimate, as it includes the carbon released by the below-ground burning of peat. If only the above-ground vegetation is included, then the figure was reduced to 50 Tg C.

Heterotrophic respiration is especially important, as it is largely responsible for the return of organically bound carbon to the atmosphere. Much of this occurs in soils or on the soil surface, with the rate of breakdown being controlled by a number of different factors, including climate, chemical composition of the plant matter, soil conditions, and others. The microbial biomass and soil detritus tends to break down quite quickly (within 10 years), whereas modified soil organic carbon may take much longer (100 years or more, depending on the climate). Turnover times for forest litter vary from less than 6 months in some tropical forests to over 350 years in boreal coniferous forests. In many forests, the rates of breakdown have been influenced by management practices, and management presents an opportunity to control in part the carbon in forests.

The biomass pools in a forest can be divided into the above- and below-ground tissues of plants, woody debris, the forest floor, the mineral soil, and the tissues of heterotrophic organisms. The proportions in each of these pools vary dramatically, depending on the type of forest, with figures for the

Table 2 Forest volume and above-ground biomass by region, as published by the UN Food and Agriculture Organization

Region	Forest area (million hectare)	Volume		Biomass	
		By area (m^3 hectare^{-1})	Total (Gm^3)	By area (t hectare^{-1})	Total (Gt)
Africa	650	72	46	109	71
Asia	548	63	35	82	45
Oceania	198	55	11	64	13
Europe	1039	112	116	59	61
North and Central America	549	123	67	95	52
South America	886	125	111	203	180
Total	3869	100	386	109	422

above-ground biomass being presented in **Table 2**. Approximately 50% of the dry biomass of a tree is thought to consist of carbon, although carbon removed from the atmosphere of the tree may also be transferred to the soil carbon pool through litterfall. The actual amount sequestered by an individual tree will depend on the species, the growing conditions, and its environment. The environment is important: in urban areas, the leaves or needles shed by a tree are often removed, preventing uptake into the soil.

A mature forest is generally considered to be 'carbon-neutral.' This means that it releases as much carbon as it absorbs. This assumption is based on looking at the carbon balance over a fairly extensive area of forest, as local stand dynamics can result in substantial changes in the carbon balance as the forest is disturbed and regrows. Using the terms described above, NPP should more-or-less equal R_H. While this may be the case for some mature forests, more often forests are in a state of dynamic equilibrium, with some net carbon either being gained or lost from the forest ecosystem. This is termed the net ecosystem production (NEP); measurements of NEP range from 0.7 to 5.9 Mg C hectare^{-1} year^{-1} for tropical forests, 0.8 to 7.0 Mg C hectare^{-1} year^{-1} for temperate forests, and up to 2.5 Mg C hectare^{-1} year^{-1} for boreal forests. The rates are very variable, and in some areas there may be negative NEPs in particular years.

The NEP represents only the difference between NPP and R_H, and does not take into account carbon losses through fire, erosion, and other processes. The overall figure of relevance to global forest carbon cycles is the net biome production (NBP), which takes into account all the processes of carbon gain and loss from the terrestrial biosphere. This has been estimated at -0.2 ± 0.7 Pg C year^{-1} during the 1980s and -1.4 ± 0.7 Pg C year^{-1} during the 1990s. The negative values for these flux estimates indicate that the land is acting as a sink for atmospheric carbon.

While the figures for global NPP, NBP, and R_H all appear to be given with some certainty, considerable care should be taken over their interpretation. Most figures are based on models, and the underlying quality of the data used to draw those assumptions and build the models is not always very good. This is particularly true in the case of forests, where great reliance is placed on the Forest Resource Assessment of the UN Food and Agriculture Organization. The quality of this inventory of the world's forests has improved with each successive inventory, but major data quality problems remain, particularly in the tropical countries and Russia. For example, emissions of carbon associated with forest fires in Russia are very uncertain, with information on both the extent and severity of forest fires in Siberia being very unreliable.

Despite these difficulties, there are increasing numbers of indications that carbon stocks in the world's forests may be increasing. In the tropics, data from permanent sample plots indicate that tree growth is increasing, although the flux is more than balanced by losses caused by deforestation. In temperate and boreal forests, an increasing forest area has been accompanied by increasing carbon stocks in existing forests. In some regions, these trends have been present for some time. In the northern hemisphere, the regrowth of forests following the deforestation of the eighteenth and nineteenth centuries is estimated to be responsible for the uptake of 0.5 ± 0.5 Gt C year^{-1}. In other areas, such as the tropics and some temperate regions, the trend appears to be new.

Global Increases in CO_2

Over the past 200 years, the atmospheric concentrations of carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) have been increasing at an exponential rate. These three gases, together with a range of others (particularly the halocarbons), are known as greenhouse gases. The term is used because the gases are able to absorb some of the longwave radiation that is emitted from the earth, resulting in an increase in the temperature of the atmosphere, the so-called 'greenhouse effect.' Since 1750, atmospheric CO_2 concentrations have increased from the preindustrial concentration of 280 parts per million (ppm) by 31%, and current concentrations (367 ppm in 1999) are higher than at any time in the last 400 000 years. Concentrations of CH_4 have increased 151% since 1750, and are also unprecedented within the past 400 000 years, whereas concentrations of N_2O have increased by 17%. The past history of atmospheric N_2O concentrations is less certain than for CO_2 or CH_4, and it is only possible to state that current N_2O concentrations have not been exceeded within the past 1000 years. In contrast to the other greenhouse gases, many of the halocarbon gases that are both greenhouse gases and ozone-depleting have been stable, decreasing or increasing more slowly since 1995, when the Montreal Protocol and its amendments introduced controls on their emissions. They have been substituted by a number of other gases, such as CHF_2Cl and CF_3CH_2F, which are not ozone-depleting, but which are greenhouse gases. These, together with synthetic compounds that are also greenhouse gases, such as perfluorocarbons (PFCs) and sulfur hexafluoride (SF_6), have been increasing in the atmosphere.

Atmospheric concentrations of these gases have varied considerably in the past, providing one of the reasons to question the cause of the current increase in concentrations. However, the rate of change in CO_2 concentrations appears unprecedented, certainly within the past 20 000 years. The preindustrial and recent (1998) concentrations of selected greenhouse gases are given in **Table 3**.

Table 3 Greenhouse gas concentrations in pre industrial times and currently

Gas	*Preindustrial*	*1998*
CO_2	*c.* 280 ppm	365 ppm
CH_4	*c.* 700 ppb	1745 ppb
N_2O	*c.* 270 ppb	314 ppb
CFC-11 (chlorofluorocarbon 11)	zero	268 ppt
HFC-23 (hydrofluorocarbon-23)	zero	14 ppt
CF_4 (perfluoromethane)	40 ppt	80 ppt

The Intergovernmental Panel on Climate Change (IPCC) is a group of government-appointed scientists responsible for looking into the nature, causes, and extent of climate change. They have reached a broad consensus that the increase in CO_2 and other gases is the result of anthropogenic activities, and that the increase is at least in part responsible for the observed increase in global average surface temperatures of $0.6 \pm 0.2°C$ over the past 100 years. It is likely that the 1990s was the warmest decade and 1998 was the warmest year in the northern hemisphere in the last 1000 years, and the IPCC has concluded that most of the observed warming over the past 50 years is likely due to increased greenhouse gas concentrations in the atmosphere.

The influence of different types of forcing factors on global temperatures is calculated using the concept of radiative forcing. The forcing is a measure (expressed in $W\,m^{-2}$) of the extent to which any particular factor influences the incoming and outgoing energy within the earth–atmosphere system. If the forcing is positive, then it results in an increase in temperature. Conversely, a negative forcing results in a lowering of temperature. The radiative forcing of different greenhouse gases is shown in **Table 4**. These figures need to be placed in the context of other forcing factors. For example, the radiative forcing associated with the burning of biomass is estimated to be $-0.2\,W\,m^{-2}$ (indicating a cooling effect), as the aerosols prevent energy from reaching the earth's surface.

During the period 1980–2000, approximately 75% of the CO_2 emissions were from the burning of fossil fuels, whereas the remainder (estimates range from 10% to 30%) was the result of land-use changes, particularly deforestation. Just over half of the emissions of CH_4 are from anthropogenic sources (such as fossil fuels, rice cultivation, cattle, and landfills), whereas only a third of current N_2O emissions are anthropogenic (sources include the chemical industry, cattle feed lots, and agricultural soils). The cumulative carbon losses occurring as a result of land use and management changes have been estimated to be between 180 and 200 Pg C. The loss of forests has been the primary factor, leading to terrestrial carbon emissions since 1850, amounting to about 90% of the total emissions.

Historical land-use changes have certainly had a major impact on the global carbon budget. Data collected by the United Nations Food and Agriculture Organization between 1990 and 2000 suggest that about 15 million hectares of natural forest are lost annually, although the data are very unreliable. This is in part compensated by a natural expansion of forest by 1 million hectares annually, and establishment of about 2 million hectares of forest plantations annually in the tropics. The greatest losses (42% of the total) occur in Latin America, with the proportions in Africa and Asia amounting to 31% and 27%, respectively. The land-use changes and forestry operations in the tropics are estimated to be releasing between 1.1 and 1.7 Gt C $year^{-1}$ (during

Table 4 Radiative forcing of greenhouse gases from 1750 to 2000

Greenhouse gas	*Radiative forcing*
CO_2	$1.46\,W\,m^{-2}$
CH_4	$0.48\,W\,m^{-2}$
Halocarbons	$0.34\,W\,m^{-2}$
N_2O	$0.15\,W\,m^{-2}$
Total	$2.43\,W\,m^{-2}$

the mid-1990s) although, again, the estimates are very approximate and based on incomplete data. The area of forested land in the temperate regions is, however, increasing by about 3 million hectare annually. This means that there was a net annual loss of forests in the period 1990–2000 of about 9.4 million hectare, equivalent to a biomass loss of about 1.6 Gt annually. This last figure should be treated with caution, as it is based on changes in forest area alone. There are also changes occurring within forests, such as the increase in productivity described above. Outside the tropics, a biomass gain within the forest of about 0.9 Gt occurred annually in the period 1990–2000. No equivalent figure is available for tropical forests.

Forests and the 'Greenhouse Effect'

The increase in global mean temperature is important as it will have a wide range of effects. For example, increased temperatures are leading to the loss of ice from glaciers and icecaps. At the same time, the increase in the temperature of the surface layers of the earth's oceans is resulting in thermal expansion of the surface waters. Combined, these processes have resulted in an increase in sea-level, with major potential consequences for low-lying land areas. In the Pacific region, several island groups are now threatened with submersion, with sea levels expected to increase by between 0.09 and 0.88 m between 1990 and 2100.

A number of potential solutions have been proposed, and an international mechanism to encourage solutions, the Kyoto Protocol, was agreed in December 1997. The Kyoto Protocol stated that industrialized countries would, by 2008–2012, reduce their combined greenhouse gas emissions by 5.2% relative to their 1990 emissions. Individual countries have specific targets, and some countries can even increase their emissions by the year 2012. A number of strategies can be adopted to reduce emissions, including increased energy efficiency, reduction in energy demand, and implementation of alternative technologies. In addition, several short-term steps can be taken through the development of carbon sinks.

The focus of the Kyoto Protocol and its amendments has been on CO_2. This is because CO_2 is the dominant human-influenced greenhouse gas, accounting for a radiative forcing of $1.46\,W\,m^{-2}$, or 60% of the radiative forcing of all the long-lived greenhouse gases. The rate of increase in the gas is variable, and in the 1990s, it ranged from 0.9 to $2.8\,ppm\,year^{-1}$, or 1.9 to $6.0\,Pg\,C\,year^{-1}$. The variation seems to be related to the occurrence of El Niño events, with higher rates of increase occurring in years with marked El Niño events (due to reduced terrestrial uptake).

Trees to Mitigate CO_2 Increases

The potential of forests to reduce the rate of increase in atmospheric CO_2 has been the subject of much debate, especially within the context of the Kyoto Protocol to the United Nations Framework Convention on Climate Change. At issue has been the extent to which countries should be allowed to offset their CO_2 emissions through the enhancement of sinks (which partly avoids the difficult issue of directly reducing CO_2 emissions). In addition, the many uncertainties associated with the quantification of the forest carbon sink has caused problems. The Kyoto Protocol (Articles 3.3 and 3.4) specifically recognized forests as carbon sinks, but it was not until November 2001 that some of the definitions were finally established (the Marrakesh Accords).

The increase in atmospheric CO_2 concentrations can be clearly linked to fossil fuel burning and to land-use change. The land-use change of greatest relevance is normally considered to be deforestation. Unfortunately, estimates of deforestation rates are extremely unreliable, making it difficult to determine precise figures. However, the net release of CO_2 from terrestrial sources, which amounted to between 0.6 and $2.5\,Pg\,C\,year^{-1}$ during the 1980s, has been attributed to deforestation in the tropics. A related problem is deforestation in high latitudes, where models of deforestation have suggested that the conversion of snow-covered forests to snow-covered open areas has resulted in an increase in the albedo (reflected energy), causing a cooling effect in the order of $-0.2 \pm 0.2\,W\,m^{-2}$. Reducing the rate of this deforestation would clearly have an impact on the global carbon cycle.

Trees are seen as a potential means to sequester carbon. This is based on the idea that a one-time benefit can be obtained by planting forests in areas where forests have previously been lost. Tree plantations in the boreal, temperate, and tropical zones are thought to have sequestered about 11.8 Gt C, with an annual sequestration rate of 0.2 Gt C $year^{-1}$. The IPCC has estimated that slowing the rate of deforestation combined with the promotion of natural forest regeneration and afforestation could increase terrestrial carbon stocks in the period 1995–2050 by between 60 and 87 Pg C. In Brazil alone, a reduction in the rate of deforestation by 50% could conserve as much as 125 Mt C $year^{-1}$.

A potentially much more valuable function of forests is as a supply of biomass for burning in power generation. While the carbon stored in the wood is immediately released into the atmosphere, the benefits are gained when the power that is generated replaces power generated from fossil fuels. This approach has been strongly advocated in some European countries, but there is still a need to look at the full costs of the power generation (i.e., including the carbon costs associated with the construction of the power generation plant and with the development and growth of the forest).

In addition to such direct methods, the IPCC has identified a number of silvicultural and management techniques that might be used to enhance carbon mitigation. These include fire prevention and control, protection against pests and disease, changes to rotation lengths, control of stand density, enhancement of nutrient supply, control of the water table, selection of useful species and genotypes, use of biotechnology, reduced regeneration delays, selection of harvesting methods such as reduced-impact logging, recovery of degraded forest, management of logging residues, recycling of wood products, increased use of wood, and efficiency of the conversion process from wood to products, and the establishment and maintenance of forest reserves. These methods all provide means by which the forest sector could contribute to the global effort to reduce anthropogenic impacts on the global carbon cycle.

Impacts of Elevated CO_2 and Climate Change

G E Jackson and J Grace, Edinburgh University, Edinburgh, UK

Introduction

Forests have always been sensitive indicators of climate change. Tree pollen, preserved in lake sediments and bogs, provides a record of how tree species migrated northwards as warming occurred after the retreat of ice about 12 000 years ago. Many tree species reached a maximum northern limit in the warm period (5000–8000 years ago) and then retreated in the somewhat cooler period that followed. On a shorter timescale, most trees leave a faithful record of their annual growth over their lifetime, as annual growth rings in their stems. For northern species there is an excellent relationship between temperature and annual growth. From such records scholars have been able to use ancient wood samples found in old buildings and bogs to reconstruct past climates.

Another indication of the sensitive response of temperate trees to climate comes from phenological gardens where the timing of bud break and leaf unfolding is observed every year. These records show that trees begin their growth earlier nowadays than they did 20 years ago, matching the rise in temperature.

In this article we examine the current rate of climate change, and the predictions that have been made about the future climate. We discuss how forests may be responding to the changing climate, bearing in mind that factors other than the climate are changing too. These factors include the rising carbon dioxide concentration and the rate at which nitrogen (as ammonium or nitrate) is deposited on the land surface.

Climate Changes

Since the end of the last glacial period some 12 000 years ago, the temperatures of the northern hemisphere have increased markedly. Of particular interest are the changes over the last 100 years, which have been unusually rapid. The Intergovernmental Panel on Climate Change (IPCC) has produced a series of reports, the latest of which (the Third Assessment Report) was produced in 2001. This comprises three volumes, the first of which, *Climate Change 2001: The Scientific Basis*, provides the most up-to-date and reliable assessment of the recent state of the global climate. It finds that the global average surface temperature has increased over the twentieth century by 0.6°C (±0.2°C) (**Figure 1**). It also states that globally the 1990s were almost certainly the warmest decade and 1998 the warmest year in the instrumental record.

The second main feature of climate change is an altered rainfall pattern across the globe. After temperature we may expect rainfall to have an important influence on the growth of forests. Over the twentieth century rainfall patterns have changed according to broad latitudinal bands. In most mid and high latitudes of the northern hemisphere continents it is very likely that precipitation has increased by 0.5% to 1% per decade. Over subtropical land areas in the northern hemisphere (10° N to 30° N) it is likely that rainfall has decreased during the twentieth century by about 0.3% per decade. Over the tropical land areas (10° N to 10° S) it is likely that rainfall has increased by 0.2–0.3% per decade, although, interestingly, little change has been found in this region over the past few decades. Over the southern hemisphere no comparable systematic changes have been found in broad latitudinal averages.

Further important changes in the climate which influence forests include changes in cloud cover and changes in extreme weather events, for example seasonal patterns of temperature, heavy precipitation events, storms, fire, snow cover, floods, and droughts. Changes in cloud cover are less certain than increases in temperature and altered rainfall patterns but it is likely that there has been a 2% increase in cloud cover over mid- to high-latitude land areas during the twentieth century. A further potential threat to global climate, which has only recently been appreciated, is the possible increase in frequency and severity of El Niño-Southern Oscillation (ENSO) events. El Niño occurs in the tropical Pacific Ocean and happens when warm water from the western Pacific flows toward the east. Warm surface water builds up off the coast of South America and the earth's atmosphere responds by producing patterns of high and low pressure that can have a profound impact on weather far away from the equatorial Pacific. El Niño is associated with a fluctuation in the circulation in the Indian and Pacific oceans called the Southern Oscillation. Modeling and observational studies suggest that ENSO events are associated with abrupt shifts in climate, which since ecological systems are particularly vulnerable to rapid changes may prove of greater consequence than the gradual changes in other climatic factors.

Reasons for the Climate Changes

The recent and rapid changes in climate are thought, in part, to be induced by human activity. Burning of fossil fuels and changes in land use, especially deforestation, have resulted in increased atmospheric greenhouse gas concentrations. The main greenhouse gases that have increased in the last 100 years are carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O). They have a warming effect on the earth by absorbing the longwave radiation being emitted from the earth that would otherwise escape to space and cool the planet. **Figure 2** shows the increase in greenhouse gases during the last millenium. Since 1750 the CO_2 concentrations in the atmosphere have increased by approximately 0.4% a year from 280 ppm to the present day concentrations of 367 ppm. Methane and nitrous oxide have

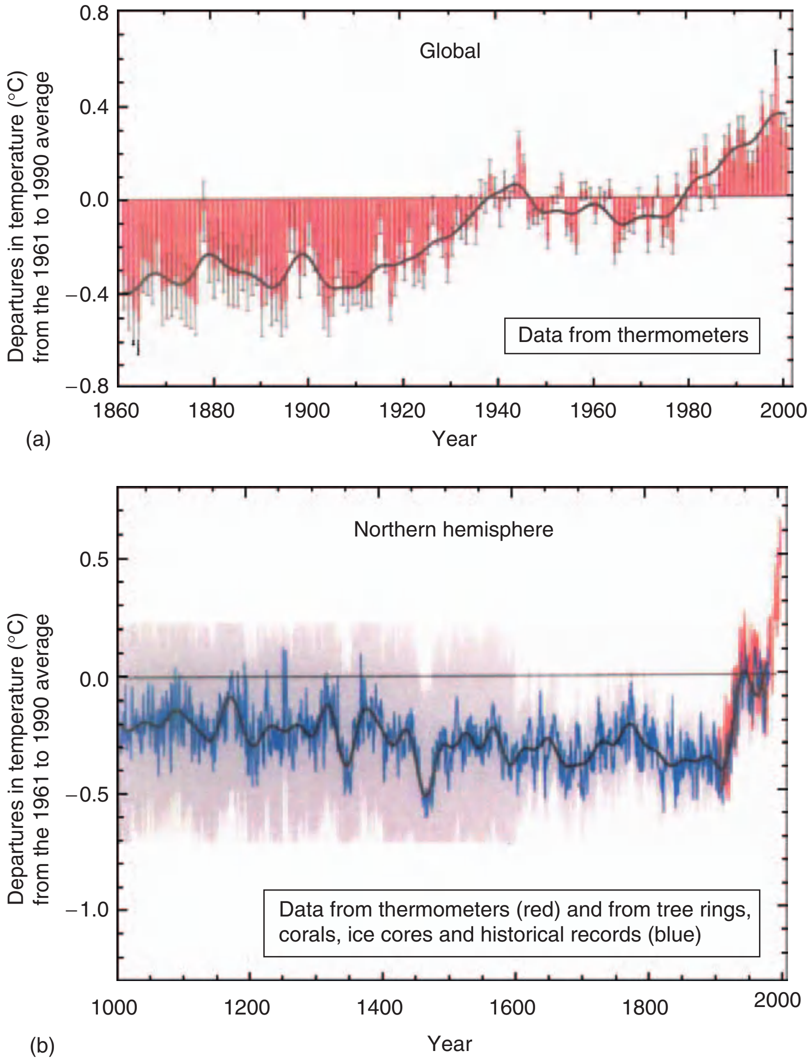

Figure 1 Variations of the earth's surface temperature over the last 140 years and the last millennium. (a) The earth's surface temperature is shown year by year (red bars) and approximately decade by decade (black line, a filtered annual curve suppressing fluctuations below near decadal timescales). There are uncertainties in the annual data represented by the thin black whisker bars (the 95% confidence range). (b) Additionally the year-by-year (blue curve) and 50-year average (black curve) variations of the average surface temperature of the northern hemisphere for the past 1000 years have been reconstructed from 'proxy' data calibrated against thermometer data (see list of the main proxy data in the diagram). The 95% confidence range in the annual data is represented by the gray region. These uncertainties increase in more distant times and are always much larger than in the instrumental record due to the use of relatively sparse proxy data. increased by 1060 ppb (151%) and 46 ppb (17%), respectively, since 1750 and continue to increase. Carbon dioxide is not only a greenhouse gas, it is the raw material from which biomass is synthesized during photosynthesis. Any increase in CO_2 concentration is therefore likely to stimulate photosynthesis.

Predictions of Future Climate Change

The globally averaged surface air temperature is projected by models to increase by 1.4–5.8°C by 2100, relative to 1990 and the globally averaged sea level is projected by models to rise 0.09 to 0.88 m by 2100. Of course, prediction is dependent on the extent to which the burning of fossil fuels increases. These projections indicate that the warming would vary by region, and would be accompanied by increases and decreases in precipitation. There would probably also be changes in the frequency and intensity of some extreme climate phenomena. For example increases in the number of storms in northwest Europe are predicted, leading to the breaking or uprooting of increasing numbers of trees. These predictions assume that the current rate of emissions will not be reduced and that there will

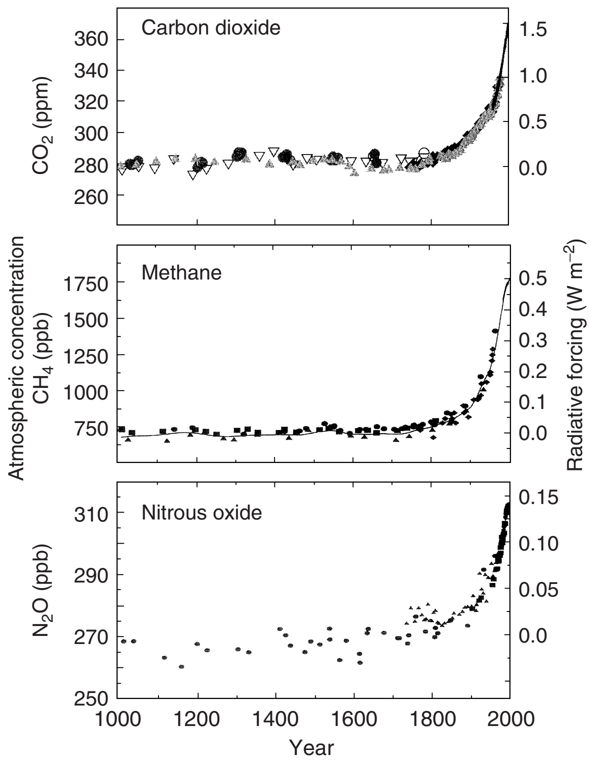

Figure 2 Indicators of the human influence on the atmosphere during the industrial era. Global atmospheric concentrations of the three main greenhouse gases (carbon dioxide, methane, and nitrous oxide) over the past 1000 years. The ice core and fern data for several sites in Antarctica and Greenland (shown by different symbols) are supplemented with the data from direct atmospheric samples over the past few decades (shown by a line for CO_2 and incorporated in the curve representing the global average of methane). The estimated positive radiative forcing of the climate system from these gases is indicated on the right-hand scale. be a rough doubling of current CO_2 concentrations by 2080. The exact effect on precipitation is not fully understood because of lack of knowledge about factors such as cloud formation and behaviour, but preliminary predictions have been made. It is thought that precipitation will continue to increase in the mid to high latitudes of the northern hemisphere, particularly in winter. In low latitudes there will be regional increases and decreases over the land areas. Changes in temperature, rainfall, and CO_2 concentration will naturally have profound effects on the growth, function, and distribution of forests.

Effects of Current Climate Changes on Forests

The results from modelling and other studies suggest that there are potentially beneficial impacts of climate change, such as an increase in the global timber supply from appropriately managed forests in regions of the world which are currently cold. However, this is tempered by the increased possibility of both disturbance factors, such as fires and insect outbreaks, and extreme climatic events which could lead to widespread forest decline. Recent work is now confirming these predictions. Using satellite observations it has been shown that there has been a 'greening trend' in the high northern latitudes associated with an advance of spring budburst by several days and a similar delay in autumn leaf fall. Other data from sample plots across Europe show that the growth of trees has been increasing. This is probably a worldwide phenomenon influenced by elevated CO_2 (the fertilization effect) and the deposition of active forms of nitrogen, ammonium, and nitrate (derived from farming, use of vehicles, and biomass burning). It is difficult to disentangle the effects of these three factors (temperature, CO_2, and nitrogen deposition) in natural systems but the results of many experimental studies focusing on one or both of them enable a clearer understanding of the processes underlying forest change. The experimental systems which have been used to conduct controlled experiments concerning the effects of elevated CO_2 are briefly reviewed below.

Experimental Systems Used to Investigate the Effects of Elevated CO_2 on Forest Systems

Initial studies into the direct effect of CO_2 on trees were necessarily performed on seedlings and often used seedlings rooted in pots. The environments in which the experiments were performed were often very artificial and in many cases the studies generated more questions than they answered. Their results were often qualitatively accurate, but quantitatively unreliable. Subsequent studies have used seedlings rooted in forest soil in larger open-topped transparent chambers (OTCs), and much of our understanding of how forests will respond to elevated CO_2 is from these studies.

Figure 3 shows a facility in Perthshire, central Scotland and is typical of many such OTC systems, in that it uses young trees rooted in forest soil. The chambers were set within a Sitka spruce forest and the trees were, as much as possible, treated in the same way as the surrounding forest. For example trees were planted around the outsides of the chambers to shade the trees within, in the same way as trees in the forest are shaded by their neighbors. The precipitation reaching the trees was that received through the chamber's open top and was therefore also realistic. Half of the chambers were continually flushed with ambient air, and half

Figure 3 Open top chambers (OTCs) at Glendevon, Perthshire, Scotland. Half of the chambers are flushed with ambient air and half with ambient air with additional CO_2 added to maintain a CO_2 concentration of twice ambient. The CO_2 tank can be seen in the foreground. The control room is just inside the site gates, and a nonchamber control area containing four plots with trees but no chambers can be seen at the rear, right of the photograph. This area was included to assess the affects of the chambers themselves on the trees. Photograph courtesy of the Forest Research Photo Library.

with ambient air with additional CO_2 added to maintain a CO_2 concentration of twice ambient. The airflow this generated helped to cool the chambers to more or less ambient levels, except if the ambient temperature was very warm. As the trees grew some were harvested to create space in the chambers, until only four trees per chamber were left and the trees were 4 years old. At this point the trees in elevated CO_2 had begun to grow out of the top of the chamber and the experiment could not be continued. Some OTC experiments have managed to grow trees in conditions similar to these for 6 years, but beyond this it is not practical.

More recently free-air CO_2 enrichment (FACE) systems have been developed in which air with additional CO_2 is delivered to a mature forest via a circle of pipework and vertical pipes containing CO_2-releasing jets projecting up through the forest. **Figure 4** shows FACE rings situated in a loblolly pine (*Pinus taeda*) forest in North Carolina, USA. The main advantage of such systems compared with OTCs is that they more nearly mimic the natural environment, but the main disadvantage is their huge expense both in infrastructure and in CO_2.

Figure 4 The free air CO_2 enrichment (FACE) rings in loblolly pine, North Carolina, USA. Three of the rings are flushed with ambient air and three with ambient air to which 200 ppm CO_2 is continually added. (The ring in the distance is a prototype.) The towers shown support white pipes with perforations for emitting CO_2 into the forest stand. Each 30 m diameter ring uses feedback control technology to control the CO_2 concentration.

Effects of Increased Atmospheric CO_2 on Forest Systems

During the course of their evolution plants have responded to atmospheric CO_2 concentrations ranging from lows of 190–200 ppm during the glacial maxima to 7000 ppm 400 million years ago when plants first colonized land. Photosynthesis itself developed at a time when CO_2 was the most abundant gas in the atmosphere. The present atmospheric CO_2 concentration of around 367 ppm limits photosynthetic CO_2 fixation in almost all tree species (some herbaceous plants are not limited by the CO_2 concentration as they have an evolutionarily more advanced mode of photosynthesis). Increasing the atmospheric CO_2 concentration therefore stimulates the photosynthetic rate of trees (and most herbaceous species) and can result in increased growth rates and biomass production.

Biomass It is usually found that trees in elevated CO_2 have a faster development, so they get bigger more quickly, but they are otherwise very similar to trees of the same size growing in ambient conditions. Results from FACE experiments show a 25% increase in growth in twice normal concentrations of CO_2. Similar results are found from trees growing near natural sources of CO_2 (geological sources, known as fumeroles).

Photosynthesis The reason for these increases in tree biomass in elevated levels of CO_2 is that the photosynthesis of trees is limited at current levels of CO_2. Growth is therefore almost always higher in air with an elevated concentration of CO_2. In one review of more than 500 reports, mostly from the USA, an average stimulation of 54% in elevated CO_2 was found. In long-term experiments (lasting years) plants often show less stimulation of photosynthesis than they do in short-term experiments (lasting hours), as a result of physiological adjustment.

Forest water use Plants absorb CO_2 into their leaves through tiny pores called stomata. They also lose water through the same pores which, when water is limiting is undesirable. In some experiments, elevated CO_2 causes a degree of stomatal closure and in experiments lasting several weeks or more the new leaves that have formed at elevated CO_2 often have fewer stomata per area. A reduction in the stomatal conductance could result in a reduction in the transpiration rate of the forest. Less water would therefore be removed from the soil for the same amount of carbon fixed. In the subtropics and other areas of the world where the rainfall has been decreasing this would enable photosynthesis and growth to continue for longer. A reduction in the quantity of water vapor entering the atmosphere above forests, as a result of reduced transpiration, would also affect regional and potentially global climate feedbacks. This plant atmosphere interaction can be the source of feedbacks from vegetation to atmosphere, which make the future climate very difficult to predict even though quite a lot is now known about the physiology of stomata.

Belowground processes A much-neglected area of research into the effects of elevated CO_2 on forest systems is the processes that occur below ground. These processes must be considered to fully understand forest ecosystem response to climate change. Elevated CO_2 concentrations cause a shift towards the production of more fine roots, compared with trees of a similar size growing in ambient CO_2. This is probably because trees in elevated CO_2 translocate much of their additional carbon below ground and it ends up not only as fine roots, but also as mycorrhizae (beneficial root–fungus associations), and as exudates of organic materials from the roots to the soil. The deposition of carbon directly into the soil stimulates the microbial population and it is frequently found that the respiration rate from soil beneath trees exposed to elevated CO_2 is greater than that beneath trees growing in ambient CO_2.

The quantity of litter (mainly leaves) falling to the ground from trees growing in elevated CO_2 is also increased since these trees have a larger biomass. This litter however usually has a lower concentration of nitrogen relative to carbon than litter from trees growing in ambient CO_2. The microbial soil decomposers of such litter generally require a higher nitrogen concentration and it is hypothesized that it will be degraded more slowly than litter beneath ambient grown trees, which could lead to the build up of recalcitrant carbon pools. Studies of this are inconclusive, and more research is needed. These belowground processes have feedbacks for the global carbon cycle, but mainly because of the difficulties inherent in working with this part of the ecosystem many questions still remain to be answered.

Effects of Increased Temperature on Forest Systems

The challenge facing forests during the current period of warming is the unprecedented rate at which the warming is occurring. Increased temperatures increase the rate of almost all enzymic reactions, up to the point where enzyme degradation occurs. Photosynthesis is therefore usually found to increase over relatively modest increases in temperature but soon reaches a maximum rate. Concomitant with the increase in photosynthesis is an increase in rates of cell division and expansion as well as an exponential increase in respiration, which uses up the products of photosynthesis. It is the balance between these processes of photosynthesis and respiration which determines whether increased temperature will have a positive effect on tree growth. Since respiration has been found to increase more rapidly with increasing temperature than photosynthesis, it is hypothesized that increasing temperature would have a negative impact on tree growth, but both positive and negative results have been found.

Phenology Evidence is now gathering that indicates that elevated temperature has increased the length of the growing season, particularly at high latitudes. Most of this evidence comes from a network of 'phenological gardens' which was established in 1957 across Europe, using plants that were genetically identical. Cloned specimens of trees and shrubs from a parent garden in Germany were planted at 49 sites across Europe, ranging from Ireland in the west to Macedonia in the east and Finland in the north to Portugal in the south. Dates of budburst in the spring and leaf fall in the autumn are noted annually. **Figure 5** shows the timing of leaf unfolding and leaf coloring of birch (*Betula pendula*) from 1951 to 1996 from a similar phenological

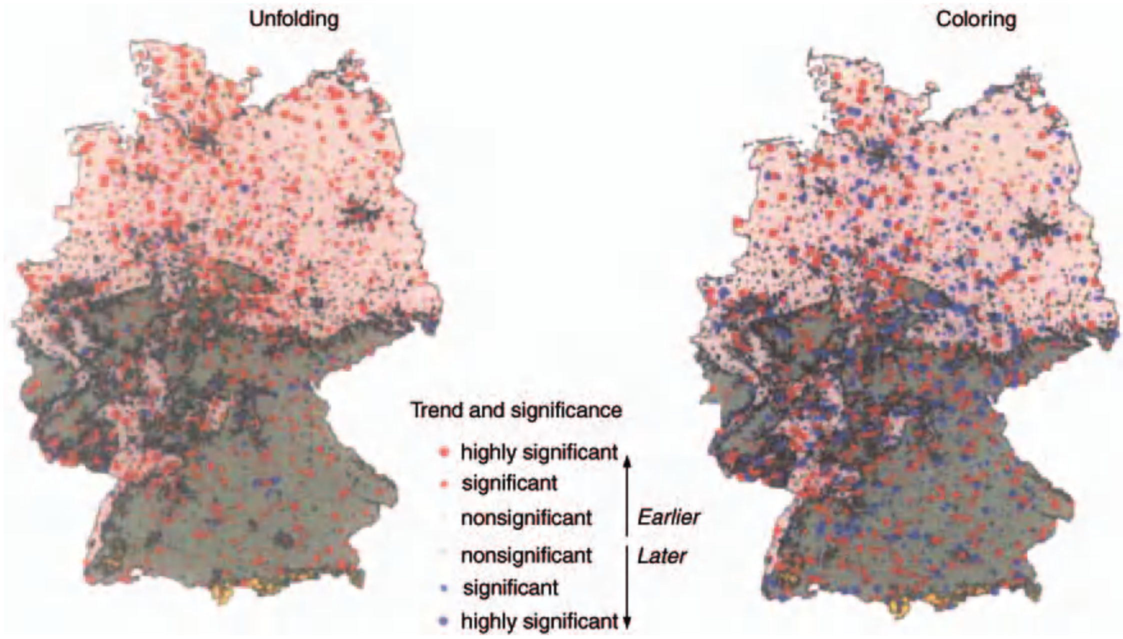

Figure 5 Linear trends in the timing of leaf unfolding (left) and autumn coloring (right) of birch (*Betula pendula*) in Germany. Data are from the phenological network of the German Weather Service and are for long observational series (20 years or more) during the period 1951 to 1996. Each point represents a series for one place. Reproduced with permission from Green RE, Harley M, Spalding M, and Zöckler C (eds) (2003) *Impacts of Climate Change on Wildlife* Cambridge, UK: WWF.

network of the German Weather Service. It shows a clear tendency for leaf unfolding to be earlier and leaf coloring to be later during this period, though the autumn shift was less than that in the spring. The Third Assessment Report of the IPCC suggests there has been a lengthening of the period during which deciduous trees bear leaves of 1.2 to 3.6 days per decade in the northern hemisphere. Moreover, spring 'greening' estimated from satellite data has advanced by 7 days since the 1960s. The regions of most greening are generally inland (except in the arctic) and are north of 50° N. In Alaska, northwestern Canada, and northern Eurasia there has been significant warming over large areas, with the greatest warming of up to 4°C occurring in the winter. This warming is associated with an approximate 10% reduction in annual snow cover from 1973 to 1992 and with an earlier disappearance of snow in the spring. However the earlier start to the growing season could increase the risk of frost damage to deciduous leaves by triggering unfurling before winter frosts have passed. Frost damage to the leaf photosynthetic apparatus would diminish photosynthetic capacity for the remainder of the season. Conifers face a similar problem timing spring dehardening and autumn hardening. There is a trade-off between fully using the extended growing season and minimizing the risk of damage by frosts.

Rapid effects at the treeline Treelines at high latitudes in the northern hemisphere shifted polewards during the early part of the twentieth century. Recent studies in the Swiss Alps show a dramatic increase in the growth of pine and spruce at the treeline. From 1820 to 2000 the temperature in the region increased by 1.02°C per century, which is much faster than the global average. The study found that the growth ring width of trees growing in the region 0–250 m below the current treeline prior to 1940 decreased with proximity to the treeline, as expected. After 1940 there was no decline in the ring width as the treeline was approached. A further study supported these finding and also found that the density of tree rings from the boreal region has decreased since 1960 – an indicator of faster growth. Despite this several studies have shown that the shift in the treeline poleward has been much less pronounced in recent decades than in the early part of the last century. It is hypothesized that increases in water stress and insect attack, amongst other factors may be possible explanations for this.

Pests and diseases Changes in climatic variables may increase frequency, intensity, and length of outbreaks of pests and diseases, especially in parts of the world which are cold. Outbreaks appear to involve range shifts northwards, poleward, or to higher elevations. For example eastern spruce budworm (*Choristoneura fumiferana*) is estimated to defoliate approximately 2.3 million ha of forest in the US and affects 51 million m^3 of timber in Canada annually. Outbreaks frequently follow droughts or dry summers, since drought and increased temperature intensify the stress on the host trees and enables the spruce budworm to lay more eggs (the number of spruce budworm eggs laid at 25°C is up to 50% greater than the number laid at 15°C). In years without late spring frosts some outbreaks have persisted and the budworm has consumed the tree's new growth. A further example is that of *Armillaria* root disease which is found throughout the world and causes significant damage on all forested continents through mortality and growth loss. In regions where the mean annual temperature is presently below the optimum (25°C) for growth of *Armillaria* a warmer climate is likely to result in increased root disease and rate of spread. In general, current forecasts of the response of forest insects and other pathogens to climate change are based on historical relationships between outbreak patterns and climate and further work to look directly at the effects of such attacks on forests which themselves are influenced by climate change is required.

Effects of Increased ENSO Frequency and Extreme Weather on Forest Systems

Many of the dry areas of the world will be particularly affected by ENSO events or other climate extremes, and forest productivity is expected to decrease. Countries in temperate and tropical Asia are likely to have increased exposure to extreme events, including forest dieback and increased fire risk, typhoons and tropical storms, floods and landslide, and severe vectorborne disease. Extreme climate events cause substantial damage to forests. For example during the 1997–8 ENSO event the drier conditions in Indonesia caused an increased frequency of forest fires resulting in a haze over the whole region lasting for many months. South America is also particularly vulnerable to ENSO and is associated with drier conditions in northern Amazonia and northern Brazil and the consequent reduction in forest biodiversity and forest productivity. In contrast southern Brazil and northwestern Peru have experienced anomalously wet conditions. Changes in precipitation levels in general are likely to lead to forest dieback and replacement of poorly adapted forest species with species more suited to the altered water availability. This will result in younger age-class distributions and altered productivity. Computer simulation modeling results have shown that ENSO events are likely to intensify under a doubled CO_2 scenario with the result that dry areas are likely to become drier and mesic areas will become wetter during ENSO events.

Computer Modeling

Computer simulation is a useful tool to address the experimental and practical limitations of research into the impacts of climate change on forest systems. For example a model called G'DAY (Generic Decomposition And Yield), developed in Australia, is an ecosystem model which integrates plant and soil processes for analysing the impact of high CO_2 on terrestrial ecosystems. The model has been used to simulate the response of nitrogen-limited forests to the expected CO_2 concentration in 2050 (about 700 ppm). It operates over periods ranging from a few years to centuries. The model predicts that there will be large initial growth increases of about 30% but that growth rates will reduce over longer timescales, as forests become limited by the shortage of nutrients. The model results change over time largely because the ratio of nitrogen to carbon in the soil changes due to the slow breakdown of organic matter.

Conclusions

Trees are sensitive indicators of climate change. There is evidence that the forests of boreal and temperate regions are responding to the current increase in temperature. They do this by unfolding their leaves earlier, shedding leaves later, and growing faster during the summer (provided there is enough water). They also respond to the increase in CO_2 concentration as enhanced CO_2 has a 'fertilization' effect on photosynthesis. In industrial and heavily agricultural regions of the world there is an additional fertilization effect because of the deposition of 'active' nitrogen (mainly ammonium and nitrate) from the atmosphere. However there are negative effects as well. As insects and pathogens complete their life cycle more rapidly at high temperatures we may expect damage by herbivorous insects and pathogens to be more acute. In the tropics, the annual growth is rarely limited by temperature but is probably very sensitive to changes in rainfall as well as CO_2 concentration. Some modeling studies suggest that Amazonian rainforest may be especially vulnerable to the effects of high temperature and drought, and decline over periods less than a century from now. Currently the temperature is increasing at an unprecedented rate, and the geographical limits of trees are likely to change. Cold regions from which trees are currently absent (at high elevation and latitude), may become colonized in the future. However, forests may die back in warmer regions.

Biometric Research

R E McRoberts, US Department of Agriculture Forest Service, St Paul, MN, USA

Published by Elsevier Ltd., 2004

Introduction

Any discussion of research in a scientific field is subject to caveats because research must of necessity be less definitive than a discussion of the field's established operational practices. First, enumerations of current research topics will be dated and subject to the perspective of the enumerator. Second, the foci of research change quickly and are subject to funding and societal priorities, perceptions of issues that demand immediate attention, and technical and technological advances. Finally, research, by definition, indicates that final solutions have not been achieved and that results may only be reported as preliminary or as works in progress. Thus, this assessment of biometric research in forest inventory should be considered a static summary in a rapidly changing discipline.

Given these caveats, current biometric research in forest inventory is focused in three major areas: forest sustainability, data delivery, and spatial estimation. With respect to forest sustainability, regional, national, and international public constituencies seek assessments of the effects on forest resources of forest management practices and environmental changes. Their demands have spawned international working groups and assessment procedures such as the Ministerial Conference on the Protection of Forests in Europe and the Montreal Process for assessing forest sustainability. Further, they have influenced national inventory programs to broaden the scope of data collection to include observation of attributes such as soil, lichens, pollutant-sensitive plant species, and down woody material. With respect to data delivery, inventory clients demand timely and precise estimates of forest attributes, summarizations, and estimates for their own areas of interest, and access to field data for their own analyses and to augment noninventory data. Finally, with respect to spatial estimation, the traditional emphasis of forest inventory has been the production of large-scale estimates of forest attributes such as area, volume, and species distribution and temporal changes in these attributes with the objective of answering the question, 'How much?' Increasingly, however, forest inventory clients are also asking the question, 'Where?' Answering the latter question requires spatial extensions of inventory plot information across the landscape. Thus, this article focuses on three biometric research topics: forest sustainability, data delivery, and spatial estimation. A vision for forest inventory that simultaneously addresses all three topics is also outlined.

Forest Sustainability

Frameworks for Sustainability Assessments

The 1992 Rio Earth Summit produced a statement of forest principles and conventions on biodiversity, climate change, and desertification. It further called upon all nations to manage development in a manner that sustains natural resources. Definitions of forest sustainability generally incorporate three components: (1) a process based on the integration of environmental, economic, and social principles; (2) satisfaction of present environmental, economic, and social needs; and (3) maintenance of forest resources to assure that the needs of future generations are not compromised. In 1993, Canada convened a seminar in Montreal on the topic of sustainable management of boreal and temperate forests. The seminar was sponsored by the Conference on Security and Cooperation in Europe and focused on defining criteria and indicators that can be used to measure progress toward sustainable development of forests. Criteria are categories of conditions or processes by which forest management may be assessed with respect to sustainability, while indicators are measurable aspects of the criteria. Following the Montreal seminar, the European countries opted to work under the framework of the Ministerial Conference on the Protection of Forests in Europe. North and South American, Asian, and Pacific Rim countries initiated a similar effort formally known as the Working Group on Criteria and Indicators for the Conservation and Sustainable Management of Temperate and Boreal Forests. Informally known as the Montreal Process, this effort focused on the development and implementation of a set of internationally accepted criteria and indicators. The criteria for both the European and Montreal Process groups are identical, and the indicators for the four criteria that can be directly addressed via forest inventory observations are very similar (**Table 1**).

Traditionally, national forest inventories have emphasized the collection and analysis of individual tree attributes such as species, age, diameter, height, mortality, removal, and regeneration and collective tree attributes such as forest cover type, proportion crown cover, and plantation versus naturally regenerated. Although national inventories collected some nontree information before the early 1990s, the 1992 Rio Earth Summit provided the impetus for the development of sampling designs and estimation procedures for entire suites of information related to the health and sustainability of forest resources. Today, national forest inventories are the primary sources of information for regional, national, and international forest sustainability assessments and reporting requirements.

Designs and Analyses

The collection and analysis of data related to the forest sustainability criteria and indicators present a

Table 1 Categories of European and Montreal Process indicators for forest sustainability criteria

Criterion	*Categories of indicators*	
	Ministerial Conference on the Protection of Forests in Europe	*Montreal Process*
Conservation of biological diversity	Forest area	Forest area
	Tree species composition	Ecosystem diversity
	Landscape pattern	Fragmentation
	Threatened species	Species diversity
	Genetic resources	Genetic diversity
	Regeneration	
Maintenance of productive capacity of forest ecosystems	Roundwood and nonwood production	Area and growing stock available for timber production
	Balance between increment growth and fellings	Removal of timber and nontimber products relative to sustainable levels
	Value of marketed services	Area and growing stock of native and exotic species
	Forest under management plans	
	Air pollutants	Air pollutants
Maintenance of forest ecosystem health and vitality	Defoliation and forest damage	Pests, pathogens, exotic species, damage
	Protective area: soil erosion, water preservation, infrastructure, natural resources	Land managed for protective functions
		Soil erosion, organic matter, compaction, and accumulation of toxic substances
		Water bodies with significant deviation from historic properties

myriad of biometric research challenges. For example, the Forest Inventory and Analysis (FIA) program of the US Forest Service has augmented its sampling efforts to include the collection of information on tree crown condition, tree damage, ozone injury to vegetation, lichen diversity as a biomonitor of pollutant exposure, understory vegetation diversity, soil chemistry and erosion, and down woody material. These variables are sufficiently different that distinct sampling designs are usually necessary, as are separate approaches to estimation. For example, down woody material information is collected from line transects, soil information is collected from soil cores, while tree crown condition, tree damage, and ozone injury to vegetation are visually estimated. The additional biometric challenge is to develop methodology for using this raw inventory data to assess more complex phenomena such as carbon sequestration and forest wildfire risk.

Also, because the greatest proportion of the total cost of measuring an inventory plot is the travel to and from the plot location, the sampling designs for the additional variables must be integrated with sampling designs for the traditional variables, either on the same plots or in close proximity to them. In addition, because of the substantial additional cost of obtaining observations for these variables, the number of plots with the additional observations per unit area is substantially less than for traditional inventory plots; for the FIA program of the US Forest Service, the ratio is approximately 1 : 16. Thus, in order to relieve analysts and users from having to choose between only moderately precise regional estimates or imprecise estimates for smaller areas, biometric research must focus on developing methods for increasing the precision of estimates of the current status and change in these variables. Finally, sustainability analyses often depend on detection of spatially disparate pest-, pathogen-, or human-induced phenomena and may require risk-based sampling designs and designs constructed to detect rare events. Although inventory plots may be inadequate for detecting such rare phenomena, they are excellent for identifying areas with high probabilities of detecting these events.

In summary, the collection and analyses of data for evaluating forest management practices with respect to sustainability are increasing in priority. Observations of at least some variables necessary for these analyses will require special sampling designs which must be integrated to the greatest extent possible with traditional inventory sampling designs. Biometric research to develop procedures for estimating the current status and change in these variables at meaningful geographic scales for relevant temporal intervals is crucial.

Data Delivery

Internet Access

Because national forest inventories are typically funded by national governments, there are valid arguments for maximizing the utility of inventory data by making it publicly accessible. Internet access is becoming the medium of choice for distributing inventory data to the public, although a variety of constraints may be necessary depending on form of the data to which access is provided. Internet access to tabular summarizations for the same estimation units as is provided in published inventory reports has become routine with few constraints. However, internet access to tabular summarizations for user-defined estimation units requires real-time computations and is more complex. An approach using map-based estimation is discussed in the section on spatial analysis below. Another approach is to select the plots located in the user's estimation unit and then calculate estimates in the same manner as does the inventory program. If inventory programs calculate estimates on the assumption of simply random sampling, this approach is fairly trivial. However, because of budgetary constraints, inventory programs frequently cannot observe enough plots to satisfy precision requirements for many variables under an assumption of simple random sampling unless ancillary data are used to augment the estimation processes. Many programs rely on stratified estimation and use remotely sensed data, particularly classified satellite imagery, as the means of stratifying estimation units. Inventory data users requesting tabular summarizations for their own estimation units often wish to increase the precision of their estimates by using the same stratifications developed by the inventory programs. However, land cover classifications based on even medium-resolution satellite imagery (e.g., $30 \times 30\,\mathrm{m}$ Landsat thematic mapper imagery) require storage of and access to such large amounts of data that real-time estimation may be severely retarded. One solution is to provide users with summarizations of stratifications for geographic units of predetermined size and configuration. Two approaches are then possible. Either the boundaries of the user's estimation unit are forced to conform to the boundaries of the stratification summary units or the user's estimation unit is used with the stratification summaries for units that do not conform to the user's estimation unit. In the first case, an approximated user's estimation unit is used with the actual stratifications, and in the second case, the actual user's estimation unit is used with an approximated stratification. The research challenge is to select the size of the stratification summarization unit that minimizes the effects of the compromises. This problem may, of course, disappear as storage space and real-time processing speed increase, although it may also be exacerbated as classifications of finer-resolution satellite imagery are used for stratification.

Plot Integrity and Data Privacy

Inventory users often request access to raw inventory data rather than tabular summarizations, frequently for purposes of combining it with noninventory data such as satellite imagery for their own analyses. For example, researchers seek inventory observations for use as training or validation data for classifying satellite imagery or for map validation. For these applications, the exact coordinates of plot locations are usually necessary, either to associate field observations with satellite image pixels or to compare them with map predictions. Although inventory programs release plot information to the public, they generally resist releasing actual plot locations. First, release of plot locations may entice users to visit plot locations to obtain additional information which could result in artificial disturbance of the ecology of the sites and, in turn, induce bias in the inventory estimates. Second, forest inventory programs rely on the goodwill of private forest landowners for permission to observe plots on their land. Landowners generally do not welcome unwarranted or frequent intrusions and often only permit visits by inventory crews contingent on assurances that the plot locations and proprietary information will not be released.

Accommodating users' desires for the greatest utility and distribution of inventory data while simultaneously protecting the ecological integrity of inventory plot locations, preventing unwarranted intrusions on private land, and protecting the proprietary nature of information obtained from plots on private lands have emerged as crucial issues. Two measures have been considered: creating uncertainty in plot locations and creating uncertainty in the ownership of plots on private land. Creating uncertainty in plot locations discourages users from attempting to visit the plots, thus protecting them from artificial disturbance and protecting the landowner from unwarranted intrusions. This measure entails releasing to the public coordinates for plots that are known only to fall within a circle of area A centered at the actual plot location. Creating uncertainty in the ownership of plots on private land protects private landowners from unwarranted disclosure of proprietary information. This measure entails swapping observations between plots on private land. Plots on private land are first grouped into similarity pools with respect to criteria that are stable over time and retain as much utility of the data after swapping as possible, and then information for a proportion of plots within similarity pools is exchanged. Potential criteria for forming similarity pools include spatial location, site characteristics, and perhaps broad forest cover types. When creating uncertainty in plot locations, the area, A, of the circle containing the actual plot location is revealed to the public, although the center of the circle is not revealed. When creating uncertainty in plot ownership, the similarity criteria may be revealed to the public, but neither the swapping proportion nor the plots with swapped observations are revealed.

Although creating uncertainty in the locations and ownerships of plots satisfies the plot integrity, privacy, and nondisclosure requirements, there remain biometric research challenges. Knowing that inventory programs do not release the actual coordinates of plot locations, users often submit maps or satellite image classifications and request that the inventory program validate these spatial products by providing the map or classification categories for locations corresponding to inventory plots. If aggregated summaries of the results for large numbers of plots suffice, then no plot integrity or disclosure requirements are violated. However, if results for individual plots are required, then challenges arise. If the circle of area A is not wholly contained within a single map or classification category, then revealing the map category for an individual plot reduces the uncertainty in the plot location to an area of size less than A.

Users also request that inventory programs assist in satellite image classification efforts by appending the spectral values of satellite image pixels associated with actual plot locations to the inventory data for the plot. Technically, this does not require that actual plot locations be revealed to the user. However, even for medium-resolution satellite imagery, combinations of spectral values are sufficiently unique that the total area of pixels with the same spectral values as the pixel containing the actual plot location is often less than A. In addition, with two or more dates of Landsat thematic mapper imagery for the same scene (i.e., 12–14 spectral bands of data), it is not uncommon for the combination of spectral values for a single pixel to be unique, in which case revealing the spectral values for a pixel associated with a plot also reveals the plot location to within the 30×30 m resolution of the imagery.

The biometric research challenge is to assure compliance with plot integrity, privacy, and nondisclosure requirements while minimizing the area, A, of the circle containing the actual plot location, selecting similarity criteria that retain maximum utility of the swapped data, and minimizing the swapping proportion. Global selections for these parameters are unlikely. First, for areas in which ownership is fragmented into parcels of area less than *A*, creating uncertainty in plot locations may also create sufficient uncertainty in plot ownership. In this case, swapping is unnecessary and would serve only to degrade further the utility of the inventory data. Second, the criteria for establishing similarity pools will differ by region. For example, in mountainous areas, elevation may be an important similarity measure because of its high correlation with species composition, whereas in other regions elevation may be of little use.

In summary, timely delivery of inventory data and data summaries in a variety of formats for a variety of users for a variety of purposes has become mandatory. The biometric research challenge is to do so in the most timely and user-friendly manner that preserves the utility of the data while simultaneously accommodating integrity, privacy, and disclosure requirements.

Spatial Analyses

Traditionally, forest inventory has relied on sample-based estimation methods and has emphasized plot configurations and sample designs that produce efficient and precise estimates of tree-based forest attributes for large areas. Increasingly, however, inventory clients request resource estimates for small areas and estimates of the spatial distribution of the resource. Thus, two related research topics have emerged. First, maps of forest attributes that fill the spatial gaps between plot locations are required, and second, procedures for precisely estimating attributes for small areas are necessary. The challenges associated with both topics require innovative approaches for combining inventory plot data with ancillary data, particularly satellite imagery.

Maps

Mapping forest attributes observed on inventory plots inevitably requires a data source that can function as a bridge between arbitrary mapping units and mapping units containing inventory plots. Satellite imagery is emerging as the bridging data source of preference, although approaches to constructing the bridge depend on the image pixel size relative to the size of inventory plots. When the image pixel size is much greater than the plot size, then the approach is to associate the spectral values of groups of pixels containing inventory plots with aggregated information for groups of inventory plots. When the image pixel size is comparable to the plot size, then plots may be associated in one-to-one relationships with pixels and a variety of classification techniques, including maximum likelihood, regression, and nearest neighbors techniques, may be used. The cost of imagery with pixel sizes orders of magnitude smaller than plot size is generally beyond the budget constraints of national inventory programs, so use of this imagery is not discussed further.

Map-based estimation Maps of forest attributes could simultaneously resolve data access and estimation issues. Estimation using maps requires the uncertainty of predictions for individual mapping units, but these quantities may usually be estimated in conjunction with mapping operation. If the satellite image pixel size is of the same order of magnitude as the inventory plot size, then models of the relationship between plot-level aggregations of inventory observations and spectral values of pixels may be formulated, and inventory plot attributes may be predicted for each image pixel using the spectral values as predictors. When using regression to estimate the parameters of a model with statistical expectation described by a function $f(\mathbf{X};\beta)$, where $\mathbf{X}$ is a vector of image spectral values and β is a vector of parameters to be estimated, the variance of a prediction for an individual pixel is approximated by:

$$\mathrm{Var}(\hat{Y}_i) = \left[\frac{\partial f}{\partial \beta}(X_i)\right]' V^{-1}\left[\frac{\partial f}{\partial \beta}(X_i)\right] + \sigma_\varepsilon^2$$

where σ_ε^2 is the variability of observations around model predictions, and V^{-1} is the covariance matrix of the model parameters where the components of V are given by:

$$v_{ij} = \sum_{k=1}^{n}\left[\frac{\partial f}{\partial \beta_i}(X_k)\right]\left[\frac{\partial f}{\partial \beta_j}(X_k)\right]$$

and where k indexes observations. Thus, the estimate, $\hat{Y}_{\mathrm{tot}}$, for the total of an attribute (e.g., volume, forest area, biomass) for a user estimation unit and the variance of the estimate, $\mathrm{Var}(\hat{Y}_{\mathrm{tot}})$, are provided by:

$$\hat{Y}_{\mathrm{tot}} = \sum_{i=1}^{N}\hat{Y}_i$$

and:

$$\begin{aligned}\mathrm{Var}(\hat{Y}_{\mathrm{tot}}) &= \mathrm{Var}\left(\sum_{i=1}^{N}\hat{Y}_i\right)\\ &= \left\{\sum_{i=1}^{N}\sum_{j=1}^{N}\left[\frac{\partial f}{\partial \beta}(X_i)\right]V^{-1}\left[\frac{\partial f}{\partial \beta}(X_j)\right]'\right\}\\ &\quad + \left[\sum_{i=1}^{N}\sum_{j=1}^{N}\mathrm{Cov}(\varepsilon_i,\varepsilon_j)\right]\end{aligned}$$

where i now indexes image pixels, of which N is the total number. A crucial issue is whether the estimate of $\mathrm{Var}(\hat{Y}_{\mathrm{tot}})$ is larger when obtained from the map or when obtained directly from the plot observations using estimations based on simple random sampling or stratified estimation. The trade-off will be between the small number, n, of plot observations, assumed to be with little or no measurement error, and the large number, N, of mapping unit predictions, each with nonzero prediction uncertainty. If the variance estimate obtained from the map is as small or smaller, then user requests for estimates may be satisfied directly from the map, do not require direct access to plot data, and alleviate concerns about ownership because predictions for individual pixels do not disclose proprietary information. In addition, if the predictions for individual pixels are unbiased, then estimates may be obtained for small areas in which there may be no plots or there may not be enough plots per stratum for stratified estimation.

The spatial challenge to biometric researchers is to construct maps depicting the distribution of forest resources that not only answer the user question, ‘Where?’ but that also facilitate unbiased and precise estimation for both large and small areas. Research on mapping and map-based estimation of forest attributes is also of considerable interest to environmental scientists wishing to relate the status and change in forest resources to climatic, soil, and other environmental spatial data and to forest industry planners wishing to plan roads and select mill locations.

A Vision for Forestry Inventory Estimation

A visionary objective of an inventory program is to associate a tree list, or an aggregation of several tree lists, with each mapping unit. The map will be constructed by imputing to each mapping unit the entire suite of observations from inventory plots associated with similar mapping units. Inventory estimates will be derived from the map rather than from plot observations using sample-based methods, because the former method produces more precise estimates. Further, appropriate correlations among map-based predictions of forest attributes are preserved because entire suites of observations are imputed simultaneously. As with the model-based approach to estimation discussed in the section on spatial analyses, realization of the vision dispenses with many plot integrity, privacy, and disclosure issues.

Realization of the vision requires two crucial components: an adequate data source for bridging the gap between arbitrary mapping units and mapping units containing inventory plots, and an analytical tool that uses the bridging data to impute simultaneously to mapping units all attributes observed on inventory plots. Although a variety of spatial products including soil, climatic, and digital elevation maps may support and enhance the bridging function, the key data source will likely be satellite imagery and will further likely include imagery from active sensors that penetrate the forest canopy. Among the candidate analytical tools, the nonparametric k-nearest neighbors (k-NN) imputation technique popularized by the Finnish National Forest Inventory merits serious consideration.

The k-Nearest Neighbors (k-NN) Approach

With the k-NN approach, for an arbitrary mapping unit, u_i, the set of mapping units, $\{u_j\}$, associated with inventory plots is ordered with respect to the distance, d_{ij}, between u_i and each u_j. Distances are calculated using variables, X, common to all mapping units. A variety of distance measures, including unweighted and weighted Euclidean distance and Mahalonobis distance, are possible. For example, the weighted Euclidean distance, d_{ij}, between u_i and u_j is calculated as:

$$d_{ij} = \sqrt{\sum_{m=1}^{M} v_m (X_{mi} - X_{mj})^2}$$

where m indexes the variables, X, used to calculate distance, M is the number of variables, and v_m is the relative weight assigned to each variable. The value of the attribute imputed to mapping u_i is calculated as:

$$\hat{Y}_i = \frac{1}{k\left(\sum_{j=1}^{k} w_{ij}\right)} \sum_{j=1}^{k} w_{ij} Y_{ij}$$

where k is the number of nearest neighbors selected, the summations are over the k neighbors closest to u_i with respect to the distance measure, and w_{ij} is the weight assigned to each nearest neighbor in the estimation process. Common selections for w_{ij} include $w_{ij} = 1$, $w_{ij} = \mathrm{d}_{ij}^{-1}$, and $w_{ij} = d_{ij}^{-2}$. Calibration of the k-NN approach requires selections for the distance measure, the variables used to calculate distance, variable and nearest-neighbor weighting schemes, and k. Calibration selections are often based on minimizing a criterion such as mean square residual or maximizing a criterion such as proportion correctly classified using a leaving-one-out cross-validation approach.

Several research challenges are associated with operationally implementing the k-NN technique. First, not all aspects of k-NN estimation are intuitive.

Selection of variables for calculating distances between mapping units that are unrelated to the attribute to be estimated may have a detrimental effect on the calibration criterion. Also, selection of a value of k that is too small may result in values of residual mean square that are greater than if the overall mean had been used as the imputation for each mapping unit. Second, implementing the k-NN technique requires all mapping units $\{u_j\}$ containing inventory plots to be ordered with respect to distance separately for each mapping unit for which an imputation is to be calculated. If $\{u_j\}$ is a large set, then the ordering process may require large amounts of time. In addition, calibration may be a trial-and-error process requiring testing all combinations of values of k, distance variables, and weighting schemes to identify the particular combination that optimizes the calibration criterion. Third, defensible approaches to estimation of uncertainty have not been fully developed.

The future of forest inventory, today as it has been in the past, is to deliver more timely, more precise, more comprehensive inventory data and estimates to more users in more formats with less cost. The near-term solution is to provide internet access to spatial products that simultaneously depict entire suites of forest attributes across landscapes and that permit unbiased and precise estimation of those attributes for both large and small user-defined areas of interest. Although certainly nontrivial, imputing tree lists to individual mapping units would not only lead to realization of this vision but would also greatly facilitate compliance with plot integrity, privacy, and disclosure requirements.

Summary

The biometric research challenges in forest inventory are many, vary by program, and change over time. Research challenges were discussed in three topic areas: forest sustainability, data delivery, and spatial estimation. In the area of forest sustainability, the challenges are to integrate sampling designs for variables providing information on the health of the forest with traditional inventory sampling designs and to develop estimation methods that permit precise estimates for temporal trends in the variables using data from a sparse spatial array of plots. In the area of data delivery, the challenge is to provide users access to the greatest amount of data in a form with the greatest utility while satisfying plot integrity, privacy, and disclosure requirements. In the area of spatial estimation, the challenge is to construct maps of forest attributes that depict their spatial distribution and that permit precise estimation for small areas. The challenges are interdependent and will continue for the foreseeable future, although the approaches to addressing them will undoubtedly change.

Design, Performance and Evaluation of Experiments

V LeMay, University of British Columbia, Vancouver, BC, Canada
A Robinson, University of Idaho, Moscow, ID, USA

Introduction

Experimental design is similar to sampling and inventory design in that information about forest variables is gathered and analyzed. However, experiments presuppose intervention through applying a treatment (an action or absence of an action) to a unit, called the experimental unit. The goal is to obtain results that indicate cause and effect.

For each experimental unit, measures of the variables of interest (i.e., response or dependent variables) are used to indicate treatment impacts. Replication is the observation of two or more experimental units under identical experimental conditions. A factor is a grouping of related treatments. For example, the factor could be fertilizer, with three levels representing three treatments (e.g., none, a moderate amount, and a heavy amount) applied to plots of trees (plot is the experimental unit). For each plot, height growth measures are taken and averages are compared among the three treatments; the null hypothesis is that there are no differences among the treatment means. The sum of squared differences (termed, sum of squares) between the average for the response variable by treatment versus the average over all experimental units represents the variation attributed to a factor. Experimental error is the measure of variance due to chance causes, among experimental units that received the same treatment. The degrees of freedom, associated with a factor, are the number of treatment levels within the factor minus one. The degrees of freedom for the experimental error relate to the number of experimental units and the number of treatment levels.

The impacts of treatments on the response variables will be detectable only if the impacts are measurably larger than the variance due to chance causes. To reduce the variability due to causes other than those manipulated by the experimenter, relatively homogeneous experimental units are carefully selected. Random allocation of a treatment to an experimental unit helps insure that the measured results are due to the treatment, and not to another cause. For example, if we have applied the no-fertilizer treatment to experimental units on north-facing sites, whereas moderate and heavy fertilizer treatments are applied only to south-facing sites, we would not know if differences in average height growth were due to the application of fertilization, the orientation of the sites, or both. The results would be confounded and very difficult to interpret.

Variations in designs, issues that arise, and methods of analyses are discussed in the context of forestry experiments. References from a selection of texts are given; however, there are many books on experimental design. The further reading section also includes more recent advances in analysis of experimental data.

Variations in Experimental Design

Introduction of More than One Factor

For many forestry experiments, more than one factor is included for design efficiencies over conducting separate experiments. This also allows for examining interactions among factors, and allows for a more efficient design if there are no interactions. A treatment represents a particular combination of levels from each of the factors. For example, if we have two species and three fertilization levels, then we have six treatments that represent the two factors, using a crossed experiment. We might be interested in the effects of species and fertilization, separately, and also whether these interact, resulting in different fertilizer impacts depending upon the species. **Figure 1** illustrates this example using a completely randomized design (CRD), where the treatments are randomly assigned to the experimental units, with factor A (three levels of fertilization: A1, A2, and A3), factor B (four species: B1, B2, B3, and B4), and four replications per treatment for a total of 48 experimental units.

If both species and fertilization are fixed effects, in that the experimenter would like to examine the mean response for each species and each fertilizer level, we obtain the analysis of variance table given in **Table 1** from the use of a general linear model and least-squares analysis.

If the assumptions of general linear models are met, in that residuals are independent, are normally distributed, and have equal variances among treatments, we can interpret the results. The null hypothesis is tested using an F-test for each factor and for each interaction. A type I error rate (α, significance level), the chance of rejecting a null hypothesis when it is true, must be selected; we reject an hypothesis if the probability value (P-value) for the test is less than the specified significance level. For this example, there is no significant interaction ($P = 0.0539$) using $\alpha = 0.05$; therefore, we can examine species and fertilizer effects separately. There are significant differences between the three fertilizer levels of factor A ($P < 0.0001$), and between the four

A1B1 = 10	A3B2 = 25	A3B4 = 35	A2B2 = 23	A1B2 = 14	A2B3 = 24
A1B4 = 24	A2B2 = 22	A1B2 = 15	A2B4 = 28	A3B3 = 32	A3B2 = 25
A3B2 = 27	A1B4 = 23	A3B3 = 29	A3B2 = 26	A1B3 = 17	A1B1 = 11
A3B4 = 35	A1B2 = 13	A1B4 = 22	A1B1 = 11	A2B3 = 24	A3B3 = 30
A1B3 = 19	A2B1 = 18	A2B4 = 30	A3B3 = 31	A2B3 = 23	A1B4 = 22
A3B1 = 22	A2B4 = 29	A3B1 = 23	A2B1 = 18	A1B2 = 15	A3B1 = 23
A2B2 = 25	A3B4 = 37	A1B1 = 9	A3B1 = 24	A3B4 = 36	A2B4 = 28
A1B3 = 17	A2B1 = 18	A2B2 = 20	A2B1 = 18	A2B3 = 26	A1B3 = 18

Figure 1 Completely randomized design with two fixed-effects factors, randomly allocated to 48 experimental units, with four replications per treatment. For example, A1B1 = 10 indicates that the response variable was 10 for this experimental unit that received factor A, level 1 and factor B, level 1.

Table 1 Completely randomized design with two fixed factors: analysis using a general linear model

Source	*Degrees of freedom*	*Sum of squares*	*Mean squares*	F	P
A	2	1258.17	629.08	514.70	<0.0001
B	3	934.75	311.58	254.93	<0.0001
A × B	6	17.00	2.836	2.32	0.0539
Error	36	44.00	1.22		
Total	47	2253.92			

species of factor B ($P < 0.0001$). The mean values based on these data are: A1 = 16.25, A2 = 23.38, A3 = 28.75, B1 = 17.08, B2 = 20.83, B3 = 24.17, and B4 = 29.08. Further analyses, such as Scheffé's test for multiple comparisons, could then be used to compare and contrast treatment means.

Significant interactions among factors lead to more difficult interpretations, and subsequent analyses must be based on a larger group of treatment means. In the example, if the interaction were significant, the 12 means for each fertilizer/species combination would be used in interpretation and subsequent analysis, resulting in fewer experimental units used to calculate each mean value. Since factors often interact in forests, interactions are often detected.

Issues that may arise in the analysis of this type of experiment include:

1. The assumptions for the residuals are not met.
2. For subsequent analysis, care must be taken to preserve the overall type I error rate.
3. There is difficulty in randomly assigning experiments in field layouts.
4. There are difficulties in inferring results to a larger population. The spatial and temporal scale of forest management is very large, whereas experiments are often small-scale.

These issues are also relevant for other types and variations in experimental design, and are discussed later in this article.

Fixed, Random, or Mixed Effects

Factors can be fixed, in that the experimenter would like to know the change that is due to the particular treatments applied (as in the CRD example), or random, in that the variance due to the factor is of interest. For example, if the impacts of species (factor) on height growth (response variable) were of interest, we could be interested in the differences among the species in the experiment, and how they rank relative to one another (fixed effect), or we could be interested in the variance in height growth due to species (random effect). Commonly, experiments in forestry include a mixture of factors, some random and some fixed (called mixed effects).

When factors are random or mixed, the default *F*-tests, as shown in the CRD example, are not appropriate. The expected mean-squares should be calculated in order to determine the correct *F*-tests. Most statistical packages allow the user to request the correct test. Alternatively, maximum-likelihood approaches may be more appropriate for mixed-effects experiments. A later section in this article presents more information on least-squares versus maximum-likelihood estimation.

Restricted Randomization Through Blocking: Randomized Block, Latin Square, and Incomplete Blocks Designs

Restricting randomization to within blocks is used when the experimental units can be grouped by another variable that may impact the results. In forestry experiments with large experimental units, blocking is often very useful in reducing error variance with only a small reduction in error degrees of freedom. Blocks (or variables that represent blocks, such as trials or sites) are most often random effects. **Figure 2** illustrates a randomized block design (RBD), with factor A (six levels of fertilization: A1 to A6), and two sites. Randomization of factor A is restricted to within sites.

Using a general linear model with fertilization as a fixed effect and sites as a random effect (mixed-effects model) gives the results in **Table 2**.

The interest with RBD is with the factor, not with the blocks; the blocks are simply used to reduce the variability among experimental units. For this example, there are significant differences among treatment means ($P = 0.0015$) As with CRD, subsequent comparisons and contrasts could be made among the treatment means.

The Latin square design extends grouping of experimental units to two variables. For example, two sites may represent north-versus south-facing stands, and there might be a moisture gradient within sites.

Another variation is incomplete blocks, where not all treatments are represented in each block. Such blocks are smaller, and, therefore, cheaper, and also subject to less environmental variation, making them quite attractive for forestry applications. Relatively recent technology on the recovery of interblock information has made the use of incomplete blocks more feasible.

As well as the issues noted for a multifactor completely randomized design, there is the concern that the blocking may not have been needed. In that case, the introduction of blocks does not result in a corresponding reduction in the experimental error. This should be addressed in the design of the experiment; variables used to group the experimental units into blocks should be those that are expected to affect the response variables.

Restricted Randomization Through Splitting Experimental Units

In many multifactor forestry experiments, the experimental unit is split, and different treatments for one factor are applied to the splits, while a single treatment from another factor is applied to the unit. For example, with six treatments representing three fertilizers and two species, we could use six small experimental units and randomly assign the six treatments to these units. However, this might result in an experimental unit that is too small for the mechanical application of fertilizer. An alternative is to apply the fertilizer treatments to three larger experimental units, and then split each unit and randomly assign the species to the split units (called split plots). This is a restriction on randomization. A further extension of this would be to split the units again, and randomly assign a third factor (e.g., particular seedling stocks for a species) to the smallest unit, resulting in split-split plots.

Although the analysis of an experiment using split or split-split plots is very similar to a multifactor experiment where there is complete randomization of treatments to each unit, care must be taken in using the correct experimental error for the units versus the subunits, and interpreting the results.

Nesting of Factors

Treatment levels for one factor may be particular to the level of another factor, resulting in nesting of treatments. For example, for the first level of fertilizer, we might use medium and heavy thinning, whereas, for the second level of fertilizer, we might use no thinning and light thinning.

Nesting of factors will affect both the analysis and the subsequent interpretation of the experiment. An example of a nested design is given in **Figure 3**, with the subsequent analysis in **Table 3**.

When factors are nested, it is not possible to isolate the nested factor from the other factors, nor is it possible to assess interactions between nested and nonnested factors. The correct *F*-tests differ from a crossed experiment, in that the error mean-squares is not used for all *F*-tests. For factor A, there were no significant differences between the treatment means

A2B4 = 22	A1B2 = 15	A2B3 = 18	A1B2 = 14

Figure 3 Nested design with two factors, where the second factor is nested in the first factor, with four replications per treatment.

Table 2 Randomized block design with one factor, randomly located with each of two blocks: analysis using a general linear model

Source	*Degrees of freedom*	*Sum of squares*	*Mean squares*	F	P
Block	1	96.33	96.33	38.03	0.0016
Fertilization	5	320.00	64.00	25.26	0.0015
Error	5	12.67	2.53		
Total	11	429.00			

Table 3 Nested design with two fixed-effects factors, where the second factor is nested in the first factor: analysis using a general linear model

Source	*Degrees of freedom*	*Sum of squares*	*Mean squares*	F	P
A	1	256.00	256.00	7.06	0.1172
B (A)	2	72.50	36.25	23.51	<0.0001
Error	12	18.50	1.54		
Total	15	347.00			

($P = 0.1172$), using the mean-squares for factor B, nested in A for the *F*-test. The means for factor B, nested in A, were significantly different ($P < 0.0001$) using the error means-squares for the *F*-test.

Interpreting nested designs is more complicated than crossed designs. However, nesting may result in efficiencies by reducing the number of experimental units over the number that would be needed for a crossed experiment. Also, nested factors result from a hierarchical design, which is discussed next.

Hierarchical Designs and Subsampling

Commonly in forestry experiments, the experimental unit represents a group of items that we measure. For example, an experiment includes several pots in a greenhouse, each with several plants germinating from seeds. A treatment (specific level of factor A) is randomly allocated to each pot (could be more than one factor, fixed and/or random), even though measures are to be taken on plants. The three factors, which affect the measures on plants, are factor A, pots, and plants. The pots are nested within factor A treatment levels, since pot 1 receiving treatment 1 is not the same treatment as pot 7 receiving treatment 1. Similarly, plants in a pot are nested within pots and factor A treatment levels. The three factors are not all crossed in this hierarchical design; some factors are nested.

A variation on hierarchical designs is measuring a sample of items, instead of measuring all items in an experimental unit. For example, if we have 50 trees in an experimental unit, we may choose to measure only 10 of them for diameter growth.

The analysis of hierarchical designs differs from an experiment with fully crossed factors. All levels in the hierarchy must be included in the analysis. Since lower levels in the hierarchy are often random-effects factors, hierarchical models are commonly mixed-effects models. Although methods for least-squares analysis have been developed, maximum-likelihood estimators for mixed-effects models may be more appropriate, as discussed later.

Introduction of Covariates

The initial conditions for an experiment may not be the same for all experimental units, even if blocking is used to group the units. Site measures such as soil moisture and temperature, and starting conditions for individuals such as starting height, are then measured (called covariates) along with the response variable, and these covariates are used to reduce the experimental error. Covariates are usually interval or ratio scale (continuous).

Issues Arising in Forestry Experiments

Failure to Meet Assumptions

When the usual assumptions of the least-squares method are not met, usual *F*-tests may not be reliable. Transformations of the response variables are commonly used, often requiring a 'trial-and-error' approach until the residuals do meet the assumptions. However, results for the transformed response variable are more difficult to interpret, as mean values do not relate well to the original measurement scale. This is particularly true if a nonparametric analysis via a ranking the response variable (called rank transformation) is used. Alternatively, generalized linear models can be used if the residuals appear to follow a distribution from the exponential family, including binomial, poisson, or gamma distributions. For temporally related data, repeated measures analysis is commonly used. Analysis for spatially correlated data can be more difficult, since data can be correlated in many directions.

Preservation of Overall Error Rate in Subsequent Analyses

The use of a particular type I error rate to test for differences among treatment means within a factor should be preserved in subsequent analyses. For example, if an *F*-test is used with a type I error rate of 0.05, appropriate subsequent pairwise tests should use the type I error rate of 0.05 over all tests.

Difficulty in Randomly Allocating One or More Treatments

Although randomizing the allocation of treatments to experimental units is fundamental to removing confounding of treatments with other impacts, sometimes randomization of all treatments is not possible. For example, the impact of burning as a site preparation method prior to planting is difficult to randomize; burning may necessarily need to be confined to one side of the experimental area, resulting in a restriction in randomization. As noted, the results are then subject to confounding, since there may be another factor in the burned area that influences the response. Experimenters often use the analysis appropriate for unrestricted randomization; however, caution must be used in interpreting results.

Missing Information

For some circumstances, particular combinations of factors may be missing, because of a lack of experimental units, because some of the experimental units are damaged, or because of the nature of the treatments. For example, all trees with the high fertilizer, species 1, die because of a failure in one section of a greenhouse sprinkler system. Analysis of the experiment as a nested experiment may be possible, allowing for different levels of one factor within a level of another factor. Imputation methods may be used to find estimates for missing data. However, at some point, statements of statistical inference may not be possible, if too much of the experimental data is missing.

Size of Experimental Units and Time Scale

For studies of young trees and plants, experimental units can be relatively small, and may be conducted in greenhouses with many experimental units. For larger trees, large experimental units are needed to reflect the scale of processes impacting growth. Difficulties arise in finding homogeneous units. As a result, the number of experimental units is often small, resulting in low power. This becomes more pronounced in studying wildlife habitat and watershed processes, where the scale of some processes is even larger. For these very large-scale processes, often a number of case studies are conducted. Results are more difficult to interpret, since unknown or known confounding may have occurred.

Another complication of forestry experiments is that long time scales are often needed to study forest changes meaningfully. As a result, missing information is more common, measurement standards may change over time, and measures might not be taken at regular time intervals, due to changes in funding. These long-term experiments are difficult to analyze and interpret. Models and graphs are commonly used to interpret trends.

Inferences Made from Experimental Results

Since the aim of experimental design is that results indicate cause and effect, experimental units are carefully selected for homogeneity. Results of experiments can, therefore, be somewhat artificial, since the usual heterogeneity of the biological system has been removed from the experiment. Often researchers include observational studies to attempt to model the biological system, and experimental components to isolate causes and effects. The results of the two types of studies are then combined for a more thorough interpretation.

Power of Experiments

The power of a test is the ability to reject a null hypothesis when it is false. An experiment may have too little power to detect an important difference among treatment means, or conversely, too much power, resulting in detection of significant differences that are of no practical importance.

The ability to detect differences between treatment means increases as the size of the experiment increases, where size is defined as the number of replicates and the number of treatments. Power analysis is the assessment of the power of test for the planned experiment, given the size of differences that have practical importance, and an estimate of the expected variation.

The method of determining the size of the difference that will be detected by an experiment will vary with the design of the experiment. For example, if a randomized block design is used, then more experimental units per block could be used to increase power (sometimes called generalized randomized block design), or more blocks could be established. For split-plot experiments, the power for the factor assigned to the split plot (subunit) is higher than for the factor randomly assigned to the whole plot (experimental unit). Careful design of the experiment should allow for varying sizes of differences for different factors. If power analysis is done following the experiment, the correct analysis given the experimental design must be followed.

Least-Squares versus Maximum-Likelihood Estimation

Many forestry experiments require and benefit from a mixture of fixed and random effects. These different effect types simplify the analysis of hierarchical designs as well as correlations in time and space. Analysis of these models using least-squares techniques can be complicated. Analysis using maximum-likelihood estimators and their variants (restricted maximum-likelihood estimators), is often much more straightforward and flexible. Furthermore, the statistical properties of the maximum-likelihood estimation-style estimators can be superior.

Although maximum-likelihood estimation allows for greater model flexibility, it requires a search algorithm to find a global maximum (overall maximum), unlike generalized least-squares models. For very complex models, only a local maximum may be found, or there may be no convergence. Many statistical packages have built-in procedures for mixed-linear or nonlinear models, allowing for easier application of these relatively new procedures.

Overall Considerations in Designing and Analyzing Forestry Experiments

In order to obtain results that can be interpreted with little or no confounding, experimental units should be carefully selected to remove factors that are not of interest to the experimenter, but would affect the variables of interest. Random allocation of treatments is also needed to equalize the impacts of any remaining factors that were not removed through careful selection. Identifying factors as fixed versus random and using the appropriate design is essential to correct interpretation of results. Also, the correct analysis of hierarchical designs should be stressed; incorrect analyses sometimes appear in literature. For least-squares analysis, expected mean-squares should be calculated to determine appropriate *F*-tests. Power analysis is strongly recommended, during the design of the experiment, to ensure that statistically significant results indicate differences of practical importance.

Because of the large time and spatial scale of many forest processes, experimental units often are large and long-term, in order to have meaningful results. This leads to problems with traditional designs, in that experimental units are large and very heterogeneous, and some are lost over time. Also, there is low power as there are few experimental units. Assumptions of least-squares analysis are commonly not met, resulting in difficulties in analysis and interpretation.

New technologies using maximum-likelihood methods allow greater variability in the analysis of data. These methods have improved our ability to conduct analyses when the assumptions of least-squares analysis are not met, and have increased the flexibility in the design of forestry experiments.

Inference

Scientific inference becomes statistical inference when the connection between the unknown ‘state of nature' and the observed information is expressed in probabilistic terms.

Statistical inference from sample surveys can be model-based, in which inference relies on a statistical model to describe how the probability structure of the observed data depends on uncontrollable chance variables and frequently on other unknown nuisance variables. Inference can also be design-based, in which reliance is placed on probabilistic sampling. The following is a brief summary of both approaches.

In nonprobabilistic or model-based sampling, inference is made by specifying an underlying superpopulation model ξ for the values of the variable in the actual population being sampled where the actual values are considered random variables from the superpopulation. Then the actual population or a sample from it is considered a sample from this superpopulation of interest. Sample elements do not have to be chosen at random or with known probability as long as they are not selected based on their values of interest $y_i, i = 1, \ldots, N$. Inferences and conclusions rely heavily on the model assumed, which can be a serious liability if the model is not correctly specified. But if correctly specified, an increase in precision can be expected over the design-based approach.

The design-based approach to inference relies heavily on probabilistic sampling, in which each unit and pairs of units in the population have a positive probability of being selected and the probability of each sample can be calculated. The statistical behavior of estimators of a population characteristic is based on these probabilities and the probability-weighted distribution of all possible sample estimates. A weakness of this approach is that samples that were not drawn are considered heavily in evaluating the properties of the inference procedure, yet should not inference about a population parameter be based solely on the actual sample drawn? But the approach is objective and the only assumption made is that observational units are selected at random so the validity of the inference only requires that the targeted and sampled populations are the same. And careful attention to sample selection within the framework of probabilistic sampling will eliminate the least desirable samples from consideration. The idea behind probabilistic sampling is to make the sample representative of the population being sampled.

A crucial difference between design-based and model-based inference is that design-based inferences are made about the finite, usually large, population sampled, whereas model-based sampling inference, although initially restricted to the usually small sample being taken, is generalized to superpopulations by the use of models. Note that there is a distinction between enumerative (or descriptive) and analytical (or comparative) surveys. In enumerative surveys a 100% sample of the existing population provides the complete answer to the questions posed, but is still inconclusive in analytical surveys (see **Figure 1** for informative distinctions between analytical and enumerative surveys). Design-based sampling is widely accepted now and we limit our discussion to it.

Basic Concepts

Why Sample?

Most decisions are made with incomplete knowledge. Your physician may diagnose disease from a single drop of blood, for example. We hope that the drop represents the nonsampled portions of the body. A complete census is rare – a sample is commonplace. A ranger advertises timber sales with estimated volume. Bidders take the truth and reliability of this information at their own risk and judgment.

Sampling will frequently provide the essential information more timely at a far lower cost and can be more reliable than a complete enumeration. There are several reasons why this might be true. With fewer observations to be made and more time available, crews will get less tired and remain more committed to careful measurement of the units in the sample. In addition, a portion of the saving resulting from sampling could be used to buy better instruments and to employ or train higher-caliber personnel. But it is critical that the sample represents the population well!

Populations, Parameters, Estimators, and Estimates

The central notion in any sampling problem is the existence of a population, a collection of units with values of variables of interest attached. The units are selected and the values of interest obtained from the selected elements, either by measurement or observation. Whenever possible, matters will be simplified if the units of the population are the same as those that can be selected for the sample. If we wish to estimate the total weight of earthworms in the top 15 cm of soil for some area, it would be best to think of a population made up of blocks of soil of some specified dimension with the weight of earthworms in the block being the unit value. Such units are easily selected for inclusion in the sample and projection of sample data to the entire population is relatively simple. If we think of individual earthworms as the

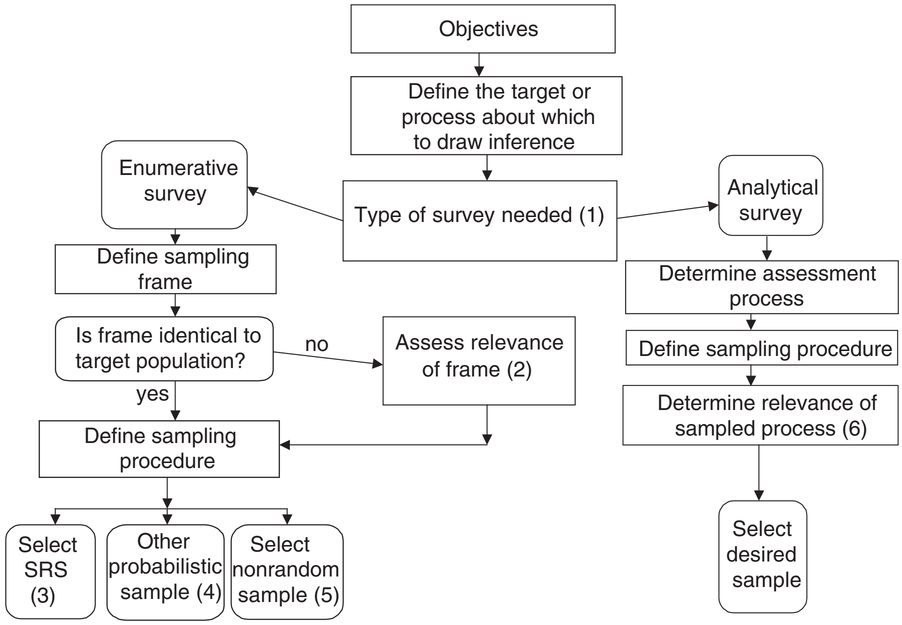

Figure 1 A comparison of enumerative and analytical surveys. The numbers refer to the following:

(1) Are the objectives to draw conclusions about an existing finite population (enumerative survey) or to act on or predict the performance of a (frequently future) process (analytical survey)?
(2) Statistical intervals apply to the frame from which the sample was drawn. Inferences could be biased if the target population is different from the population used for the frame.
(3) Often simple random sampling (SRS) is assumed in constructing confidence intervals.
(4) Confidence intervals can also be constructed for other probabilistic procedures; for example, bootstrapping intervals for the most complex ones.
(5) Statistical confidence intervals are not meaningful here.
(6) Statistical confidence intervals apply to the sampled process and not necessarily to the process or population of interest.

units, selection of the sample and expansion from the sample to the population may both be very difficult.

To characterize the population as a whole, we often use certain constants of interest called parameters. The proportion or the number of living seedlings in a pine plantation are parameters. Usually the parameters estimated are the population mean or total of one or more variables or change therein over time but we are now often also interested in potential explanations of why interesting changes in parameters happen. Parameter estimates are generated from samples using mathematical formulas called estimators.

Bias, Accuracy, and Precision

A good estimate of a population trait or parameter is one that is close to the true value and obtained from a sample at a reasonable cost. But what happens if the person selecting the sample is prejudiced in some manner in terms of either selecting the sample or making measurements? Either one of these would introduce bias into our estimate.

Statisticians have well-defined expressions for bias, accuracy, and precision. Bias is a systematic distortion. A distinction is made between bias in measurement, in method of selecting the sample, or in estimation of the parameter.

Measurement bias can result, for example, when an observer counts trees on plots and systematically excludes or includes border trees.

Bias due to sampling selection arises when certain units are given a greater or lesser representation in the sample than in the population and this is not compensated for in estimation. If we only sample recreation preferences of visitors to a park on weekends, bias would occur because weekday users had no opportunity to appear in the sample.

The technique of estimating the parameter after the sample has been taken is also a possible source of bias. If the most common recreation preference of users on two national forests is estimated by taking a simple arithmetic average of the preferences from the two forests, the resulting average may be seriously biased if there is a considerable difference in their size and use.

Selection and measurement biases are rarely acceptable. Estimation bias may be acceptable when some biased estimator is more precise with only slight bias relative to unbiased ones.

A biased estimate may be precise but it is not accurate. Accuracy refers to the success of estimating the true value of the parameter; precision refers to the clustering of sample values about their own average, which, if biased, cannot be the true value. Accuracy, or closeness to the true value, may be absent because of bias, lack of precision, or both (**Figure 2**).

Variables, Continuous and Discrete

Variation is a fact of life. Coping with some of the sampling problems created by variation is an important part of making valid inferences. For example, tree height is a variable.

Continuous variables are those expressed in a numerical scale of measurement, any interval of which may, if desired, be subdivided into an infinite number of values, say amount of time spent recreating. Discrete variables are qualitative or those represented by integral values or ratios of integral values, either attributes such as the proportion of trees having a specific attribute or counts such as number of people in a recreation group.

Continuous and discrete data may require different statistical procedures. Most of the sampling methods and computational procedures discussed are for use with continuous variables and we focus on those. The procedures for discrete variables are generally more complex. Often count variables can be treated as continuous variables, especially for larger sample sizes.

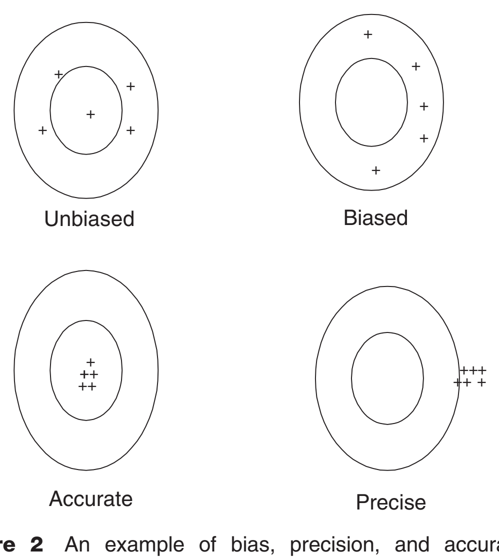

Figure 2 An example of bias, precision, and accuracy if average distance to plot center is used in estimating distance to center of target for five shots.

Distribution Functions

A distribution function shows, for a population, the relative frequency with which different values of a variable occur so that the proportion of units within certain size limits can be determined. Each population has its own distinct distribution function that can often be approximated by certain general types of function, such as the normal, binomial, Poisson, and negative binomial. The bell-shaped normal distribution is often encountered in dealing with continuous variables such as volume per hectare in old-growth stands of timber. The binomial is associated with data where a fixed number of individuals are observed on each unit, characterized by the number of individuals having some particular attribute such as number of seed germinating on a dish. The Poisson distribution may arise where individual units are characterized by a count having no fixed upper limit, particularly if zero or very low counts tend to predominate, such as number of dead trees per hectare. For such data the negative binomial may be useful if low counts do not dominate.

The form of the distribution function dictates the appropriate statistical treatment of a set of data. The exact form of the distribution will seldom be known, but some indications may be obtained from the sample data or from a general familiarity with the population. The methods of dealing with normally distributed data are simplest and fortunately the distribution of means of large samples may be approximated well by this distribution.

Sample estimates are subject to variation just like the individual units in a population. The mean diameter of a stand as estimated from a sample of three trees will frequently be different from the mean estimated from other samples of three trees, and a sample of size 6 would usually produce a more precise estimate than a sample of size 3.

The measure of variation most commonly used is the variance, a measure of the dispersion of individual attribute values about their mean estimated from a sample. Large and small variances indicate wide and little dispersion respectively. The variance of an attribute is a parameter.

The estimator of the variance from a simple random sample is given by:

$$s^2 = \frac{\sum_{i=1}^{n}(y_i - \bar{y})^2}{n-1}$$

where s^2 = sample estimate of the population variance, y_i = the value of the i^{th} unit in the sample, $\bar{y}$ = the arithmetic mean of the sample, i.e., $\bar{y} = \sum_{i=1}^{n} y_i/n$, n = the number of units observed in the sample, and s is the standard deviation, the square root of the variance. Measures of the same form, called the variance of the estimate (s^2/n for simple random sampling (SRS)) and the standard error of estimate (standard error of estimate = square root of the variance of the estimate) are merely the variance and standard deviation among estimates rather than among individual units. Repeated sampling is unnecessary; the variance and the standard error can be obtained from a single set of sample units where the variability of an estimate depends on the sampling method, the sample size, and the variability among the individual units in the population. A sample estimate should be presented with an indication of its reliability as measured by the standard error.

With the standard error, confidence limits can be estimated suggesting how close we might be to the parameter being estimated. For large samples (usually more than 30) the parameter estimated will be on average roughly within 2 standard errors of the estimated parameter (based on an approximation to the normal distribution) unless a 1 in 20 chance occurred (95% confidence limits).

Design

Objectives can be to:

1. Generate current status estimates such as area or volume in a forest, where the forest is, and how it is distributed, and monitor change in such parameters.
2. Identify possible cause-and-effect relationships such as a growth decline in pine forests that could be due to drought or pollution.

Sampling Frame and Representative Sampling

Sampling Frame

Each unit in the population should have a positive, known probability of being selected for the sample so a list of units in the population, called a sampling frame, is required. This frame gives for all N units in the population:

1. The known positive probability of selection, π_i, $i = 1, \ldots, N$ for each unit.
2. The joint positive probability of selection, π_{ij}, i, $j = 1, \ldots, N$, $i \neq j$ for all pairs of units.

In the following we only discuss without replacement sampling of units since it is more efficient than with replacement sampling. Potential sample units can have equal or unequal probabilities and joint probabilities of selection. One of the big advantages of unequal probability sampling is that all single-phase probabilistic procedures used are special cases. Understanding the concept of unequal probability sampling will facilitate comprehension of the other procedures and why and when it is advantageous to use them. This flexibility leads us to the designs discussed: SRS, stratified sampling, cluster sampling, sampling with probability proportional to size (PPS), and systematic sampling with a random start. We then discuss estimation so that we have a sampling strategy consisting of both the sampling design and the estimation procedure used.

Sample Designs

Unequal probability sampling If π_i is the probability of selecting unit i and π_{ij} is the joint probability of selecting units i and j, then the unbiased Horvitz–Thompson estimator of the population total Y is:

$$\hat{Y}_{HT} = \sum_{i=1}^{n} y_i/\pi_i \tag{1}$$

with variance:

$$V(\hat{Y}_{HT}) = 1/2 \sum_{i \neq j}^{N} w_{ij}(y_i/\pi_i - y_j/\pi_j)^2 \tag{2}$$

with $w_{ij} = \pi_i\pi_j - \pi_{ij}$.

Unbiased variance estimators are:

$$v_1(\hat{Y}_{HT}) = 1/2 \left\{ \sum_{i \neq j}^{n} [(\pi_i\pi_j - \pi_{ij})/\pi_{ij}](y_i/\pi_i - y_j/\pi_j)^2 \right\} \tag{3}$$

and

$$v_2(\hat{Y}_{HT}) = \sum_{i=1}^{n} [(1 - \pi_i)/\pi_i^2] y_i^2 + \sum_{i \neq j}^{n} [(\pi_{ij} - \pi_i\pi_j)/\pi_{ij}](y_i y_j/\pi_i\pi_j) \tag{4}$$

Examination of the above equations for understanding If $\pi_i = ky_i$, with k a constant, then $\hat{Y}_{HT}$ in eqn [1] is a constant, and Y and V in eqn [2] would be 0, the ideal situation. This won't happen in practice but we can approximate it. For example, we can practically select trees proportional to their diameter breast height squared if we are interested in tree volume and then the ratios y_i = volume for tree i/x_i = basal area for tree i are essentially constant, so that $(y_i/\pi_i - y_j/\pi_j)^2$ in eqn [2] is close to 0. Similarly, if we are interested in tree counts, then giving each tree an equal weight in selection is efficient. The efficiency of the methods discussed depends on the strength of the relationship between the variable of interest y and the covariate x used for probability of selection, how the covariate is used in selection, and joint probabilities of units. With this background on the ideas behind the sampling designs, we now list them specifically.

Simple random sampling This is the simplest probabilistic approach. All samples of size n have the same probability of selection from the N units in the population. SRS sampling has the advantages that since all units have the same probabilities of selection, applicable analysis techniques are easy to implement and estimation is straightforward and understandable, for example when estimating the mean or total of a population. The estimator of the mean $\bar{y}$ is:

$$\bar{y} = \sum_{i=1}^{n} y_i/n$$

with sample size n and y_i the value for variable of interest on sample unit i.

An unbiased estimator of the population variance of the mean is:

$$\begin{aligned} v(\bar{y}) &= [(N-n)/(Nn)]\left[\sum_{i=1}^{n}(y_i - \bar{y})^2/(n-1)\right] \\ &= [(N-n)/(Nn)]s^2 \end{aligned}$$

where N = number of elements in population, s^2 is the sample variance and $(N-n)/N$ is called the finite population correction. An estimator of the total Y, $\hat{Y}$, would be obtained by multiplying $\bar{y}$ by N, so $\hat{Y} = N\bar{y}$ and its variance would be $v(\hat{Y}) = N^2 v(\bar{y})$.

In various circumstances we may have complete knowledge on a covariate associated with the variable of interest for which we know all the values in the population or we can get those with relative ease. Usually this information is combined with the information on the variable of interest measured on a subsample of the units in the population. This information can be used in various manners in sample selection and in estimation.

Denoting by y = variable of interest and x = covariate, numerous sample selection schemes and estimators are possible.

Stratified sampling This is a simple but powerful extension of SRS where the population of interest is divided into subpopulations or strata of interest. The idea behind stratification is as follows:

1. We are interested in those subpopulations (strata) too.
2. The subpopulations are internally more homogeneous than the population so we can gain efficiency in estimation by distributing the sample in a good manner over them.
3. We are thus able to apply different sampling procedures in the different subpopulations for convenience.

Estimator of the population mean is:

$$\bar{y}_{st} = \sum_{h=1}^{k} N_h \bar{y}_h / N$$

with estimated variance of the mean:

$$v(\bar{y}_{st}) = \sum_{h=1}^{k} (N_h^2/N^2)[(N_h - n_h)/N_h] s_h^2/n_h$$

where: $\bar{y}_h$ = sample mean for stratum h, k = number of strata, $s_h^2 = \sum_{i=1}^{n_h}(y_{hi} - \bar{y}_h)^2/(n_h - 1)$ and N_h and n_h are number of elements in the population and sample respectively in stratum h.

Cluster sampling In this extension of SRS, clusters of (say) trees are sampled by SRS. The idea behind cluster sampling is twofold:

1. It is useful when no list of sample units is available, as is often true with trees, but lists of clusters are available or easily constructed (e.g., stands or plots respectively).
2. It is usually cheaper to visit clusters of trees than individual trees as in SRS because travel expense is often the biggest item in sampling forests.

Ideally, clusters are very heterogeneous, in contrast to strata, because it is more efficient that way. Usually, reduced cost is the reason behind cluster sampling.

If we select n out of N clusters at random and each cluster sampled is measured completely for the variable of interest, then a biased estimator, $\bar{y}_{cl}$, of the mean per unit is:

$$\bar{y}_{cl} = \sum_{i=1}^{n} M_i \bar{y}_{i.} \Bigg/ \sum_{i=1}^{n} M_i$$

where M_i is the number of units in cluster i, with an estimator of the variance:

$$v(\bar{y}_{cl}) = [(N-n)/Nn] \sum_{i=1}^{n} (M_i^2/M_n^2)(\bar{y}_{i.} - \bar{y}_{cl})^2/(n-1)$$

with N = number of clusters in the population, n = number of clusters selected by SRS, $M_n = \sum_{i=1}^{M} m_i/n$

is the average number of units per cluster in the sample, and $\bar{y}_{i.} = Y_{i.}/M_i$, where $Y_{i.}$ is the total for all observations in cluster i.

PPS sampling In PPS sampling it is assumed that there is a covariate (or independent variable) available which is positively correlated with the variable of interest and units are selected proportional to the value of the covariate. The information collected on the covariate and on the variable of interest are combined into an estimator such as the Horvitz–Thompson estimator in eqn [1].

PPS sampling is useful when individual selection probabilities are nearly proportional to the variable of interest.

Estimator of the population mean is:

$$\bar{y}_{HT} = \sum_{i=1}^{n} y_i/(N\pi_i) \text{ with estimated variance :}$$

$$v(\bar{y}_{HT}) = (1/2)\sum_{i\neq j}^{n}[(\pi_i\pi_j - \pi_{ij})/(N^2\pi_{ij})](y_i/\pi_i - y_j/\pi_j)^2$$

with n and N = number of elements in the sample and population respectively and all π_i and π_{ij} are assumed to be larger than 0.

Systematic sampling with a random start In systematic sampling with a random start, a random starting unit is selected and then every kth unit is selected. Systematic sampling assumes that the population can be arrayed in some order, which may be natural, say, days of the week in recreation sampling, or artificial, such as numbered plot locations on a map. The ordering may be haphazard in the latter case but needs to be carefully considered in the earlier one. For example, in sampling use of a recreation area we probably do not want to sample every seventh day, say every Sunday. Systematic sampling has not in the past been generally endorsed by theoretical statisticians because it is not a strictly probabilistic procedure in that several units have joint probabilities of selection of 0. But practitioners and applied statisticians have prevailed in getting it used widely because it is a very practical way of collecting information in the field and avoids the problem of poorly distributed samples in the field, as can happen with some of the earlier procedures discussed. Generally, systematic sampling (with a random start) is treated as SRS, the assumption being that the variance estimate for SRS should usually give an overestimate of the variance achieved with systematic sampling.

Estimator of the population mean is:

$$\bar{y}_{syst} = \sum_{i=1}^{n} y_i/n$$

with variance estimator:

$$v(\bar{y}_{syst}) = [(N-n)/N]s^2/n$$

Note that the formulas are the same as for SRS.

Another estimator Although the Horvitz–Thompson estimator is quite efficient in many situations, it can be quite unreliable in some cases. A specific example involves populations where some of the covariate values, x, are quite small relative to the values of the variable of interest, y. It is clear that if some of the sample units contain y and x values where x is quite small, for those ratios in the estimator, y/x can be quite large yielding large estimates. For example, if $x = 0$ for one or more units, the ratio would be ∞. Units with $x = 0$ would not be selected by PPS sampling (causing bias in the estimation) but would be with SRS. Having extreme values is a general problem with such mean of ratio estimators which are generally not recommended to be used at all with SRS.

In general, more complex – but also more robust – estimators such as the very general, efficient generalized regression estimator developed by C. E. Sarndal should be used if possible:

$$\hat{Y}_{gr} = \sum_{i=1}^{n} y_i/\pi_i + a_{gr}\left(N - \sum_{i=1}^{n} 1/\pi_i\right) + b_{gr}\left(X - \sum_{i=1}^{n} x_i/\pi_i\right) = \sum_{i=1}^{N} \hat{y}_i + \sum_{i=1}^{n} e_i/\pi_i$$

where:

$$\hat{y}_i = a_{gr} + b_{gr}x_i, e_i = y_i - \hat{y}_i$$

$$a_{gr} = \left[\sum_{i=1}^{n} y_i/(\pi_i v_i) - b_{gr}\sum_{i=1}^{n} x_i/(\pi_i v_i)\right] \Bigg/ \sum_{i=1}^{n} 1/(\pi_i v_i)$$

$$V(\hat{Y}_{gr}) = (1/2)\sum_{i\neq j}^{N}(\pi_i\pi_j - \pi_{ij})(e_i/\pi_i - e_j/\pi_j)^2$$

and a variance estimator:

$$v(\hat{Y}_{gr}) = (1/2)\sum_{i\neq j}^{n}[(\pi_i\pi_j - \pi_{ij})/\pi_{ij}](e'_i/\pi_i - e'_j/\pi_j)^2$$

where:

$$e_i = y_i - \tilde{y}_s - b_{gr}(x_i - \tilde{x}_s)$$

and:

$$e_i' = e_i - e_i \left\langle \left\{ \left[(\hat{N} - N) \sum_{l=1}^{n} x_l^2/(\upsilon_l \pi_l) - (\hat{X} - X) \sum_{l=1}^{n} x_l/(\pi_l \upsilon_l) \right] \bigg/ \upsilon_i \right\} + \left\{ \left[-(\hat{N} - N) \sum_{l=1}^{n} x_l^2/(\upsilon_l \pi_l) + (\hat{X} - X) \sum_{l=1}^{n} 1/(\pi_l \upsilon_l) \right] \right\} (x_i/\upsilon_i) \right\rangle \times \left\langle 1 \bigg/ \left\{ \sum_{l=1}^{n} x_l^2/(\pi_l \upsilon_l) \sum_{l=1}^{n} 1/(\pi_l \upsilon_l) - \left[\sum_{l=1}^{n} x_l/(\pi_l \upsilon_l) \right]^2 \right\} \right\rangle$$

where:

$$\hat{N} = \sum_{l=1}^{n} 1/\pi_l, \tilde{N}_s = \sum_{l=1}^{n} 1/(\pi_l \upsilon_l),$$

$$\hat{X} = \sum_{l=1}^{n} x_l/\pi_l, \tilde{x}_s = \left\{ \sum_{l=1}^{n} x_l/(\pi_l \upsilon_l) \right\} \bigg/ \tilde{N}_s$$

and:

$$\tilde{y}_s = \sum_{l=1}^{n} y_l/(\pi_l \upsilon_l)/\tilde{N}_s$$

The generalized regression is biased but consistent in the sense that as $n \to N$, the bias goes to 0.

Variance estimation in general Classical variance estimators discussed above are typically derivable and usually give unbiased or at least consistent estimates of the actual variance. In many cases the actual sampling strategy used is quite complex and such variance estimators cannot be derived. For such situations and even in cases where the actual variances can be derived and computed, other methods can be used, the best-known one being bootstrapping.

Bootstrapping takes full advantage of the computing power now available. It is a computer-based method that allows us to assign measures of precision to statistical estimates. Confidence intervals can be constructed without having to make normal theory assumptions. To illustrate for SRS, if we have a sample of n units of y, with sample mean $\bar{y}$ and variance $\upsilon(\bar{y})$, then in bootstrapping we take B samples of n units with replacement from the n sample units. Then, for each of the B samples we compute means $\bar{y}_b$, $b = 1, \ldots, B$ with overall mean $\tilde{\bar{y}}_B = \sum_{b=1}^{B} \bar{y}_b / B$. The variance between these bootstrap estimates is: $\upsilon(\bar{y}_B) = \sum_{b=1}^{B} (\bar{y}_b - \tilde{\bar{y}}_B)^2/(B-1)$, which can also be used for $\bar{y}$. In addition, the B sample estimates generate a distribution of estimates that can be used for easy confidence interval construction. There are various ways of bootstrapping.

Multi-Information Sources and Sampling over Time

Often covariates are available or information on them can be more easily and cheaply obtained than for the variable(s) of interest, but not for all units in the population, so more than one sampling phase is required. A voluminous literature is available on this topic and on sampling over time too (see Schreuder *et al.* (1993) in Further Reading, below).

GENETICS AND GENETIC RESOURCES

Contents

Genetic Systems of Forest Trees

V Koski, Vantaa, Finland

Introduction

The term ‘genetic system’ was coined in 1932 by C.D. Darlington, one of the renowned pioneers of cytogenetics. His original definition was limited:

> Properties of heredity and variation, methods of reproduction and the control of breeding, we now realize, are in various ways bound up together in each group of organisms. They constitute a genetic system. The genetic systems of different groups of organisms differ widely.

The concept and its definition have later been elaborated as follows. Genetic system refers to any of the species-specific ways of organization and transmission of the genetic material, which determine the balance between coherence and recombination of genes and control the amount and type of gene combinations. Evolution of the genetic systems means the evolution of those mechanisms effecting and affecting genetic variability.

The latter definition contains three crucially significant points:

1. The system is considered species specific.
2. The balance between recombination and maintenance of advantageous gene combinations requires both promoting and restricting mechanisms.
3. Genetic systems are under genetic control and thus subject to evolutionary processes. Species formation is fundamentally based on changes in the genetic system, especially in isolation mechanisms.

A genetic system comprises various components, such as:

- the mode of chromosome organization (genetic information all in one linkage group or distributed to several such groups)

- chromosome cycle (normal meiosis in both sexes)
- recombination index
- mating pattern: outcrossing (allogamy) or self-fertilizing (autogamy), population size, the mode of reproduction (sexual, asexual)
- isolation mechanisms.

Cytological Factors

The genetic information in the nucleus is packed in structures called chromosomes. Each chromosome contains genes in a linear arrangement, with its genes linked together in a consistent sequence, such that the gene programming a given protein (and all its resulting functions) is at a particular position or locus within its chromosome. For higher plants the basic state is diploid, such that there are two homologous versions of each chromosome, one from the mother and another from the father. This comes about from the fusion of haploid gametes, which contain one version of each chromosome from the male and one from the female parent. During meiosis, which is a part of the formation of haploid gametes, maternal and paternal homologs of each chromosome in the parent join together, and these bivalents reassort at random. The higher the chromosome number the larger the number of various combinations of maternal and paternal elements. Furthermore, in a process of duplicating each original chromosome, crossing-over causes exchange of parts of maternal and paternal strains of the chromosome. Towards the end of meiosis the double sets are pulled towards the opposite ends of the mother cell, and finally the single sets draw apart, which leads to a tetrad of four haploid nuclei. Recombination index, a nonlinear function of the chromosome number and the average chiasma frequency, is proportional to the potential number of various recombinant gametes (**Figure 1**). Normal meiosis mixes the maternal and paternal parts of the chromosome set so effectively that the probability of repeating exactly the parental gametes is negligible. Recombination also breaks apart many favorable combinations ('complexes') of genes, but can create some new complexes that are even more favorable in the context of natural selection. Within the overall plant kingdom there are numerous deviations from this classical pattern of meiosis.

Mating Pattern and Gene Flow

The mating pattern, or breeding system, is the second fundamental part of the genetic system. Mating pattern refers to the mode of combining haploid female and male gametes, which leads to the formation of a diploid zygote, embryogeny, and a new individual. The classical function of sexual reproduction is based on cross-fertilization, i.e., the female gamete and male gamete originate from different parents. This process requires cross-pollination, with pollen transported from one individual to the pollen-receptive site of the seed parent. As plants are almost all immobile, an external factor is needed. Wind, insects, birds, and bats are the main pollen vectors, although water rarely and other small mammals occasionally are effective.

Within the plant kingdom numerous kinds of deviations from cross-pollination have evolved, from complete self-pollination to partial cross-pollination. Cross-pollination requires large amounts of pollen, especially in wind pollination. Complete self-pollination leads to loss of heterozygosity (diversity between

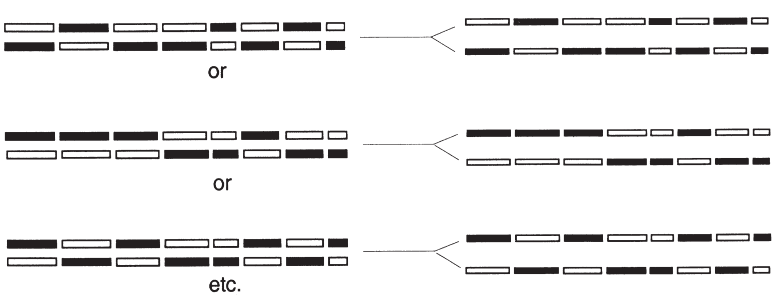

Figure 1 Diagrammatic illustration of chromosomal recombination during meiosis of a species with a diploid chromosome number $(2n) = 16$. The eight chromosome pairs are made up of the maternal part (here white) and the paternal part (here black). During the early part of meiosis the original pairs of chromosomes rejoin and the pairs (bivalents) are assembled to the so-called metaphase plane. The orientation of the maternal and paternal components is random. Consequently, the haploid daughter nuclei (on the right) contain various combinations of maternal and paternal chromosomes. The ideograms show some examples of the orientations. In fact there are 256 different combinations of 8×2 chromosomes. The number of possible combinations (N_R) is a function of the haploid chromosome number (n), $N_R = 2^n$. For instance in case of pines the number of chromosomal recombinants would be 2^{12}, i.e., 4064. Owing to crossing-over, the total number of variations is much higher still. Consequently, the probability of any two of the parental gametes being identical is extremely low in ordinary meiosis.

duplicate copies of the same gene) and recombinants during a few generations, and thus wipes out the original benefit of sexual reproduction. On the other hand, selfing can preserve favorable gene combinations, with minimal allocation of energy to pollen production.

Outcrossing plant species have several mechanisms to enhance cross-pollination. One sure solution is dioecy, i.e., female and male flowers on separate individuals (e.g., *Cedrus* spp., *Populus* spp., *Juniperus* spp.) (**Table 1**). Monoecy means that, while there are separate female and male structures, they both occur in one and the same individual, but it is often combined with features that favor cross-pollination. For instance, female strobili may develop in the upper part of the crown and male strobili in the lower part (e.g., *Abies* spp., *Picea* spp.), reducing chances of self-fertilization. Timing of female and male flowering can be slightly different. When female flowers open prior to pollen shedding in the individual parent, foreign pollen is at an advantage, especially if the space for pollen grains is limited. This phenomenon is called metandry. In monoecious plants sexual asymmetry is common; some individuals carry predominantly female strobili, some others mostly male strobili. Some flowering plants have structural heteromorphism in their hermaphrodite flowers, which results in pollen being deposited on separate parts of the pollinating insects. Cross-pollination requires some external agent to transfer pollen grains of one individual on the receptive organs, ovules, or pistils of another individual of the same species.

Table 1 Occurrence of dioecy and monoecy among 24 genera of conifers. Some genera (e.g., *Cedrus, Juniperus and Podocarpus*) include both monoecious and dioecious species, and exceptional individuals exist in most species.

Genus	*Dioecy*	*Monoecy*
Abies		x

Wind pollination is characteristic of gymnosperms, but is also quite common among angiosperms. Wind carries light pollen grains over considerable distances, but successful wind pollination must be based on some key factors: (1) synchronization of flowering time, (2) abundant pollen production and (3) avoidance of harmful effects of pollen from other species. Animal pollination is rather recent in the evolutionary time scale, and it represents a huge diversity of coevolution of generative organs in the plants and the respective animal pollinators. In addition to various kinds of insects, birds and mammals (mainly bats) also transfer pollen while collecting food from flowers. There are many fascinating examples of highly specialized pollination systems. Even though many pollinating insects use pollen for their nutrition because of its high protein content, essentially lower pollen production is sufficient than in wind pollination. On the other hand, the probable distance of pollen transfer is much shorter.

Except for dioecious plants, the pollen deposited on the pistils (or ovules of gymnosperms) contains more or less pollen grains of the same individual; in other words, partial self-pollination is common. If the plant's own pollen is accepted, self-fertilization follows. In outcrossing flowering plants (angiosperms) a special self-incompatibility system prevents the germination of own pollen or retards the growth of the pollen tube. This incompatibility mechanism is usually based on one locus, denoted *s*, with a large number of alleles. If a pollen grain (or even its parent, in some cases) carries the same allele as the pistil, incompatibility prevents fertilization. This kind of system evidently does not exist in conifers, because pollen grains deposit directly on the ovules. After entering the pollen chamber self pollen grains germinate normally and, after the species-specific, shorter or longer rest period, fertilize archegonia as successfully as foreign pollen. During embryogeny, however, most of the selfed embryos abort owing to homozygosity of embryonic lethals. Because there are several archegonia and pollen grains in each ovule, a sound seed may still develop despite the abortion of one or more embryos, if there is at least one outcrossed zygote (or a 'balanced heterozygote' from selfing).

Self-incompatibility and embryonic lethals may be considered a part of the genetic load because they restrict seed production. In combination, however, they maintain high outcrossing rates despite partial self-pollination. Outcrossing and subsequent heterozygosity must be advantageous in long-lived plants, especially trees, as either self-incompatibility or embryonic lethals in combination with archegonial polyembryony are so predominant. Neither of these systems is absolute; spontaneous selfing does take place, and controlled self-pollination results in some germinable seeds. The inbred seedlings usually display strong inbreeding depression, and most soon die under competition. Self-fertilization can occasionally produce offspring of full vigor, through fortuitous lack of genetic load in parents or fortuitous occurrences of balanced heterozygotes. In this respect the typical genetic system of a gymnosperm is highly flexible in its stochastic (probabilitistic) discrimination against results of self-fertilization rather than self-incompatibility.

Gene flow is a process that affects the rate of recombination and population structure of species. A theoretical, so-called Mendelian population is closed and tends to preserve its genes and its genotype frequencies in a Hardy–Weinberg equilibrium. Exchange of genetic material between populations, however, alters gene frequencies and enhances recombination. As trees are immobile organisms the only option is through reproductive material. The most mobile medium is pollen but many trees have seed that can be transported over considerable distances. Windborne pollen, in particular, may travel hundreds of kilometers without losing viability. On the other hand, pollen must meet receptive female flowers in order to generate a new individual; a pollen grain carries only a haploid genome.

Mode of Reproduction

Simple organisms, such as bacteria, reproduce asexually though cell division. Multiplication of genetically uniform lines is exponential in favorable circumstances. Occasional mutations and recombination events provide adaptability when they are coupled with short generation time and exponential reproductive capacity. Typical sexual reproduction of flowering plants requires considerable allocation of resources to reproductive organs, and the complex array of events is vulnerable. Altogether, sexual reproduction is not optimal in all respects. A large number of plant genera and species have in fact diverged from ordinary sexual reproduction and continue their existence with various forms of reproduction. Cleistogamy, apomictic seed, bulbs, buds, root suckers and other forms of vegetative propagation are common means of reproduction among plants, although in the long term most of these are generally interspersed with at least occasional outcrossing events.

Isolation

Each species is by definition essentially a closed biological unit, within which mating and subsequent sexual reproduction is possible. In the formation of new species the development of isolation mechanisms, following for example disruptive selection, is a crucial step. As long as the new lines that are produced are able to interbreed they are not separate species in the strict sense. Thus, isolation is the factor that is antagonistic to overwhelming recombination and gene flow. The function of isolation is to maintain the species' specific gene complexes and to prevent contamination from other species that will threaten the species' integrity if not its fitness as well. Isolation is predominantly a one-directional phenomenon. The escape of pollen grains from a population of any species does not cause change in the gene pool of the donor population. The participation of the pollen in the paternity of the offspring in the receptor population must be prevented by means of isolation.

Several types of isolation exist. Geographic isolation, i.e., isolation by distance, is a special case. It has come as a result of ancient external forces, such as tectonic processes or climate changes, that separated parts of the original range by even thousands of kilometers. The evolutionary processes caused divergence in morphological and ecological characteristics of those sister species or allopatric species, but there was no pressure to develop cross-incompatibility barriers. Consequently, sister species from Europe and North America often hybridize if artificially grown next to each other. Species hybrids of larch (*Larix*), fir (*Abies*), and poplar (*Populus*) are well known examples in many arboreta. The lack of isolation causes trouble in certain instances of gene conservation, when autochthonous populations are subject to pollution from stands of introduced species. The problem may be even more serious in case of *ex situ* conservation of species, especially rare (e.g., *Abies*) species with extremely small, endangered natural stands. When species share a common territory, in other words they are sympatric, they must have effective mechanisms to preclude interspecific hybridization.

Spatial Isolation

Spatial isolation at least reduces interspecific pollination in animal-pollinated species, especially when they grow on ecologically different habitats. On the other hand, bats and solitary bees can travel significant distances while visiting different trees of a species. Windborne pollen of forest trees can travel over 10 km, and spatial isolation is rather ineffective.

Temporal Isolation

Temporal isolation is caused by nonoverlapping flowering times. Typically wind pollination occurs during a short seasonal period, being heavily dependent on close synchrony among individuals in their flowering times. This kind of behavior, in addition to being needed for effective pollination, facilitates the avoidance of interspecific pollination.

Incompatibility

Incompatibility, i.e., a biochemical mechanism that prevents the normal functioning of pollen grains of foreign species, is the most effective barrier against interspecific hybridization. This barrier may sometimes partly fail such that hybrids appear at low frequency. Sometimes the hybrids may lack fitness in the wild, but sometimes they may even show hybrid vigor.

Hybrid Sterility

Hybrid sterility is the final alternative of culling species hybrids. Sterility is thought to be mostly caused by meiotic disturbances, when the homology of chromosomes is imperfect, or when the chromosome numbers do not match. There are still other isolation mechanisms even though the hybrid may be fertile. They may for example have poor field survival, or segregation may cause unbalanced phenotypes in the second generation. On the other hand, rare coincidences of successful hybrids and 'failure' of isolation, often coupled with polyploidy, have resulted in new species.

Forest Trees

Forest trees are large, long-lived organisms, which have immense ecological and economic value. The sustainability of forest ecosystems and the maintenance of genetic diversity may be threatened by exploitation and changes in land use. As the genetic system and its components determine the capability of a population to adapt and to undergo evolutionary changes, the components promoting genetic variability and regeneration are considered to be of utmost importance. From the biological point of view, however, isolation mechanisms must not be neglected. Introduced tree species may hybridize with autochthonous ones, which is usually undesirable (e.g., in black poplar, *Populus nigra*).

Forest trees comprise a huge number of species, which in terms of plant systematics do not form any uniform group. Even though conifers represent only a small fraction of the total, the components of their genetic systems have been investigated much more comprehensively than those of angiosperms. This is mainly due to the great economic value and ecological significance of many conifers. Also, their chromosomes are much easier to study, and their reproductive organs, pollen grains and ovules are large enough to study with small magnification.

Conifers

The number of remaining genera of conifers is around 50 and the number of species close to 600. The numbers of genera and species vary among textbooks and catalogs, depending on each author's taxonomic views. The crucial fact is that the extant species are only a small fraction of the ancient diversity.

The chromosome numbers of conifers are extremely uniform when compared to those of angiosperms. With very few exceptions, the somatic chromosome number ($2n$) is 22, 24 or 26. Thus, almost the entire group is diploid. There are differences in the chromosome morphology, e.g., in the length of the arms among species, so that the karyotypes are variable. Normal meiosis, including crossing-over, takes place in both female and male gametes. The chiasma frequency is above 2; in other words there are, on average, at least two crossing-over events in each bivalent. These figures indicate that the potential for recombination is high, owing to recombination of maternal and paternal chromosomes and is further increased by numerous chiasmata. The huge amount of gametes, especially pollen grains, makes possible the manifestation of immense numbers of potential recombinants.

Conifers are wind-pollinated plants. Most species are monoecious, but there are dioecious species (e.g., *Cedrus* spp., *Juniperus* spp., Podocarpaceae) too. As the transport of pollen grains from male catkins to the female inflorescence is largely a random process, the effective pollination of ovules requires abundant and simultaneous pollen shedding. One big tree produces several hundreds of grams of pollen at one time, even though the individual pollen grains of conifers are very light. One tree releases some 10^{10} pollen grains, and on a per-hectare basis the order of magnitude is 10^{12}. Air currents carry pollen grains far from a source and only a very small fraction happens to hit the female strobili of the neighborhood. Conifer pollen is quite resistant to desiccation and ultraviolet radiation. So the pollen cloud immigrating from another stand of the same species can cause effective gene flow. This kind of gene flow has been detected as pollen contamination in many seed orchards (**Figure 2a**).

Partial self-pollination is common in monoecious species despite the temporal and spatial differences

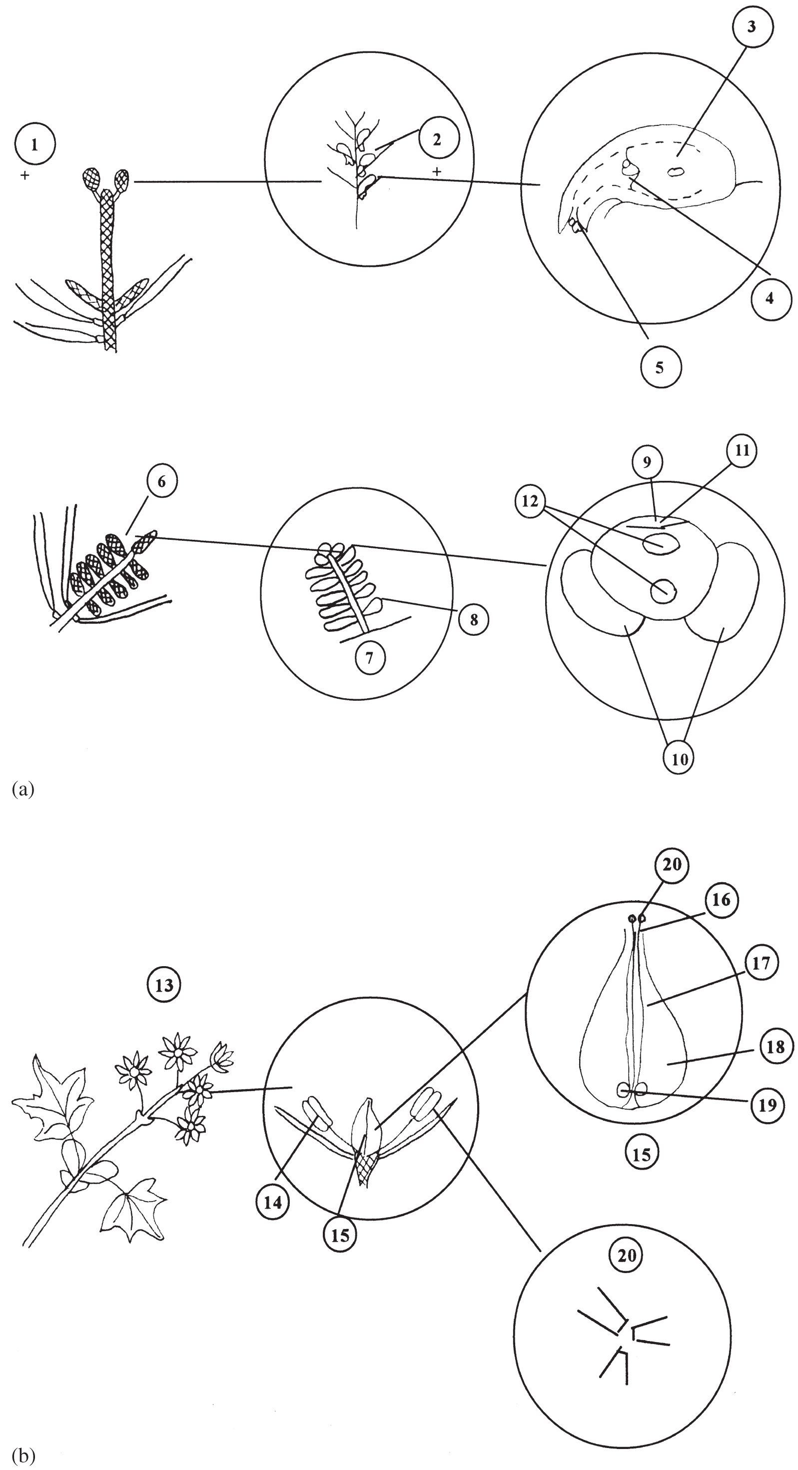

Figure 2 Schematic illustration of the differences in the floral organs of (a) conifer (pine) and (b) angiosperm (maple). (a) A female strobilus (1) of pine consists of an axis, supporting scale and ovuliferous scales. There are two ovules (2) at the base of each fertile scale. An ovule consists of nucellus (3), pollen chamber (4), and micropyle (5). Pollen grains attach on the micropylar filaments and they are transported into the pollen chamber by a pollination drop. Male strobili (6) of pine are on the basal part of the new shoot, mainly in the lower part of the crown. A male (7) strobilus (catkin) has nothing but an axis and scales (microsporophylls) (8) with saclike microsporangia that are filled with pollen. Pollen grains (9) are rather big and they have two air sacs (10). The body of the pollen grain contains a few haploid cells (11) and two haploid sperm nuclei (12). (b) In angiosperms the basic type of flower has both female and male parts. Often numerous flowers make up an inflorescence (13). A single flower of maple has four sepals, four petals, eight anthers (14), and a pistil (15). The pistil consists of stigma (16), style (17), and ovary (18). The ovules (19) are inside the ovary, and the pollen grains (20) are deposited on the stigma (by insects). Pollen tubes have to grow through the style until they reach the egg cells within the ovary. Immense variability of structure of the reproductive organs exists especially among angiosperms.

of female and male flowering. Inbreeding is, however, significantly restricted by embryonic lethals, which cause abortion of selfed embryos. The embryonic lethals are recessive genes which make their homozygotes nonviable. They are a part of the genetic load. Conifer species with large distributions and a continuous population structure usually carry numerous such embryonic lethals. Some species with a small distribution area have been purged and they may be relatively self-fertile. Altogether, most conifers studied so far display high rates of outcrossing and large genetic diversity among individuals in populations. Conifers have never been found to have self-incompatibility mechanisms as such to prevent self-fertilization, but incompatibility does exist to some extent between even closely related species.

Angiosperms

Broadleaved trees are representatives of flowering plants, which are younger than conifers from the evolutionary point of view. Diversity is characteristic of broadleaved trees when compared to conifers. An estimate of species is 25 000, all belonging to the group dicotyledons. The number of genera is in the thousands, and numerous families include trees. Often there are both herbaceous and woody plants in the same genus. In fact there are probably still numerous broadleaved tree species undiscovered, especially in tropical forests. On the other hand, the components of the genetic system have been investigated only in relatively few species. The commercially important species of the temperate and boreal zones are fairly well known, but many basic features of flowering biology and cytology of most species are unknown.

The chromosomes of broadleaved trees are very small, which does not mean that they contain less genetic information than the large chromosomes of conifers. The minute size causes problems in cytological studies. Even the counting of the exact number is tedious, and a detailed survey of meiosis is most difficult.

The chromosome numbers vary widely. This is not surprising because the group consists of various taxonomic categories. Polyploidy has played an important role in species formation, and different levels of ploidy are found even within one genus (e.g., *Betula*). Sometimes the geographical races of one species can have different levels of ploidy. In any case, the chromosome numbers are large enough to produce a large number of chromosome recombinations in meiosis (**Figure 2b**).

Flowering biology and pollination mechanisms are extremely diverse. The wind-pollinated species of the temperate and boreal zones have rather similar pollination to that of conifers. Where the pollen vectors are animals, the pattern is highly variable. Most of these tree species grow in mixed forests and do not occur in stands or even groves but as scattered individuals. In general, animals do not carry pollen over such long distances as wind does. Thus gene flow through pollen migration tends to be lower than in wind-pollinated species. On the other hand, fruit and seed may be dispersed by animals or float on water over considerable distances.

The structure of the gynoecium of angiosperms facilitates the functioning of incompatibility mechanisms. Outcrossing tree species have self-incompatibility, and interspecific incompatibility very often prevents the germination of foreign pollen grains.

Conclusion

The life-form and strategy of forest trees is typically coupled with high degrees of heterozygosity and potential to produce broad genetic variation in the offspring. The genetic system of successful species must have met this requirement. These features of the genetic system appear to have been crucial to the long-term success of forest tree species. The profuse production of pollen and seed becomes understandable against this background.

A sound knowledge of the structure and functioning of the genetic system of trees not only helps to understand trees' life but it is also essential when planning the management of genetic resources. This applies especially to all efforts to conserve genetic resources and to maintain genetic diversity of forest trees. Even though many species are capable of vegetative regeneration, e.g., coppicing or root suckers, sexual reproduction is essential and outcrossing seems to be the predominant mating pattern. Therefore, in addition to a sufficient number of trees to sample an adequate proportion of the gene pool, the requirements of the functioning of the genetic system deserve attention. As regards wind-pollinated species the stands should be fairly large and separated from undesirable pollen sources. In any case of animal pollination the pollen vector should be known, too, and its environment be maintained.

Quantitative Genetic Principles

R D Burdon, New Zealand Forest Research Institute Ltd, Rotorua, New Zealand

Introduction

Response to selection is the basic prerequisite for successful genetic improvement. Within a species, the entities that are selected can be populations (or provenances) or individuals that can be used as seed parents or as clones for mass propagation. Where selection of individuals is involved the genetic improvement amounts to breeding, in which cumulative genetic gain is sought over successive generations. Efficient breeding is dependent on an understanding of the factors governing response to selection, in both the short term and the long term. Prediction of response can indicate what genetic gain is achievable and, when applied to alternative selection scenarios, it can be used to indicate how best to achieve the gain.

The classical tool for predicting response to selection, and optimizing various selection procedures, is quantitative genetics. This is based upon a model of individual gene action. It embodies the neo-Darwinian synthesis, which reconciles the usual pattern of continuous variation with Mendel's discovery that units of heredity represent discrete factors. Practical implementation is usually based on assuming that each trait is controlled by large numbers of genes ('polygenes'), each of very small effect, at widely dispersed sites or loci in the genome. This treatment will often be a major oversimplification of reality. Nevertheless, it is typically a powerful and remarkably robust framework for predicting response to selection and illustrating various guiding principles.

After a basic exposition of the genetic model, important topics are:

- how response to selection is governed by the different parameters, which need to be known at least reasonably well
- how the same principles can be extended to responses to progeny testing
- the factors governing the efficiency of various forms of indirect selection for breeding goals
- how the principles can be applied to multitrait selection
- how genotype × environment interaction can affect response to selection, appropriate structuring of a breeding program, and appropriate deployment of genetic material
- factors governing longer-term response to selection, as opposed to short-term, which need to be considered in structuring populations.

Complementary information needed by the breeder (but often very imperfectly known) includes the cost structures for the various breeding operations, and the economic worth functions for metric values of various traits. Such information allows efficient allocation of effort, and enables the breeder to decide on the appropriate emphasis to place on different traits.

The principles are far from specific to forest tree breeding, but certain features of forest tree breeding, notably the amount of physical resources entailed, have favored much explicit use of the quantitative genetic model.

The Basic Model

It is appropriate to state the basic role of genetic influences in governing the phenotype (P), the phenotype being the tree as one sees it and can measure it for any particular trait. We have the relationship

$$P = G + e = A + NA + e$$

where G denotes the effect of the genotype, and e denotes the effect of the environment. The latter is typically a local environmental effect, e.g., an effect of poor planting of the individual tree or a patch of ground with missing topsoil, as opposed to measurable effects of the general environment.

It can be seen that G has two components: (1) A, which results from additive gene effects, whereby offspring tend to be intermediate between their parents, and which are the effects that form the basis of cumulative genetic gain over generations, and (2) NA, which results from nonadditive gene effects, whereby offspring tend to depart from intermediacy between their parents, and which cannot be recaptured and accumulated over successive generations. Such effects can include dominance of expression of one allele over another at a single locus, or epistasis, whereby the effect of one allele at a locus can be conditional upon what allele(s) is/are represented at one or more other loci.

Note that $A/2$ represents the general combining ability (GCA) of the parent when it is crossed with the rest of the population to produce a half-sib family.

Complications that can arise, but are generally disregarded here, are epigenetic effects. Such effects can often masquerade as true genetic effects. They can include maternal effects which, in the case of seed-weight effects, are usually transient. However, clonally propagated material is subject to 'C-effects,' which typically reflect the state of the material at time of propagation and often can be erased only by sexual reproduction (seed production).

Key Genetic Parameters

Variances In terms of variances (which represent the squares of standard deviations, and for which usual notation is either V or σ^2), the basic model means that

$$\sigma_P^2 = \sigma_G^2 + \sigma_e^2 = \sigma_A^2 + \sigma_{NA}^2 + \sigma_e^2$$

where σ_P^2 is the phenotypic variance, and so on.

Heritability Heritability, the percentage of phenotypic variance that is heritable, is a key parameter, with bounds 0 and 1. It has two forms:

- narrow-sense, given by the ratio σ_A^2/σ_P^2, and usually denoted h^2, which is applicable to propagation by seed
- broad-sense, given by the ratio σ_G^2/σ_P^2, and usually denoted H^2 ($\geq h^2$), which is applicable to mass propagation of selected clones.

A heritability is specific to a trait, and, in some measure, to the population and the macroenvironment (e.g., site). Narrow-sense heritabilities tend to be low (0.2 or less) for growth rate traits, but much higher (≥ 0.5) for wood properties.

Genetic correlation A genetic correlation (denoted r_A or r_G) between traits is a measure of the degree of common genetic control for the two traits concerned. Its bounds of 1 and -1 relate to complete common control to perfect inverse control respectively. Genetic correlations, if they are adverse, impose severe constraints on the genetic gain that is simultaneously achievable in the traits concerned. Common examples of adverse correlations in forest trees include wood density and diameter growth, or growth potential and hardiness. On the other hand, favorable or even neutral genetic correlations can provide major opportunities for the breeder.

Some Simple Expectations

Assuming the usual quantitative genetic model of polygenic control we have the following expectations for composition of variances (ignoring certain minor components of nonadditive gene effects):

- among half-sib families (each parent in question mating with a random sample of a large population) $-\frac{1}{4}\sigma_A^2$; this amounts to GCA variance
- within such families $-\frac{3}{4}\sigma_A^2 + \sigma_{NA}^2 + \sigma_e^2$
- among full-sib families (crosses between random pairs of parents) $-\frac{1}{2}\sigma_A^2 + \leq\frac{1}{4}\sigma_{NA}^2$
- within such families $-\frac{1}{2}\sigma_A^2 + \geq\frac{3}{4}\sigma_{NA}^2 + \sigma_e^2$.

Note: It is very convenient for forest geneticists and tree breeders that, with pollination by wind, seed collections from individual trees often approximate closely to half-sib families.

Thus a heritability (or repeatability) of half-sib family means (h_{HS}^2), with n individuals per family, is given by:

$$h_{HS}^2 = \tfrac{1}{4}\sigma_A^2/[\tfrac{1}{4}\sigma_A^2 + (\tfrac{3}{4}\sigma_A^2 + \sigma_{NA}^2 + \sigma_e^2)/n]$$

Intercrossing among parents can be done in a range of systematic mating designs, which almost all give some forms of both half- and full-sib family information.

Applying the same approach to heritability of clonal means (H^2_C), we have the expectation

$$H^2_C = \sigma^2_G/(\sigma^2_G + \sigma^2_e/n)$$

which will tend to be much higher for given n than h^2_{HS}, illustrating how clonal material can give information with a much better signal-to-noise ratio than seedling families.

Also of interest is the variance attributable to interaction between parents, reflected in the component of family performance that cannot be predicted from the additive genetic merit or GCA values of the two parents; such variance is specific combining ability (SCA) variance, of composition $\leq 1/4\sigma^2_{NA}$.

Response to Selection

Direct Selection

For a single trait, expected response to selection (E(R)) is the product of selection differential (D) which is the difference between the mean for the selected individuals and that of the population from which they are selected, the heritability (h^2, or H^2 for clonal selection), and the phenotypic standard deviation (S), such that:

$$E(R) = D \times h^2 \times S$$

If the distribution is normal, such that equal (or symmetrical) responses can be expected to equivalent selection for high or low values of the trait, D can be expressed in terms of number (i) of phenotypic standard deviations of the population in which selection is done. Thus

$$D = i \times \sigma_P$$

The formula for expected genetic gain (E(R)) can be expanded and manipulated into various forms, but the following features may be noted:

1. If h^2 is low, with σ^2_e fixed and large, gain will vary in proportion to σ^2_A.
2. If σ^2_A (or σ^2_G) is fixed, but h^2 varies through variation in σ^2_e, E(R) will vary in proportion to h, and will therefore be reduced far less than in proportion to an associated drop in h^2 (σ^2_e may be inflated by measurement error).
3. While i (number of phenotypic standard deviations, or selection intensity) always increases as the number screened for each one saved increases, it does so non-linearly, according to the law of diminishing returns (**Table 1**).

Table 1 Selection intensity (standardized selection differential, or *i*) in relation to number screened per individual saved, for global proportion and within finite subgroups

Trees screened per tree saved	*Global proportion*		*Finite subgroups*
	i	*Marginal* i *per tree screened*	i
2	0.798	0.399	0.564
5	1.400	0.201	1.163
10	1.755	0.071	1.539
100	2.665	0.010	2.542
1000	3.367	0.000 78	3.241
10 000	3.958	0.000 068	3.852
100 000	4.479	0.000 0058	4.384
1 000 000	4.948	0.000 000 052	4.863
10 000 000	5.380	0.000 000 004 8	5.301

4. If selection is done within finite subgroups (e.g., the best out of every two individuals instead of the top 50% of a very large population), i is less, especially when the subgroups are small (**Table 1**).
5. Percentage gain obtainable is dependent on the coefficient of variation (phenotypic standard deviation divided by population mean) as well as i and h^2.
6. If, with cost constraints, there is a choice between screening more trees cheaply or fewer trees thoroughly, there is effectively a trade-off between i and h^2.

Indirect Selection

It is often possible to select for a 'target' trait (y) that represents part or all of a breeding goal by using another ('index') trait (x) as a proxy, in what is termed indirect selection. Examples may include stem volume as y and stem diameter as x, or a mechanical property of wood as y and wood density as x, or else harvest-age performance as y and early performance as x, or even a DNA marker or an identified gene (x) that is strongly associated with desirable expression of a trait (y).

For indirect selection to be more efficient than direct selection there must be at least a fairly strong genetic correlation between the target and index traits. Other conditions, of which one or more needs to be met are:

- markedly higher heritability for the index trait than for the target trait, either as an inherent heritability or through more precise measurement
- much cheaper determination of the index trait, allowing more intensive selection than is possible with direct selection

- earlier expression of the index trait, allowing a shorter generation interval and thence more rapid gain per unit time.

The roles of these conditions are illustrated by the equation for the relative efficiency of indirect selection E(*x*/*y*) compared with direct selection. In a single generation it is given by

$$E(x/y) = (i_x/i_y)(h_x/h_y)r_{G_{xy}}$$

where i_x and i_y denote the intensities of selection achieved for the respective traits, h_x^2 and h_y^2 are the corresponding heritabilities, and $r_{G_{xy}}$ is the genetic correlation between the two traits.

Multiplying the right-hand side by the ratio t_y/t_x, for the generation intervals under the two forms of selection, gives E(*x*/*y*) in terms of gain per unit time.

Cases of indirect selection with forest trees include using wood density, which is usually very heritable yet not very expensive to determine, as the selection criterion where strength and/or side hardness may figure in the underlying breeding goal. In the case of *Pinus radiata*, selecting for closely spaced branch clusters, a highly heritable feature, has been used as a selection criterion to control branch size which is very subject to environmental influences. DNA markers will have the advantage of perfect heritability and can be determined very early in the life cycle, but may not be well correlated genetically with the trait of interest. Efficient early selection is very widely sought with forest trees.

Using Information on Relatives

Progeny Testing

The essence of progeny testing (and clonal testing) is to improve the effective heritability. Selection wholly on progeny test results, which often amounts to reselection of parents, can be termed backwards selection. For instance, with half-sib families, the heritability of family means (formulated above), will increase with the number of individuals per family. However, the number of parents, will be limited by the number of selections made from the preceding generation. This will often impose a practical constraint on i, even though trading off smaller family size and thence lower h_{HS}^2 for higher i may have a theoretical advantage.

Note that gain expected from selection on half-sib family information for seed orchards has a coefficient of 2 inserted in the adapted form of the equation for response to selection; this is to take account of the fact that both pollen and seed parents will be selected.

More General Use of Information on Relatives

Selection purely on the basis of progeny test performance is a special case of using information on relatives, in this case placing 100% reliance on information from offspring. It is in principle possible to use information from almost any class of relatives, including parents and siblings in selecting individual offspring. A simple but common case in forest tree breeding is selecting individual offspring on both sib-family and individual information, weighting individual information heavily if heritability is high and family information heavily if heritability is low, in a combined family-plus-individual selection index.

Information from multiple classes of relatives, with varying representation of relatives among candidates, can be used to estimate the genotypic merit of candidates by best linear unbiased prediction (BLUP).

Genotype × Environment Interaction

This phenomenon represents differential performance of genotypes with respect to each other in different environments. To accommodate it, the basic genetic model can be expanded to:

$$P = G + E + GE + e$$

where E is the effect of the macroenvironment (e.g., a site category), which can be allowed for, and GE is the genotype × environment interaction.

The interaction can have two components: that tending to cause changes in genotypic ranking among environments (which is usually of prime interest), and that reflecting differential expression of genetic difference among the environments. As above, G is composed of $A + NA$, and (in principle, at least) GE of $AE + NAE$.

Applying this extended model to variance components, and partitioning off macroenvironmental effects, we have

$$\sigma_P^2 = \sigma_G^2 + \sigma_{GE}^2 + \sigma_e^2 = \sigma_A^2 + \sigma_{NA}^2 + \sigma_{AE}^2 + \sigma_{NAE}^2 + \sigma_e^2$$

where $\sigma_G^2 + \sigma_{GE}^2$ denotes σ_G^2 and $\sigma_A^2 + \sigma_{AE}^2$ denotes σ_A^2, within a single site.

Hence the heritability (narrow-sense) for selecting an individual for performing in its particular environment is given by

$$h^2 = \sigma_A^2 + \sigma_{AE}^2/(\sigma_A^2 + \sigma_{AE}^2 + \sigma_e^2)$$

Deleting σ_{AE}^2 from the numerator gives the heritability for selecting the individuals for performing across the various environments. Substituting

$\sigma_G^2 + \sigma_{GE}^2$ for $\sigma_A^2 + \sigma_{AE}^2$ gives H^2. This extended model can readily be applied to expected response to selection.

It may be noted that the ratio $\sigma_A^2/(\sigma_A^2 + \sigma_{AE}^2)$ is actually a genetic correlation between the performance from one environment to another, if corresponding variances are all expressed equally in all the environments. Such a correlation can be calculated either for a set of environments, or between a pair of environments. A favorable test environment is one that shows both high genetic correlations for tree performance with other important growing environments and a high heritability.

There are important implications for whether or not to institute regional subdivisions in a breeding program. Key points are:

1. A high ratio σ_{AE}^2/σ_A^2 favors regionalization, particularly if fairly discrete site categories can be identified.
2. However, even with quite substantial interaction, if progeny testing can be well spread across environments it may be possible to produce a set of selections that are near-optimal for all the individual environments.
3. That said, failure to screen in an environment that is strongly interactive with respect to the others can sacrifice much potential gain in that environment.

Genotype × environment interaction is the subject of a voluminous literature. Much of that, however, focuses on characterizing the interactive behavior of specific plant genotypes (which are often cultivar varieties). For forest tree breeding, the main interest often lies in the roles of environments in generating interaction.

Multitrait Selection

Selection for more than one trait usually dilutes the gains obtainable for individual traits (**Table 2**). However, if several traits are uncorrelated but of equal economic worth and equal heritability, it may be better to spread the selective effort among several traits, especially if large numbers of candidates can be easily screened for each of several traits. This is also illustrated in **Table 2**. In practice, traits will differ markedly in heritability, economic worth, and cost of evaluation per individual, which means that selection needs to be focused on just a very few key traits.

Table 2 Selection intensities (standardized selection differentials, or *i*), for varying numbers of individuals screened for each one saved, assuming either a single trait or three uncorrelated traits for selected at equal culling rates. All cases relate to selection within single large population

Trees screened per tree saved	i		
	Single trait	*Three traits*	
		Per trait	*Summed over traits*
8	1.65	0.798	2.39
30	2.22	1.114	3.34
125	2.72	1.400	4.20
1000	3.37	1.755	5.26
1 000 000	4.95	3.367	10.10

Genetic correlations between traits are crucial. Adverse correlations, if strong, severely restrict the gains that can be achieved simultaneously in the traits concerned. In forest tree breeding such correlations may exist between growth potential and hardiness, or between wood density and stem volume production. Conversely, if intercorrelations are favorable, selecting for additional traits may dilute gains achievable in individual traits little if at all.

Four ways of selecting for multiple traits in any one generation are:

1. Independent culling levels, setting thresholds of acceptability for each trait.
2. Sequential culling (sometimes called tandem selection), first for one trait and then another, and so on. This may be cost-efficient if evaluation costs differ widely among traits, so one might, for example, select first for stem diameter and only then evaluate wood properties and cull for them.
3. Tandem selection which, in the true sense of the term, involves selecting for different traits in successive generations. For forest tree breeding, deliberate adoption of this method from the outset is unlikely to be realistic, although elements of it may be practiced as a fortuitous result of changed perceptions of breeding goals.
4. Multitrait index selection, attaching weights to the values for individual traits, like the partial regression coefficients in multiple regression. Thus an indifferent ranking for one trait may be offset by a candidate being outstanding for one or more other traits. Various bases exist for weighting. A theoretical optimum takes account of economic weights of the respective traits and variance–covariance matrices that encapsulate the heritabilities of all traits and all the phenotypic and genotypic intercorrelations among those traits. There can thus be elements of both direct and

indirect selection. In practice, this optimality depends on various assumptions, notably concerning cost structures and the quality of the information on heritabilities and all the intercorrelations between traits. Various modifications of the multitrait selection index are possible, including use of elements of independent culling levels, and setting restrictions on expected gains in one or more traits.

In fact, it is possible in principle to combine multitrait information with information from various classes of relatives, and unequal representation of relatives among the candidates, to obtain a multitrait BLUP solution.

Long-Term Gain

Assuming polygenic control, pair-crosses will continue to show genetic segregation, each containing roughly half the base population additive genetic variance. This segregational variation is expected to persist over generations, although it will decay over time, especially if populations are small and/or selection is intense, but it will tend to be replenished by mutation. It is the key to cumulative genetic gain over generations of crossing and selection, which lead to increases in frequencies of favorable genes (alleles) at the various loci. Some genes of quite large effect can be present without causing behavior that is obviously different from that expected with polygenic inheritance. However, the use of DNA technology to recognize such genes offers greater selection efficiency.

Initial response to selection will involve mainly the loci of intermediate gene frequencies, which contribute most to expressed genetic variation. If favorable alleles approach 100% frequencies at such loci, these loci will contribute little to continued genetic gain. However, initially rare favorable alleles at other loci may increase in frequency to the point where they become the prime basis of response to selection.

There are some situations where the quantitative genetic model may not suffice for the tree breeder. In breeding for disease resistance there may be genes of large effect, and some can mask the expression of resistance genes at other loci. These genes of large effect need to be recognized and managed carefully, in order to select efficiently and ensure durability of resistance against mutation and genetic shifts in the pathogens. DNA technology offers a general means of recognizing and capturing favorable genes of significant individual effects, thus going beyond the classical polygenic model.

Inbreeding

With normally outbreeding organisms, which include almost all forest trees, the quantitative genetic model may not be straightforwardly applicable when significant inbreeding occurs. With outcrossing, the genetic load, which mainly represents genes that are individually rare but very deleterious in the homozygous state, contributes almost nothing to the expressed genetic variation. Inbreeding, however, allows such genes to be expressed strongly, thus contributing a different element of expressed genetic variation.

Population, Conservation and Ecological Genetics

C Mátyás, University of West Hungary, Sopron, Hungary

Introduction

Intraspecific genetic variation is an often overlooked, but none the less essential, biodiversity component of forest ecosystems. Genetic diversity provides the fine-tuning in adjustment to dynamic processes in species and intraspecific competition and determines the pace of adaptation and microevolution on a population level.

Developments in genetic analysis techniques of recent decades yielded an impressive amount of knowledge about reproductive processes in forest tree populations. It turned out that forest trees are unique in their ability to accumulate and maintain exceptionally high levels of genetic variability, compared to other organisms, both plants and animals. Undoubtedly, this strategy must have an evolutionary significance and is related to the long lifespan of trees.

Typically intense gene flow, phenotypic plasticity and other heritable and nonheritable effects contribute to the robustness of tree species, i.e., to their ability to evade genetic degradation and drift even in isolated populations and at low density of occurrence. Nevertheless, genetic analyses also demonstrate effects of human activities on the genetic resources of trees (see **Figure 9**). Silviculture and various indirect environmental loads have some bearing on the genetic make-up of populations. This fact supports the need to include genetic considerations in both sustained management and conservation strategies of forest ecosystems.

Significance of Genetic Regulation in Forest Ecosystems

Living systems have a remarkable ability to maintain and restore their uniqueness and identity under both spatially and temporally changing environmental conditions. Ecosystem stability is largely dependent on biodiversity which is detectable at the three main levels of biotic organization: the landscape (associations), species, and genetic levels. Species diversity is generally perceived as biodiversity *per se*. However, it is within-species genetic diversity that safeguards the adaptability and integrity of individual species. Intermating populations are the basic units of adaptation and evolution. An important task of forest genetics is therefore to understand the complexity of genetic regulation and to detect patterns that give it meaning from the gene to the ecosystem level. Within-species genetic patterns determine the rules for use of forest reproduction material and the strategy of conservation of genetic resources.

Defining and Interpreting Genetic Diversity

Diversity on the genetic level is usually described by the number and frequencies of alleles (different forms of the same gene) per locus in the population or species. Accordingly, two basic components of diversity are the allelic number (A) and the proportion of loci that are polymorphic, i.e., with more than one allele. Polymorphism (P) is expressed as a percentage of all investigated loci. Expected heterozygosity (H_e) is used as the numeric expression of gene diversity within a population or species. Within-species diversity is further characterized by genetic differentiation between populations, i.e., the ratio of variation found among population averages.

Calculation of gene diversity measures At a locus, effective number of alleles: $A_E = 1/\sum p_i^2$

Expected heterozygosity: $H_e = 1 - \sum p_i^2$

Genetic differentiation between populations:

$$G_{ST} = 1 - \frac{H_{eP}}{H_{eT}}$$

where p_i is the frequency of allele i across loci, H_{eP} is the average expected heterozygosity within populations; and H_{eT} is the total expected heterozygosity if all populations are pooled.

Beside gene diversity there are, however, reasons to use a broader definition for genetic diversity. First, the described measures are based on predominantly neutral genetic markers (isozymes, randomly amplified polymorphic DNA (RAPD), restriction fragment length polymorphism (RFLP), microsatellites) which are chosen for being polymorphic. Yet the key importance of diversity is maintaining adaptability and stability, which are expressed in adaptive (nonneutral) quantitative traits in response to the environment. For trees, it is especially true that there is no expression of genotype without environment. Therefore, genetic diversity in the broad sense also includes quantitative genetic variability, i.e., that part of phenotypic variability which can be identified as genetic, based on quantitative genetic analysis.

Gene diversity characteristics of forest trees Using genetic marker techniques, the genetic structure of species and populations (gene diversity, level of inbreeding, deviations from Hardy–Weinberg equilibria) can be drawn up and used for comparison. Of great practical importance is the distribution of diversity within and between populations and regions. Compared with other organisms, forest trees generally display high heterozygosity (**Figure 1**), reflecting relatively high allele numbers.

Also within the plant kingdom, average polymorphism, allelic number, and heterozygosity of trees are conspicuously high, but among-population genetic differentiation is low (**Table 1**). Weak differentiation in most species with large natural ranges reflects high rates of gene flow in trees. Although the differences in average allele numbers may seem minor, it should be remembered that the potential number of genotypes (G) rises sharply with increasing average allele numbers (A) and number of loci considered (n):

$$G = \left[\frac{A(A+1)}{2}\right]^n$$

Counting with just 10 loci, the difference between annual plants and trees of only 0.2 in A means an increase in potential genotypes from 70 000 to 340 000.

Gene diversity is profoundly influenced by the genetic system (mating pattern, reproductive strategy, genomic organization) of the species and its distribution (e.g., local endemic versus large, continuous). For example, population density of individual species decreases from the boreal zone toward the tropics. With decreasing density, polymorphism and allelic numbers tend to diminish. The effect of evolution, distributional pattern, mating, and reproduction system on species diversity is illustrated by data in **Table 2**. Failing concrete genetic information, likely genetic characteristics of a species may be inferred from these basic relationships.

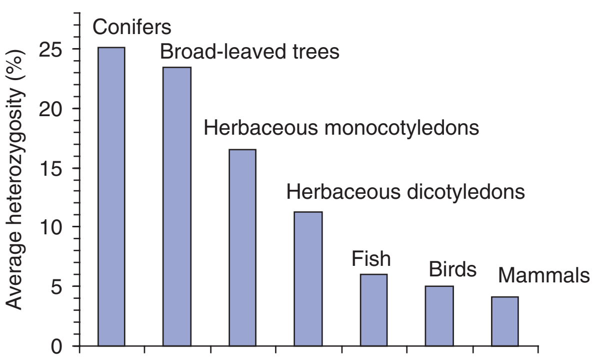

Figure 1 Average heterozygosity (in percent) for some organism groups.

Table 1 Average genetic diversity within species of different plant life forms

Life form	P	A	H_e	G_{ST}
Annuals	49.2	2.02	0.15	0.36
Perennials, herbaceous	43.4	1.75	0.12	0.25
Trees	65.0	2.22	0.18	0.08

Genetic diversity is expressed by the measures polymorphism (*P*), average allele number (*A*), expected heterozygosity (H_e) and genetic differentiation (G_{ST}). For further details, see chapter on defining and interpreting diversity.

Directed and Random Genetic Changes in Large Populations

Owing to various, partly random genetic effects, such as natural selection (i.e., genetic adaptation), mutation, genetic drift, gene flow, or unequal sexual contribution of individuals, allele frequencies change over time, unlike in idealized populations in Hardy–Weinberg equilibrium. In large populations, gene flow and adaptation are the prime forces influencing genetic diversity and intraspecific variability.

Hardy–Weinberg Law

In infinite, random-mating populations, allele and genotype frequencies remain constant from generation to generation in absence of selection, migration, drift, and mutation effects. For two alleles of p, q frequency at a locus, the equilibrium ratio of homozygotic (p^2 and q^2) and heterozygotic ($2pq$) genotypes will be $p^2 + 2pq + q^2 = 1$.

Table 2 Connection between genetic diversity and distribution, density, and mating type in trees

Statistical significance (probabilities of zero difference) of differences within subcolumns indicated as follows: * 5%, ** 1%, *** 0.1% probability; NS, nonsignificant. For explanation of letters in table heading, see **Table 1**. Compiled from data of 191 tree species. The calculation is based on the assumption that the population is in Hardy–Weinberg equilibrium.

Gene Flow

Gene flow describes the spatial movement of genes, typically through seed and pollen dispersal, either within a population or between separated stands. (An alternative term, 'migration,' is reserved here for shifts in time of the geographic range of species or populations.) Wind-pollinated species, producing abundant pollen, such as most temperate forest trees, show major gene flow. In favorable weather, pollen clouds may travel hundreds of kilometers and contribute significantly to local pollination (**Figure 2**).

Animal-pollinated (mostly tropical) tree species depend on the movement of their pollen vectors. Investigations have shown pollen transport of several kilometers and medium-level gene flow between trees and stands. The very rare apomictic and self-pollinating tree species show the lowest gene exchange rate.

The evolutionary and practical significance of gene flow is high. Its function is to counter genetic drift (random fluctuations in allele frequencies) within the range, to disperse fitness-improving mutant alleles, to maintain high levels of genetic variation and adaptability, and to avert inbreeding in fragmented populations. Gene flow has therefore a decisive role in shaping within-species genetic variation patterns (**Table 2**), and consequently influences appropriate strategies for forest reproductive material use and conservation.

Natural Selection, Adaptation

The prerequisite of the selective force described by Darwin and Wallace is easily visible in forests, namely conspicuous differences between individual trees in competitive and reproductive ability, the two key components of fitness. Natural selection acts through higher mortality and fewer offspring of less-fit individuals. Consequently, the gene pool of the next generation will be selected for greater fitness.

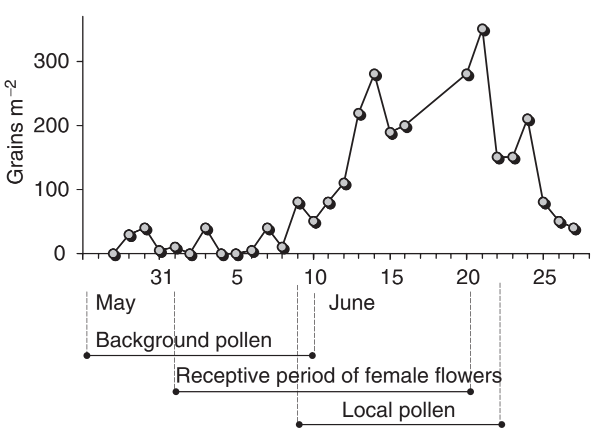

Figure 2 Density (grains m^{-2}) of pollen in a Scots pine seed orchard. Fifty percent of the female strobili was receptive before the appearance of local pollen. Reproduced with permission from Lindgren D, Paule L, Xihuan S, *et al.* (1995) Can viable pollen carry Scots pine genes over long distances? *Grana* 34: 64–69.

The shift in genetic variability tends to change the population profiles and over several generations may lead to evolution. Darwinian natural selection is an important, although not exclusive, driving force of evolution, as random effects play an important role too.

Genetic adaptation and fitness While natural selection explains the 'statistical' aspect of selection, adaptation describes the sum of biological processes that safeguard the survival of the population under constantly changing conditions. Some of these mechanisms are nonheritable.

Genetic adaptation operates on populations through fitness selection. Fitness encapsulates the differential effect of many traits expressed during the life cycle. The selective value of individual traits depends on the actual environment, which can change constantly. In environments influenced by humans, e.g., in managed forests or plantations, fitness will be modified (cultivation- or domestic fitness).

Fisher's fundamental theorem of natural selection postulates that the increase of average fitness ($\Delta\bar{W}$) is a function of the average relative fitness of the parent population ($\bar{W}$) and the within-population additive genetic variance (V_W):

$$\Delta\bar{W} \approx \frac{V_W}{\bar{W}}$$

i.e., progress of natural selection depends on adaptedness ($\bar{W}$), and adaptability of a population depends on the available genetic variance – if genetic variability is depleted, adjustment to a changed environment becomes difficult or impossible (**Figure 3**).

The consequences of reduced genetic diversity on adaptability on species level can be illustrated by the examples of two contrasting boreal pine species, jack pine (*Pinus banksiana*) and red pine (*P. resinosa*), which have similar life histories and ecological niches in boreal forests of eastern North America. While the former displays very broad genetic variability, the latter seems practically devoid of diversity. Regarding distributions, red pine has only restricted, fragmented occurrences and is becoming rare in certain areas, while jack pine is the dominant species in many forest associations. The difference in distribution pattern may be attributable to the loss of diversity in red pine, probably through 'genetic bottlenecks' of glacial periods.

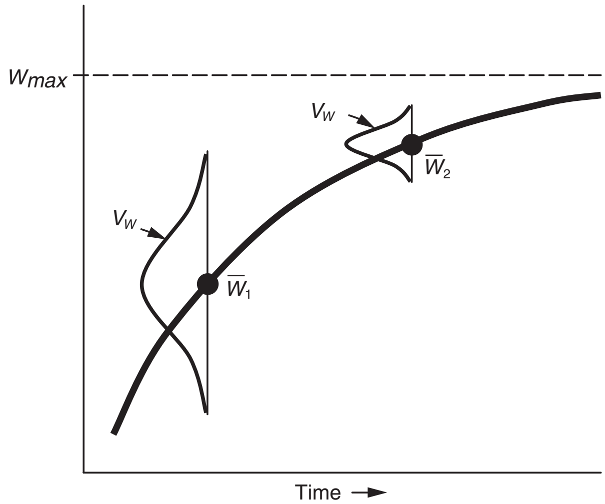

Figure 3 Improvement of the fitness average of populations over time in a theoretical niche. The progress of population 1 is slower toward the fitness maximum (W_{max}), because its genetic variability is smaller, and its average fitness is closer to the maximum. Population 2 has a larger genetic load (L), but also the selection pressure is stronger. In practice, the progress is not very effective owing to environmental fluctuation and heterogeneity, resulting in ever-changing fitness optima. The precondition for the improvement of fitness is sufficient genetic variability!

Variation in Reproductive Fitness: Unequal Sexual Contribution of Individuals

Differences between genotypes in flowering and seeding vary over 10-fold, even among dominant trees in a forest stand. Owing to unbalanced flowering and seeding, neither natural regeneration nor the seed crop collected in a stand or in a seed orchard is genetically identical to the gene pool of the parents. Many genotypes contribute insignificantly to the next generation. The top quartile of genotypes may be represented in over two-thirds, and the bottom quartile in less than 3% of the progeny. Therefore the effective population size (N_e) is usually far smaller (by roughly an order of magnitude) than the total number of individuals, and can be calculated for a monoecious species from the reproductive contribution of each individual (W_i):

$$N_e = \frac{1}{\sum(W_i^2)}$$

Effectiveness of Fitness Selection in Natural Populations

The effect of fitness selection on individual traits depends strongly on both the (adaptive) importance of the trait for total fitness (e.g., budbreak timing versus leaf morphology) and on the simplicity of the traits' inheritance. Rapid adaptation could be demonstrated, e.g., in 'industrial melanism' in various insect species, or in heavy-metal tolerance in grasses growing on mine spoils. In trees, diversity patterns of adaptive traits indicate more gradual adaptive shifts.

Constraints on 'Perfect' Adaptation

The idea of perfectly adapted natural populations is a widespread misconception. There are several genetic reasons why 'perfect' adaptation is impossible, such as:

- genetic interdependence of traits, making simultaneous adaptive shifts relatively slow
- polygenic inheritance of quantitative traits, preventing ready fixation (attaining 100% frequency) of favorable alleles
- trade-offs between reproductive and vegetative traits in contributions to fitness, which maintain a conspicuous variation of reproductive ability within populations
- environmental heterogeneity and fluctuations (on the life-cycle scale of trees, the changes are two orders of magnitude faster than for annual plants)
- gene flow: the more continuous the distribution, the stronger the effects to limit differentiation between populations
- biotic complexity: e.g., long-term competition, and spasmodic epidemics of pests and diseases, which point toward evolutionary complexity rather than toward precise adjustment to local conditions.

Adaptation lag can be demonstrated in comparative experiments, where populations of local origin often show less adaptedness than introduced ones.

Local Patterns Arising from the Balance of Gene Flow and Adaptation

Genetic neighborhoods are intermating groups of related individuals within larger populations. The size and even the existence of such neighborhoods depend on the sexual system and dispersal pattern of the species. In outcrossing, wind-pollinated species, occurring at high density, neighborhoods cannot readily develop. In some species with more restrictive sexual systems (e.g., mixed-mating eucalypts) neighborhoods are much more extensive than usually suspected (**Figure 4**).

The balance of gene flow and adaptation forms adaptively homogenous areas (AHAs) within the species, which should serve as a basis for seed and conservation zones. Within the AHAs populations vary little in adaptive features. Owing to gene flow, AHAs are much larger than selective environments with roughly uniform ecological conditions.

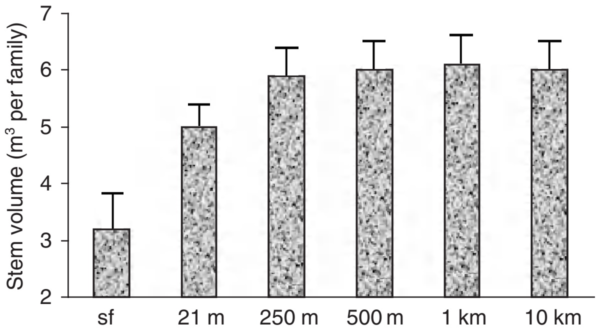

Figure 4 Average stem volume of 4-year-old progenies of a selected tree of *Eucalyptus globulus* from controlled crossings (*sf*., selfed). The crossing partners were chosen at various distances (horizontal axis) from the subject tree. The poorer performance from pollination by closer neighbors is probably caused by inbreeding depression, which indicates the existence of genetic neighborhoods in this species. Reproduced from Hardner CG, Potts BM, and Gore PI (1998) The relationship between cross success and spatial proximity of *Eucalyptus globulus* parents. *Evolution* 52: 2, 614–618.

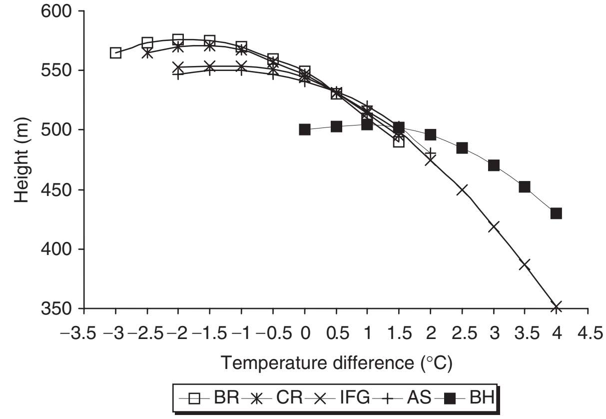

Figure 5 Response regressions calculated for 12-year height of *Pinus ponderosa* progenies in five Californian tests (different plotting symbols). The horizontal axis shows differences in average temperature between the original and the test site (0 means local). Almost without exception, populations transferred from warmer environments performed better.

Nonheritable Ways of Adaptation

Phenotypic Adjustment

A genotype may grow and develop in different ways, in interaction with the environment, resulting in the actual phenotype. The change of the phenotype of a population or an individual genotype may be plotted along site factor gradients. Genotypes clearly vary in their phenotypic responses to environment, and this is termed genotype-× environment interaction. (Naturally, the ability itself is genetically determined.) Populations or genotypes maintaining their relative performance (relative to a standard genotype or experimental average) across sites are considered phenotypically stable and, if inherently productive, are highly desirable.

Genetic Imprinting

Genetic regulational changes triggered by environmental signals that lead to persistent phenotypic change are termed genetic imprinting or epigenetic effects. Indications that epigenetic effects may contribute across generations to the phenological and growth differentiation of populations in different environments were recently traced in certain boreal conifer species. The extent and inheritance of this effect in trees are still unexplored.

The importance of nonheritable adaptation is that it allows adjustment to the environment by reducing the role of natural selection; this offers a saving of resources and of response time. Nonheritable adaptation 'masks' the true genotype and contributes therefore to the maintenance of a broader adaptability.

Intraspecific Genetic Variation Patterns

Large-Scale Adaptive Geographic Variation

Provenance research, which has a tradition of more than a hundred years of study in forestry, has revealed a clear geographic differentiation between populations for adaptive traits in widely distributed species. Provenance is a population originating from a defined geographic location or area.

Clinal variation Genetic variation showing gradual trends linked to ecological gradients is termed clinal. In continuously distributed, wind-pollinated species clinal variation is caused by gradually changing selection effects despite gene flow, leading to gradual allele frequency changes; however, a gradual allele frequency trend itself may also reflect gene flow effects. In temperate species, variations in daylength and temperature cause latitudinal clines in stem form, phenology, and growth potential. In temperate pines, for example, southern origins exhibit faster growth, extended vegetation period, longer needles, but poorer stem form than northern ones. Particularly steep clinal variation may occur on mountain slopes. Significant differences appear over altitudinal differences of only 200–300 m (at high elevations, even less). Such differentiation tends to be weaker in broad-leaved than in coniferous species (**Figure 5**).

Ecotypic variation An ecotype is a population adapted to local site (usually edaphic) conditions that occur in patches rather than in gradients. Traditionally, within-species genetic variation is considered by most silviculturists as ecotypic. However, site differences seldom exert enough selection pressure to override gene flow. Accordingly, there are very few proven cases of ecotypes in forest trees. Their existence may be restricted to species with minimal gene flow between populations (**Table 2**). European ash (*Fraxinus excelsior*), for example, occupies conspicuously different habitats. Still, even thorough field tests could not reveal any clear genetic differentiation between populations of 'water ash' of the floodplains and 'lime ash' of dry, calcareous mountain ridges.

Nonadaptive Geographic Variation

Racial differentiation Historical fragmentation of species ranges during Ice Ages (and associated migration) affected the genetic diversity of species, causing genetic bottlenecks, as mentioned for *Pinus resinosa*. For many others (e.g., beech or firs) the loss of alleles along the migrational route could be demonstrated. In many cases migration and isolation have led to fragmentation and strong within-species differentiation and even speciation. The effect of the migrational past persists especially on neutral loci (**Figure 6**). These patterns reflect combinations of adaptive and random effects and therefore have limited or no ecological significance. This variation is therefore not ecotypic and should be better termed racial.

Polymorphism

Phenotypic (quantitative) polymorphism A well-known feature of many forest trees is the broad variation of traits and the parallel presence of alternative phenotypes (morphs) in the population. Some of these have clear ecological-adaptational significance (early- or late-flushing, branching types), while others obviously not (cone scale form, male flower color in conifers). Ecologically relevant differences between populations can be expected only for traits of adaptive value (**Figure 7**).

Polymorphism at genetic marker level In contrast to quantitative traits, most of the marker-allele polymorphism of forest trees exists within populations. In widespread species, differentiation between populations (G_{ST}) seldom exceeds 4–5%. Exceptions are species with fragmented or dispersed distribution (e.g., *Pinus radiata* isozymes: 16%), and some tropical forest trees of low density (<1 flowering tree ha^{-1}; e.g., *Cavanillesia platanifolia*: 26%). Obviously, an adaptive geographic variation pattern, as is observable with quantitative traits, is seldom evident in genetic markers. This phenomenon raises the question of interpreting results of genetic marker analysis. From the neutralist viewpoint, gen(et)ic diversity at the marker level is held in equilibrium by mutation and genetic drift. The selectionist interpretation maintains that frequency differences have selective value; even neutral alleles may mark adaptive effects if genetically linked to loci of adaptive significance.

In fact, for a few izozyme systems the selective value of alleles could be proven. For example, the B_1 allele of the enzyme gene *IDH-B* (isocitrate

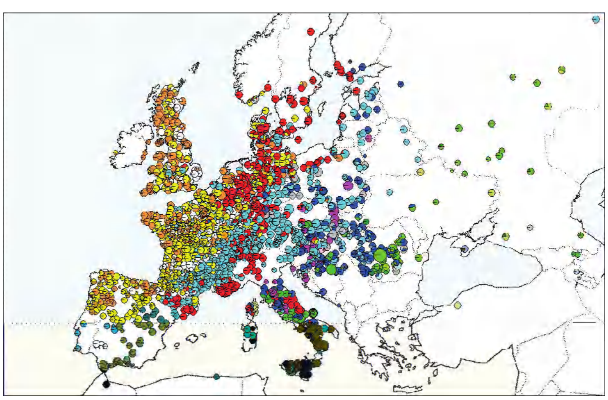

Figure 6 Beside the nuclei, chloroplasts also contain genetic material which is inherited maternally in broad-leaved species. A Europe-wide analysis of chloroplast haplotypes of white oaks revealed the prolonged effects of postglacial migration from South European refugia. Reproduced with permission from Kremer A *et al.* (2002) Chloroplast DNA variation in European white oaks. *Forest Ecology and Management* 156: 5–26.

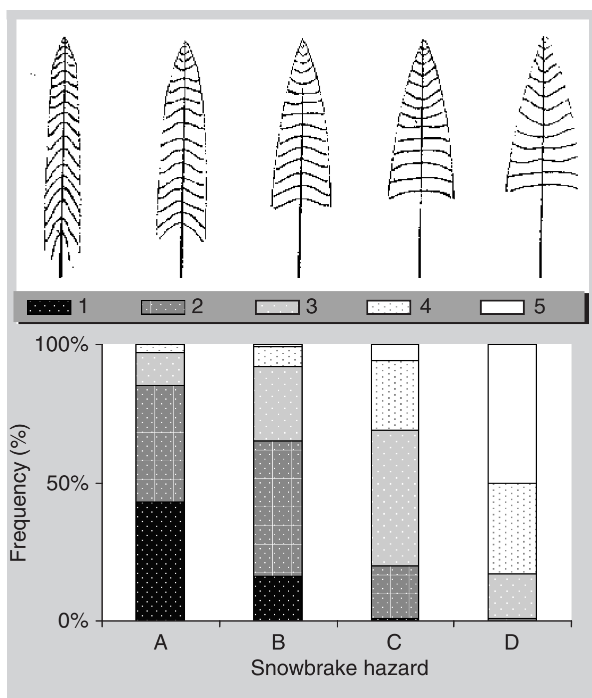

Figure 7 Frequency of spruce crown types in the Slovenian Alps. The diagrams represent different categories of snow-break hazard: (A) extreme cold, hazardous sites, (B) exposed sites on a plateau, (C) transitory sites, and (D) low hazard sites.

dehydrogenase-B) has a lower temperature sensitivity than allele B_2. In silver fir (*Abies alba*) populations, the higher frequency of B_1 in Mediterranean populations as compared to temperate-montane populations was confirmed.

Gene Pool Changes in Small Populations

Small, isolated populations are often considered as resulting from human activity, but many species have naturally restricted, or scattered distributions. Reduced population size becomes problematic if random genetic forces prevail over selection and adaptation.

Genetic Drift

Differential pollen and seed production means a 'random genetic sampling' of the parent population. The smaller the sample, the more the offspring depart from the Hardy–Weinberg allelic ratios. If the population size remains low, drift recurs every generation. Drift effects may persist long after the population regains its size, if the original allelic richness is not replenished through gene flow, e.g., after a demographic bottleneck (through a catastrophic fall in numbers), or if very few individuals colonize a new habitat (founder effect). For example, the loss of alleles during postglacial recolonization is still evident in many temperate species, despite gene flow over many generations.

Figure 8 shows that diversity loss in small populations depends on the effective number of population members. Through random fluctuations, alleles might be lost or fixed even if their initial frequencies were high or low respectively.

As a result, small populations typically show an excess of homozygotes due to a higher number of fixed (monomorphic) loci. Random fixation of some deleterious alleles (harmful mutants) is also probable if the effective number is small or if selection pressure (s) is mild. At the species level, drift in single fragmented populations does not necessarily lead to loss of diversity and may even increase among-population additive variance. For example, in island populations of sugar maple (*Acer saccharum*), fragmented by agricultural fields, polymorphism was found to be higher than in closed, large stands.

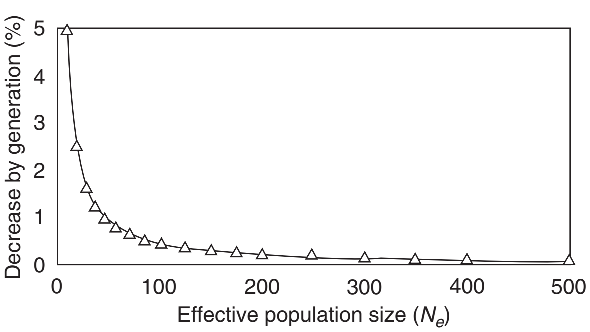

Figure 8 Decrease of gene diversity (heterozygosity) by generation (as a percentage) in function of effective population size. Adapted from Wright JW (1976) *Introduction to Forest Genetics*. New York: Academic Press.

Genetic drift may be compensated by gene flow. Model calculations show that relatively low migration rates suffice to offset drift effects. The maintenance of gene flow between scattered stands is therefore important for avoiding divergence of species fragments.

Inbreeding

Inbreeding happens if individuals of common ancestry mate. Selfing is an extreme form of inbreeding, which can only happen in monoecious species. The inbreeding coefficient (F) depends, like genetic drift, on the size of the effective population (N_e): $F = 1/2N_e$.

The mating probability of identical alleles matters if the allele adversely affects fitness, causing inbreeding depression. Forest trees are typically outbreeders and carry relatively high genetic loads (deleterious alleles) to avoid inbreeding. Experiments with conifers show that growth depression of selfed plants typically reaches 20–25%. The practical importance of selfing is generally low, owing to mechanisms that effectively limit fertilization with self-pollen (in angiosperms, self-incompatibility alleles; in conifers, embryonic lethals). Viable offspring from selfing and matings between close relatives are therefore uncommon, and few survive competition.

Human Effects on Forest Gene Resources

Selective cutting has been practiced over millennia in most of the accessible forest complexes in inhabited areas. Negative effects of associated dysgenic selection ('high-grading') on both gene diversity and quantitative traits have been proven. Consequences may be especially serious if the species occur at low density, such as in tropical forests. For instance, as a result of overexploitation, Cuban mahogany (*Swietenia mahagoni*) presently reaches only shrub size in the Caribbean.

Various other silvicultural practices may cause dysgenic effects, such as the unconsidered introduction of certain exotics (causing introgression between related, otherwise separated species), but especially the uncontrolled collection and commerce of reproductive material blurred the pattern of natural genetic variation in managed forests (**Figure 9**).

Figure 9 Scots pine provenances in a comparative test in the Ukraine. Compared to the autochthonous population (right), the German population (Darmstadt, left) shows the effect of severe dysgenic selection.

Proper forest management, however, may also have positive effects. In some cases genetic improvement of growth and resistance traits has been found to follow proper silviculture, certainly for introduced species.

Contrary to many beliefs, well-managed artificial stands display gene diversity characteristics comparable or even superior to natural forests. **Table 3** illustrates that statistics of controlled artificial regeneration and of first-generation seed orchards are not inferior to those of natural populations.

Table 3 Comparison of gene diversity statistics of natural and artificial populations of Douglas fir in British Columbia. A negative effect on genetic diversity can be traced after intense genetic selection only

Population type	P *(%)*	A	H_e
Natural stand	53	2,14	0,171
Artificial regeneration	65	2,65	0,167
First-generation seed orchard	63	2,28	0,172
Second-generation seed orchard	56	2,25	0,163

Conservation and Management of Genetic Resources

Genetic resources are elements of genetic variability that are (or might be) used to meet human needs and objectives. In forestry, the term covers naturally occurring populations and individuals, plantations, and collections, which carry currently or potentially valuable genetic information, and their protection is considered necessary from standpoints of economics, ecology, or conservation.

A basic concept for conservation is minimum viable population (MVP) size – the number of individuals that is necessary for the long-term survival of a population. It has to be large enough to conserve genetic diversity and to safeguard evolutionary ability. One approach to estimate MVP size is to calculate the probability of loss of low-frequency alleles. **Table 4** shows that MVP should include several hundred individuals. The numbers refer to effective population sizes; so gene reserves may need to be at least an order of magnitude larger. *MVP* size may largely vary according to species, depending on diversity conditions, mating patterns, dispersion, and density.

Table 4 Estimation of minimum viable population size (MVP) based on probabilities of allele loss (*P*)

P	q	*Population size*			
		M = 1	M = 10	M = 100	M = 1000
0.01	0.05	45	67	90	113
	0.01	230	343	458	573
	0.005	460	689	919	1148
0.005	0.05	52	75	97	119
	0.01	264	379	493	622
	0.005	529	758	988	1217

The table gives estimates for three allele frequencies (*q*) and different number of rare alleles at unlinked loci (*M*). The calculation is based on the assumption that the population is in Hardy–Weinberg equilibrium. Reproduced with permission from Mátyás C (ed.) (1999) *Forest Genetics and Sustainability*. Forestry Sciences vol. 63. Dordrecht, The Netherlands: Kluwer.

Why Specific Forest Gene Conservation Strategy is Needed

Although nature conservation areas protect valuable genetic resources, they are not sufficient because:

- the areas do not necessarily represent ecological conditions typical and important for silviculture
- there may be legal obstacles to management interventions in protected areas (regeneration/or seed collection).

A strategy of forest gene conservation should be based on some knowledge of past and present human influence, the diversity conditions and genetic system of the species, the probable size of MVP, and of adaptively homogenous areas.

Methods of Gene-Resource Management

1. Dynamic, *in situ* (on site) conservation of natural or naturalized populations is the ideal. Although natural forest dynamics should usually be preferred, human intervention to regulate succession or density, and even to regenerate artificially (with authentic material), is acceptable. The species-oriented protection of evolutionary potential is best served by a network of gene reserves.
2. *Ex situ* conservation: reproductive material is brought to units outside the natural habitat. Gene banks include seed-, pollen-, and tissue-culture banks, as well as field collections (clonal archives, stool beds, etc.). *Ex situ* conservation stands (progeny stands) may be established with evacuated populations where the original site is threatened, or with plantations of valuable selected populations or exotic species.

Gene conservation and sustainability Gene conservation forms part of the conservation of biodiversity and, more generally, of nature conservation. The general aim of conserving genetic resources of forest trees, i.e., to safeguard adaptability and long-term evolutionary potential, has high priority given the current pace of environmental changes in relation to trees' generation intervals.

The emerging concept of ecosystem management includes the sustained management of genetic resources. Genetic sustainability depends on the maintenance of processes determining genetic diversity, such as population size, conditions of gene flow, mating, and reproduction. In a world dominated by humans, genetic sustainability cannot rely on nature conservation and gene reserves alone. Genetic principles must form part of national forest policy, especially with regard to the management of close to natural forests.

International scope of gene conservation As the distributions of some key forest trees straddle many countries, reasonable conservation of genetic resources requires international collaboration. At present no binding international agreement exists for forest genetic resources. However various international initiatives (notably the Convention on Biodiversity) and institutions (such as the Food and Agricultural Organization of the UN, International Plant Genetic Resources Institute, Rome) promote internationally coordinated conservation efforts. Perhaps the most advanced is the European initiative (EUFORGEN), with nearly 30 actively participating countries.

Genecology and Adaptation of Forest Trees

S N Aitken, University of British Columbia, Vancouver, Canada

Introduction

Genecology is the study of intraspecific genetic variation in relation to environmental conditions. It reveals patterns of adaptation of populations to their environments that result from differences in natural selection among locations. Genecological studies are conducted for the practical purposes of: (1) determining how far seed can be moved from the collection site to a reforestation site without risking maladaptation of the trees to the planting site; (2) delineating geographic breeding zones for which a single breeding program would suffice; (3) selecting optimal provenances within the native range for nonnative (introduced) species; and, more recently, (4) predicting the ability of populations of forest trees to adapt to rapidly changing climates.

To meet these objectives, seed is collected from different provenances (geographic origins) throughout all or a portion of a species range and planted in one or more field or nursery common-garden experiments. The survival and growth of trees of different provenances are observed under the same set of environmental conditions, allowing for the separation of genetic and environmental effects. Genetic variation in resistance to biotic (e.g., insects and diseases) or abiotic (e.g., cold and drought) stresses can also be observed in different environments or tested artificially. Variation among provenances is quantified and related to patterns of geographic variation in climate or other environmental factors. Species that show a high degree of genetic differentiation among provenances require the management of genetic resources on a more local scale than those that show relatively little genetic variation. If seed for reforestation is moved too far from the environments to which it is well adapted then losses in growth, health, and survival may result. The ability of populations to adapt to climate change will depend on current geographic patterns of genetic differentiation as well as the amount of genetic variation for adaptive traits that exists within populations.

Background

The recognition of genetic variation among populations of trees occupying different environments is not new. A full century before both Darwin's theory of evolution was published in *On the Origin of Species*, and Johann Gregor Mendel determined the mechanics of heredity, Carl von Linné (also known as Carolus Linnaeus, the father of modern taxonomy), reported in 1759 that yew trees (*Taxus baccata*) from France were less cold-hardy than those from Sweden. Around the same time, Henri Louis Duhamel du Monceau, Inspector-General of the French navy and noted botanist, established the first forest genetic trials on record. He collected seed from Scots pine (*Pinus sylvestris*) from various locations across Europe and established plantations in France in which to compare the performance of different provenances (seed origins). Later in the eighteenth century, the importance of provenance was recognized by guidelines of the Swedish Admiralty for selection of seed sources of pine and oak, and in Germany for the use of tree species introduced from North America. Similarly, the importance of using local, well-adapted provenances was recognized in Japan centuries ago.

While early botanists and foresters lacked an understanding of evolution and genetics, they recognized that the survival, health, and growth of planted individuals of a tree species depended jointly on the location where seed was collected and the environment in which the resulting seedlings were planted. Maladaptation can result in slow growth, and injury or mortality due to biotic (e.g., insects, diseases, or competition) or abiotic (e.g., cold or drought) agents. When seed was planted in an environment very different or very far from the one in which it was collected, the likelihood of maladaptation was clearly high; however, nonlocal provenances sometimes outperformed local material.

Investigations of provenance variation continued through the nineteenth century, most notably for

Scots pine in France, Germany, and Switzerland, and Norway spruce (*Picea abies*) in Germany, Austria, and Switzerland. Adolf Cieslar studied variation in Norway spruce among provenances from different elevations and latitudes, and found that seed from higher latitudes and higher elevations produced slower-growing seedlings than seed from lower or more southerly locations when planted in the same location. He also suggested that the different performance of provenances was inherited.

Early provenance trials were often located in a single environment, on one site, with limited replication. Thus, while the effects of source environment of provenances could be studied, and the optimum provenance for the test plantation site determined, the effects of planting environment and interactions between source and planting environments could not, nor could the results be extrapolated to select provenances for other planting sites. Not until well into the twentieth century was the first published systematic genecological study established, involving multiple experimental sites as well as many provenances, with sufficient replication for robust statistical analysis. The focus of this study was not a tree species, but the herbaceous perennial yarrow (*Achillea millefolium*). Clausen, Keck, and Heisey collected seed from yarrow plants along an east–west transect in California from the Pacific Ocean (sea level) over the coastal range, across the Central Valley, up to the crest of the Sierra Nevada (3300 m) and down its dry eastern slope. They then established common-garden experiments, in which plants from all populations sampled were grown together in a replicated experiment, on experimental sites along the original transect sampled. Similar to earlier studies of Norway spruce, at low-elevation experimental sites the populations from higher elevations were the slower-growing. They also observed that, at each experimental site, the population that grew to the greatest size was the one from closest to the experimental site. Thus, the relative rankings of populations, from largest to smallest based on mean plant size, changed with planting environment, which has been observed since then for many tree species. This is an example of genotype × environment interaction (G × E) (**Figure 1**). If there was no G × E, the fastest-growing population at one experimental site would be the fastest-growing throughout.

The basic genecological experimental design used by Clausen, Keck, and Heisey was repeated for many tree species around the world in the second half of the twentieth century, very often revealing similar patterns of local adaptation: **Figure 1** illustrates a typical pattern. The majority of these tests have been in temperate forest regions in Europe and North America, with fewer published studies of tropical or boreal species. While these trials were initially established to generate information for operational forestry, they have been used for new applications in recent years, including predicting response to climate change, determining the underlying genetic basis of adaptive traits (i.e., ecological genomics) and testing evolutionary and ecological theories about factors limiting the evolution of species range. The extensive body of scientific literature on local adaptation in forest trees may well exceed that for any other type of organism.

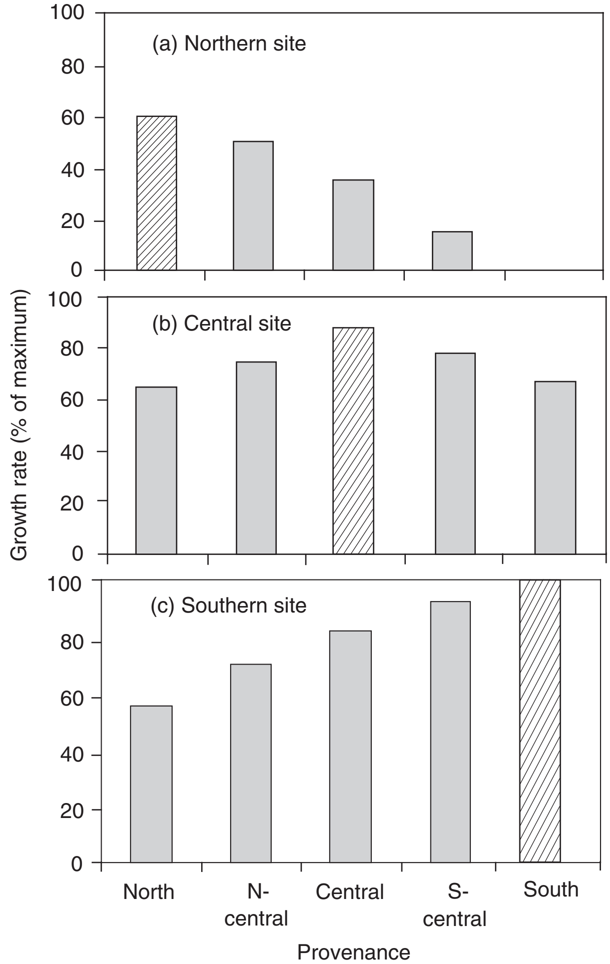

Figure 1 Results of a hypothetical genecological experiment illustrating typical results for widespread, temperate tree species. In this example, seed was collected from five locations (provenances or populations) along a latitudinal transect in the northern hemisphere and grown in common-garden experiments at three of those locations (north, central, and south). Growth is illustrated as a percentage of the mean of the fastest-growing provenance on the fastest-growing site. Average growth is highest at the southernmost site, and lowest at the northernmost site, but the fastest-growing provenance on any one site is local (indicated by the cross-hatched bar). There is genotype-by-environment interaction: the ranking of provenances is different at each site.

Evolutionary Forces

The pattern of genetic variation among and within populations within a species results from the cumulative effects of five evolutionary forces: (1) mutation; (2) gene flow (migration); (3) genetic drift (random changes in allele frequencies from generation to generation due to sampling effects); (4) natural selection; and (5) mating system (the degree to which sexual reproduction occurs through self-pollination, consanguineous mating between related individuals, or mating between unrelated individuals). Genecological studies of tree species with large distributions and historically large populations reveal the efficacy of natural selection in a given environment in favoring locally adapted phenotypes (**Figure 1**). Patterns of genetic variation among populations often mirror environmental gradients, revealing the strong effects of natural selection despite considerable gene flow introducing alleles conferring adaptation to other environments. Genecological studies of species with small ranges, small or isolated populations, or species that have experienced major bottlenecks (e.g., during glacial periods in the Pleistocene) often reflect the effects of genetic drift to a greater extent than other evolutionary forces, and as a result have more random patterns of genetic variation among populations rather than clines along environmental gradients.

Species that show strong patterns of genetic variation among populations in growth and other adaptive traits associated with environmental gradients are referred to as adaptive specialists, while those with weak or no geographic patterns are referred to as adaptive generalists. Generalists may lack such patterns owing to one of two reasons: either they have a high degree of phenotypic plasticity, i.e., the same genotype (genetic make-up) can produce a range of phenotypes (outward appearance, performance, or physiological behavior) depending on the environment, or local adaptation has not had an opportunity to develop as natural selection has been countered either by gene flow or by genetic drift in small populations. In North America, lodgepole pine (*Pinus contorta*) and Douglas-fir (*Pseudotsuga menziesii*) are examples of adaptive specialists, while western white pine (*Pinus monticola*) and western red cedar (*Thuja plicata*) are generalists. Adaptive specialists require more restrictive seed transfer guidelines and smaller breeding zones than adaptive generalists, as there is a greater risk of maladaptation with seed transfer or deployment of genetically selected material. The variation among species in the degree and patterns of specialization means that provenance trial results for one species cannot be extrapolated to another.

Some species have intraspecific taxonomic structure resulting from past isolation of portions of the range leading to more abrupt genetic differentiation among regions due to both random genetic drift and natural selection. This taxonomic structure can persist after previously isolated varieties or subspecies come into secondary contact through range expansion or migration. Examples of such species include *P. contorta* comprising subspecies *contorta*, *latifolia*, *murrayana*, and *bolanderi*, and *Pseudotsuga menziesii* coastal variety *menziesii* and interior var. *glauca*. In species with intraspecific taxonomic structure, genetic differentiation resulting from both isolation and past adaptation can overlay and complicate the interpretation of variation resulting from adaptation to current or recent environments in continuously distributed populations. Hybridization resulting from secondary geographic contact between previously separated species can also produce strong geographic patterns of adaptive variation, for example, in the introgression zone between *Picea glauca* and *P. sitchensis* in the coastal mountains of British Columbia and Alaska.

Genecological Methods

Provenance Trials

Traditional provenance trials require five steps: (1) collection of seed; (2) growing of seedlings; (3) planting of a replicated experiment on multiple field sites; (4) measurement of traits; and (5) analysis and interpretation of results. Seed is typically collected from 10 to 25 trees per location, to ensure a representative sample of the natural population from each provenance. Parent trees sampled are usually 50–100 m (or more) apart, to minimize sampling of closely related individuals. Seeds are sometimes kept separate by seed parent (called a provenance–progeny trial), to allow for the estimation of within-provenance genetic variation and trait heritabilities as well as to facilitate some initial selection for selective breeding; however, bulk seedlots are often used, with seed pooled across parents within provenances. Seed is collected from accessible locations scattered throughout the zone of interest within the species' range, with anywhere from just a few to over 100 locations sampled, depending on the size of the area and the resources available.

Seeds are usually sown in greenhouses or nursery beds and seedlings grown in randomized, replicated blocks for 1–2 years before outplanting. Field provenance test sites are usually selected to cover the range of planting environments that are typical for a species within a given political jurisdiction, although some trials are rangewide, particularly those coordinated by international organizations. To ensure that a range of environments is sampled for native species, sites are usually selected to cover the full range of latitude, longitude, elevation, and ecological conditions across which the target species is found or actively managed. For exotic species, sites are selected across the range of potential planting sites for that species.

Blocks are delineated within planting sites, hopefully grouping similar environments together; for example, with block boundaries following contour lines along slopes, or separating wetter and drier areas. Within blocks, a complete, randomized block design can be used where trees from individual provenances are represented by single-tree plots; a split-plot design can be used where provenances are allocated to main plots and individual-tree progenies within provenances to single-tree subplots. Where such families are identified, equal numbers of seedlings from each family represent a provenance in all blocks, and families are randomized within provenances, usually in single-tree plots.

Traits assessed in provenance trials are often limited initially to survival, height, and diameter. Tree size is used as a cumulative index of tree health and degree of adaptation, and individual tree growth is an indicator of potential stand-level productivity. As trees age, insect or disease outbreaks, and unseasonable weather events such as frost and drought offer opportunities for studying population variation in resistance to biotic and abiotic stresses. However, response to these agents is often best studied under more controlled conditions. While mortality is usually periodically recorded, differences among provenances in survival must be large or replication (blocks and sites) high for these to be statistically significant. In addition, trees can often survive a much broader range of environments than those in which they can be highly productive. In most areas of the world with a focus on industrial plantation forestry, survival is more dependent on good silvicultural practices than on the choice of provenance. Choice of the wrong provenance can reduce the realized production of a high-productivity site, just as planting an optimum provenance can increase site productivity, so growth is usually emphasized. Wood cores can be sampled from older provenance trials and wood properties analyzed including wood density, fiber length, microfibril angle, lignin content, extractives content, and other economically important traits, although within-population variation in wood properties is usually of greater interest than among-population variation.

Short-Term Genecological Experiments

Some traits related to adaptation to specific environmental stresses can be assessed in long-term field provenance trials such as phenology (e.g., timing of bud burst, bud set, leaf abscission, pollination, and seed maturation); cold-hardiness; and drought-related traits (e.g., water-use efficiency as measured by stable carbon isotope ratios in wood samples). Adaptive traits such as these are more commonly assessed in short-term nursery, greenhouse or growth-chamber experiments under more controlled conditions. These trials have several advantages over field provenance studies. They can typically be completed in 2–3 years, can involve more uniform environments and thus have a greater ability to detect genetic differences, can be located close to laboratory facilities for repeated observations or for assessment of time- and equipment-intensive traits, and can allow the isolation, control, and testing of specific environmental factors such as temperature, moisture, photoperiod, and nutrients. Disadvantages include a lack of long-term information on survival and health in natural environments, and the inability to assess mature characteristics. Ideally, these short-term experiments are linked with long-term provenance trials containing similar genetic materials.

The experimental designs for short-term genecological experiments can be similar to or quite different from those for provenance trials. If a genecological mapping approach is taken, instead of sampling from many trees at relatively few locations, many locations are sampled with seed collected from just one or two trees per location. This method, pioneered by R.K. Campbell, allows for the fine-scale mapping of genetic variation and, using spatial analytical techniques, results in detailed spatial maps with isoclines that connect and delineate environments with similar natural selection pressures. Including progeny of two trees at some or all locations allows for the estimation of within-location genetic variation for estimation of trait heritabilities.

Short-term genecological experiments can allow the separation of temperature- and moisture-related adaptation more easily than long-term provenance trials, where factors contributing to tree injury or death may be unclear; treatments controlling environmental factors allow detailed assessments of physiological responses to these treatments. Soil–temperature treatments have been successfully created through the use of soil heating cables, and such treatments have revealed provenance × treatment interaction in some species.

Rather than develop experimental systems to grow seedlings under different temperature regimes, most investigators use artificial freeze-testing of shoots or other tissue samples collected from genecological experiments or provenance trials to assess genetic clines in cold-hardiness. Shoot samples, or small pieces of leaves, buds, or stems, are placed in computer-controlled freeze chambers and the temperature is slowly reduced to a target freezing level. Damage is then assessed using one or more of several available methods, including visual scoring of damage following freezing, measuring the release of electrolytes from injured cells, measuring chlorophyll fluorescence of foliar samples following freezing.

Drought treatments can be created in seedling trials through the use of soils with low water-holding capacity in raised nursery beds with barriers to moisture entry, by withholding irrigation, and by using clear covers to block precipitation. The use of individual-seedling containers for the study of adaptation to drought is not recommended, as this approach usually confounds plant size with drought stress intensity owing to fixed soil volume and no competition.

Data Analysis

The first step in analyzing provenance and genecological trials is usually analysis of variance (ANOVA) to test the significance of phenotypic variation among sites and provenances, as well as within-site environmental effects, including block effects. Provenance–progeny trial analysis also tests for the effects of families nested within provenances and their interactions with site, along with certain other effects. If provenances have been chosen randomly for inclusion in the experiment, unbiased estimates of variance components can be calculated for each effect and the proportion of variation due to provenances, and to families within provenances if applicable, can be estimated.

The next step in the analysis is to test for and characterize genetic clines. A cline is a geographic or environmental pattern of change in the mean of a trait associated with an underlying environmental gradient (**Figure 2**). Where specific environmental descriptors of provenances are lacking, geographic variables such as latitude, longitude, elevation, and distance inland from oceans are used as surrogates. Climatic records provide a better indication of source environments than these geographic variables but weather stations are typically underrepresented in extensively forested areas away from major human settlements. Some provenance trials have selected provenances with available weather records to address this problem, but this may result in a biased sample. More recently, climatic models have been available in some regions, or have been generated by forest geneticists in partnership with meteorologists, to provide better descriptors of provenance environments. For example, predictions from the PRISM model are now available for much of North America.

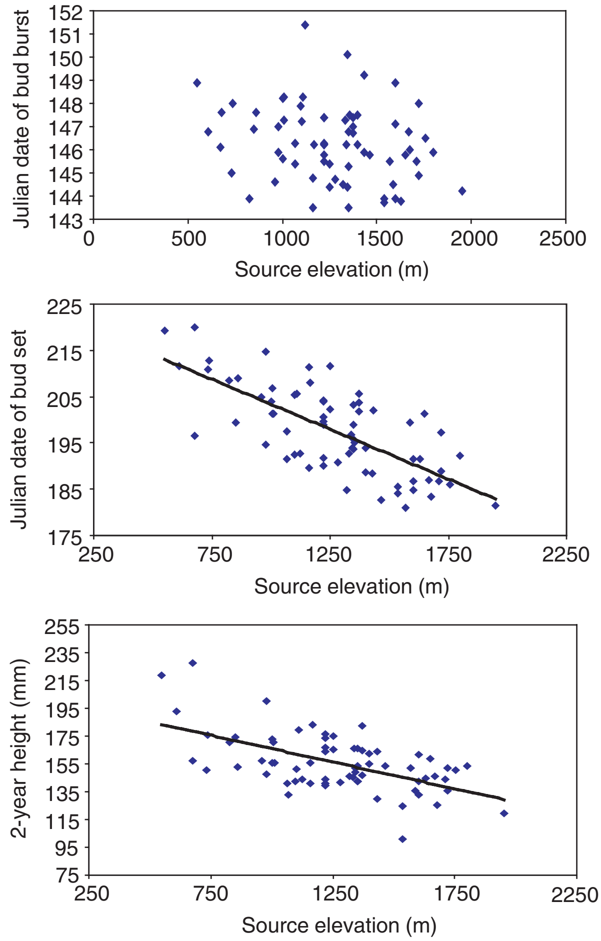

Figure 2 Genetic clines associated with elevation in *Picea engelmannii* (with possible introgression from *P. glauca* at lower elevations) in southeastern British Columbia, Canada, for 2-year-old seedlings in a common-garden experiment established in nursery beds. Plotted against source elevation are the mean values of the open-pollinated progeny of individual seed parents. There is no pattern of variation in mean date of bud burst with elevation; however, date of bud set reveals a fairly strong, significant ($P \leq 0.05$) elevational cline ($r^2 = 0.45$) while height shows a weaker but significant cline ($r^2 = 0.30$).

To test for genetic clines, univariate or multiple regression analyses are conducted on each provenance trial or controlled environment separately, with geographic, environmental, or climatic descriptors as independent variables, and provenance means for assessed traits as dependent variables. A significant genetic cline, particularly if provenance means are significantly associated with a parallel environmental gradient in more than one geographic area, is considered evidence of varying natural selection pressures at different locations along that gradient.

Genetic clines associated with the elevation of parent origin observed in a short-term seedling genecological study of Engelmann spruce (*Picea engelmannii*) are illustrated in **Figure 2** for timing of bud burst, timing of bud set, and height. It is worth noting that, at any elevation, there is still substantial within-population variation for all traits, providing the raw material for adaptation to new conditions or for breeding programs. As traits vary in the strength of clines and spatial patterns of variation, and many traits are often assessed, statistical methods such as principal component analysis are often used to combine traits into multivariate indices.

Genecological Trends

For widely distributed tree species in temperate and boreal regions, most species have broad genetic clines associated with gradients in mean annual temperature, growing-season length (i.e., frost-free period) and, to a lesser extent, total and growing-season precipitation. In mild test environments, overall growth is generally highest for populations with the mildest source environments, and lowest for those from particularly cold (or dry) locations. In harsher test environments, populations from warmer source environments often suffer higher mortality, while populations from similarly cold or dry environments have higher survival and good growth rates for those particular environments.

While local provenances in general are the safest to use for reforestation in the absence of good provenance data, as they have higher survival and productivity than provenances from afar, there are two common exceptions to this pattern. For a number of species, superior provenances have been identified, trees from which have higher than expected growth rates and perform well above the norm for the genetic cline over a wide range of test environments. The second trend is that for many western North American species, the most rapidly growing genotypes with comparable survival and health to local provenances are from slightly milder environments than the test site, e.g., 1–2° S, or 100–300 m lower in elevation. This may reflect adaptational lag, that is, the local adaptation of populations to past rather than current environments, given the long generation interval of trees, or it may reflect a lack of extreme climatic events as agents of natural selection since the provenance trials were planted.

The steepness of genetic clines varies with trait assessed (**Figure 2**). The steepest genetic clines often exist for phenological traits and cold-hardiness. The period of active primary growth from bud break (or growth initiation for indeterminate species) to bud set (or growth cessation) varies with annual frost-free period of source environments. There is typically more variation within species for timing of growth cessation (or bud set) than for timing of growth initiation (or bud burst). Populations within species typically differ in the timing of growth cessation and initiation of cold acclimatization in autumn, or in the timing of dehardening in the spring, rather than in the level of maximum cold-hardiness achieved mid-winter. It should be noted that autumn and spring cold-hardiness are really different traits from a genetic standpoint, as variation in these traits is relatively uncorrelated. In Douglas fir, genetic mapping of quantitative trait loci (QTL) controlling cold-hardiness has revealed that autumn and spring cold-hardiness are controlled by largely independent sets of genes. These processes have different cues: acclimatization (hardening) in the autumn is triggered by photoperiod, while first sufficient chilling, then exposure to warm temperatures, initiates dehardening.

Areas with late summer drought generally have populations with earlier growth initiation and cessation, and greater allocation of biomass below ground (higher root/shoot ratios) than locations with more summer precipitation. The mean total growth of trees in populations tends to be correlated with length of the growing season (period between primary growth initiation and cessation), which explains at least part of the lower growth potential of populations from colder or drier source environments, even under favorable conditions. Populations adapted to dry environments are often phenotypically similar to those adapted to frost-prone locations.

Drought-avoidance mechanisms such as a shorter, earlier growing season, preemptive stomatal closure (resulting in cessation of photosynthesis at a higher water potential), and greater allocation of biomass to roots (as opposed to increasing photosynthetic leaf area) tend to decrease net growth; thus provenances from drier regions often have a lower inherent growth capability. Tolerance mechanisms include higher water-use efficiency (less water used per unit of photosynthesis) and a lower vulnerability to cavitation (the water potential at which xylem water columns embolize). Significant interprovenance variation has been observed for all of these drought-related traits in genecological studies of temperate forest trees, with changes in growth phenology and biomass allocation being the best documented.

Phenotypic versus Genetic Estimates of Differentiation

Many studies rely on the use of selectively neutral DNA markers rather than genecological experiments to determine population differentiation. The results of such studies provide an indication of historic population size based on levels of genetic diversity, as well as the strength of gene flow. Genetic marker variation is commonly partitioned among and within populations, and the amount of total genetic variation due to among-population differences estimated by F_{st}. The proportion of total genetic variation in a phenotypic trait due to differences among populations can also be estimated in a genecological test using a similar parameter, Q_{st}. If Q_{st} exceeds F_{st}, it is evidence of past differences in natural selection on different populations. F_{st} values in forest trees are usually between 5 and 10%, while Q_{st} values are usually higher and vary widely, with published values up to 80%. Thus, while useful for other purposes, selectively neutral genetic markers can greatly underestimate population differentiation and the potential for local adaptation.

While most genetic markers that are widely used for population genetic studies are not useful for studying variation in adaptive traits, as genomic methods develop and gene sequence databases grow, there will soon be new classes of markers available that reveal single nucleotide polymorphisms (SNP) in genes that affect adaptive traits. While most of the adaptive traits of interest are likely influenced by many genes, it will be possible to look for clines in allele frequencies for some of these genes, rather than just characterizing phenotypic variation, using methods of the emerging field of ecological genomics.

Predicting Response to Climate Change

Local populations facing rapid environmental change have three possible fates. They can adapt *in situ* to new conditions. They can migrate, and track the environment to which they are adapted across the landscape. Or they can be extirpated due to maladaptation to new conditions. The pollen and macrofossil records indicate that tree species have migrated in response to past climate change, but the fossil record cannot reveal the extent to which adaptation has also played a role. It has been suggested that population structure and differentiation may have persisted during range expansions and contractions in the Pleistocene, and maintained adaptive structure within species during migration. With rates of anthropogenic climatic change predicted to be much higher than most of those in the past, combined with considerable range fragmentation by human development in some areas, it is likely that species migration will often be unable to keep pace with expected changes.

Established long-term provenance trials have been the focus of renewed interest in recent years; not only do they provide an opportunity to study differences among populations from different environments, but they also provide the ability to study the effects of a changing environment on these populations by substituting spatial for temporal environmental variation. As a result of moving seed from the point of origin to a series of new environments, the genetic and ecological response of these populations to these environments can be assessed.

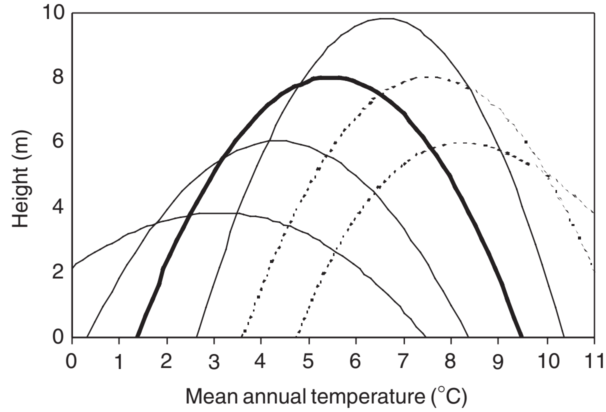

Figure 3 Norms of reaction of six *Pinus contorta* subsp. *contorta* populations to mean annual temperature (MAT) as derived by Rehfeldt GE, Ying CC, Spittlehouse DL and Hamilton DA (1999) Genetic responses to climate in *Pinus contorta*: niche breadth, climate change and reforestation. *Ecological Monographs* 69: 3375–3407, based on height at 20 years in a field provenance trial planted on 60 field test sites. Genotypes typical of each population will be found in geographic areas with an MAT for which that population has higher productivity than other populations. Each population has an optimum MAT at which its productivity is maximized; however, it may not occupy areas with that MAT due to displacement by more competitive genotypes. If climates warm 3–5°C, as predicted by models, productivity losses due to maladaptation will be substantial.

This type of climate change analysis has been most thoroughly conducted by noted genecologist G.E. Rehfeldt, who analyzed provenance data for lodgepole pine in a provenance trial involving 140 populations and 60 field sites. **Figure 3** illustrates the derived responses, called norms of reaction, of height growth of just six of those populations to mean annual temperature of the planting environment. If mean annual temperature increases at the predicted rate of 3–5°C in the next century, it is clear that massive maladaptation will result in this species. It is predicted that it will take 4–12 generations of natural selection, or massive redeployment of genetic resources across the landscape for reforestation, for populations of lodgepole pine once again to be genetically matched to their environments.

Cytogenetics of Forest Tree Species

Ž Borzan, University of Zagreb, Zagreb, Croatia
S E Schlarbaum, University of Tennessee, Knoxville, TN, USA

Introduction

The discipline of cytogenetics was first defined by Sutton in 1903, as a field of investigation which developed from the separate sciences of genetics and cytology. It is concerned with studies on the correlation of genetic and cytological (especially chromosomal) features characterizing a particular genetic system under investigation. With respect to forest trees, cytogenetic studies have generally been limited to chromosome studies, on the number, appearance, and behavior of chromosomes during mitosis and meiosis, chromosomal and karyotypic evolution, and the role of chromosomes in the transmission and recombination of genes.

Plant breeding can be traced to the ancient Babylonians, but a clear understanding of genetics has its beginning in the nineteenth century with Mendel's hybridization experiments and their subsequent rediscovery by de Vries, Correns, and von Tschermack in 1900. Cytology required the invention of the microscope, and began when Robert Hook observed cork cells in 1665. Early scientists studied cell structure, organelles, and division. Nageli first described chromosomes as visual bodies during cell division in 1844, and Fleming in 1882 described the complete process of mitotic nuclear division. However, it was not until the independent observations of Sutton and Boveri that chromosomes were first linked with the emerging field of genetics.

Cytogenetic investigations of forest tree species were first conducted in the early 1900s, after cytological investigations in most crop plants and animals were well established. Leading discoveries were made in the research of insect cytogenetics, and then followed by maize (*Zea mays*) cytogenetics, especially from the standpoint of the applied methods and materials. Thomas Hunt Morgan and his group of students and scientists made fundamental discoveries in the early decades of the twentieth century, investigating giant chromosomes of fruit fly, *Drosophila melanogaster*. The fly's short life cycle and variant phenotypes/genotypes allowed rapid progress in understanding cell differentiation, cell divisions, and breeding results. In contrast, the relatively long time to reproductive maturity of many forest tree species, and logistical problems in sampling, make trees less desirable for cytogenetic research. However, papers written at the turn of the twentieth century pointed to the suitability of conifer species for cytological research.

The main interest in forest tree cytogenetics in the early 1900s was in discovering and interpreting the process of fertilization in pines. Ferguson conducted very detailed observations on the development of the egg cells, fertilization, and microsporogenesis in various pine species (*Pinus strobus*, *P. nigra*, *P. rigida*, *P. resinosa*, and *P. uncinata*). She determined the precise number of chromosomes in the haploid state for these pine species ($n = 12$). Early embryological research, such as Ferguson's, also revealed that chromosomes of coniferous species are relatively large and easily investigated by techniques used at that time, including sectioning and chromosome smears. Working with large conifer chromosomes was made easier after 1921, when the squash technique was developed and camera lucidas utilized for illustrations.

The classic study of that era was by Sax and Sax in 1933, who pioneered karyological studies of 53 gymnosperm species and presented their results using rudimentary idiograms. They discussed the similarities and differences in karyotypes among species and advocated the use of female gametophyte tissue, which showed advantages in analyzing cells without thick cell walls and containing only the haploid number of chromosomes. Their paper was a prototype for further karyological research of coniferous species.

Karyological research of angiospermous (= hardwood) species in that era was hampered by chromosomes that were numerous and generally too small for detailed observations of morphology. Chromosome counts of many species, however, were registered and published in reference books of cumulative presentations of plant chromosome numbers, beginning with Darlington and Wylie's *Chromosome Atlas of Flowering Plants* in 1955, and followed by Moore in 1973, Fedorov in 1974, and by others.

Forest trees occur in a wide variety of taxonomic families and span different orders and classes. Correspondingly, there is a wide variation in the number and size of chromosomes among and even within different species (**Figure 1**). In some taxonomic groups, e.g., Pinaceae, there is great similarity in the chromosomes of different species, which makes identification and comparison difficult. Standardization in karyotype analysis was suggested by some authors, but was inconsistently adopted in later papers. This caused difficulties in comparing results of different cytological investigations. Additionally, differences in terminology, in statistical analysis procedures (if used), and in number of analyzed cells per species contributed confusion.

Forest tree cytogenetic research over much of the twentieth century was dominated by somatic studies on coniferous species, particularly in Pinaceae and Taxodiaceae, using conventional staining methodology. Studies by Saylor, Khosho, Mergen and Burley, Mehra, Hizume, Muratova and Kruklis, Stebbins, Schlarbaum and Tsuchiya, Borzan, and Toda and other representative studies were quoted by Schlarbaum, in his review of cytogenetic studies of forest trees. Many studies were botanical in nature, investigating inter- and intraspecific variation, cytotaxonomy, and phylogeny. In the latter part of the twentieth century, cytogenetic studies of trees exposed to air, heavy metal, and radioactive pollution were made under difficult conditions, and demonstrated the effects of pollution on the meiotic and mitotic processes.

Cell Division and Chromosomes

Cell division includes nuclear (karyokinesis) and cytoplasmic (cytokinesis) division. Simply, it is a cell reproduction process that enables growth (cell multiplication) and development (cell differentiation and growth) of an organism through mitotic division (mitosis), and parental transfer of hereditary determinants to their offspring through meiotic division (meiosis). The process of mitosis and meiosis is fundamentally similar in all organisms, but can differ in details among species.

Mitosis is a genetically controlled process that provides two identical daughter cells with chromosome numbers identical to their parental nucleus. It is followed by cytokinesis and gives rise to genetically equivalent cells in the growing somatic regions of eukaryotic species. This continuous process can be observed under the microscope and is usually described in five stages: prophase, prometaphase, metaphase, anaphase, and telophase. The period between division cycles is the interphase stage, when single-stranded chromosomes become double-stranded chromosomes due to DNA duplication prior to mitosis, with two identical chromatids attached to a common centromere (= primary constriction). Under a light microscope, the chromosomes appear as chromatin granules. As mitosis begins, each chromosome becomes visible as a distinct structure due to coiling, shortening, and thickening during the prophase stage. The spindle (= microtubules) is formed in prometaphase and becomes attached to the kinetochore within the centromere region of each chromosome. During prometaphase, the chromosomes migrate to the spindle equator. The metaphase chromosomes are most often analyzed for determining number and karyotype, as they are maximally condensed and appear as stretched or curved bars divided usually in long and short arms by centromere. In anaphase, the two sister chromatids of each chromosome are separated by movement to the opposite spindle poles. The "daughter chromosomes" of each chromosome arrive at each spindle pole, a cell wall is formed between the two new cells as the nucleus is reconstituted, and the cell proceeds into interphase.

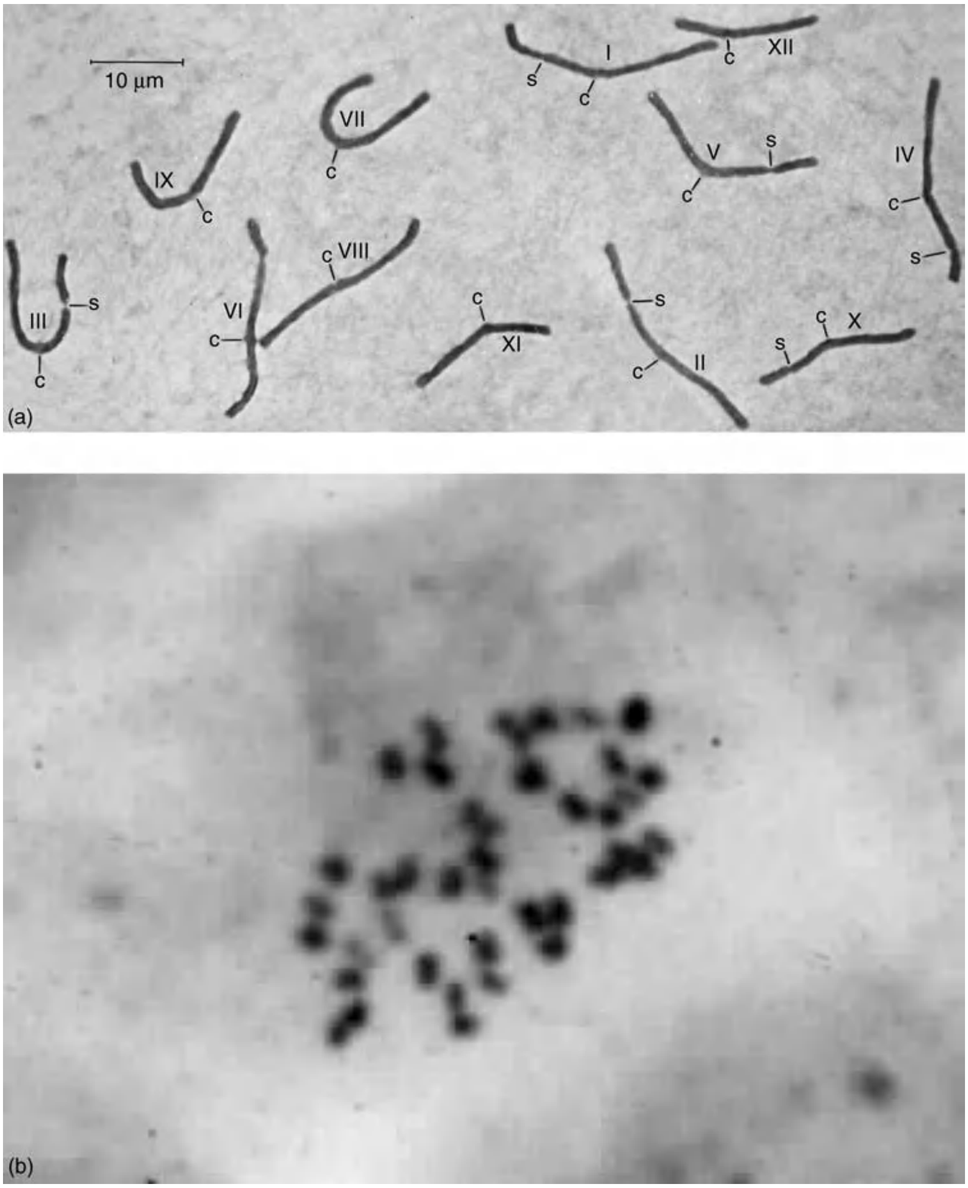

Figure 1 (a) Haploid chromosomes in the female gametophyte tissue of *Pinus nigra*; (b) Diploid chromosomes in somatic cells of root-tips in *Salix sitchensis* ($2n = 2x = 38$).

Meiosis differs from mitosis in having two successive nuclear divisions, with a reduction of chromosome number in the first division from the somatic (= sporophytic) state ($2n$) to the gametic (= gametophytic) state (n) in cells that will proceed to form gametes. Meiosis is a continuous process under genetic control and occurs over a number of stages in each division. The first meiotic division contains the stages leptotene, zygotene, pachytene, diplotene, diakinesis, prometaphase I, metaphase I, anaphase I, and telophase I. The chromosomes are loosely coiled in leptotene and become progressively more densely coiled through telophase I. Pairing of homologous chromosomes (= bivalents) begins in zygotene and is completed in pachytene, where genetic recombination can take place through reciprocal exchanges of genetic material that may occur between homologous nonsister chromatids (= crossing over). Chromosome contraction continues to occur in diplotene and diakinesis. During prometaphase I, the spindle fibers (= microtubules) are organized and become attached to the bivalent centromeres. In metaphase I and anaphase I, the chromatids do not divide as the homologous chromosomes are pulled to the opposite poles, thereby reducing the chromosome number to the haploid state.

The interkinesis stage between the first and second division of meiosis may or may not occur. During this

Figure 2 Asynapsis in *Cunninghamia lanceolata*.

stage, the chromosomes are partially uncoiled. Interkinesis is followed by the second meiotic division, which contains the stages prophase II, metaphase II, anaphase II, and telophase II. The second meiotic division is similar to mitosis, although prophase II does not occur in organisms where interkinesis is omitted. In telophase II, haploid (n) interphase nuclei are reconstituted, and cell walls are formed to separate the four cells, which in turn go through microsporogenesis (male) or megasporogenesis (female).

There can be many variations and anomalies in the meiotic process, particularly when polyploidy, instead of the typical diploidy, is involved. These variations and anomalies can be under genetic control, such as asynapsis where chromosome pairing fails completely among all chromosome pairs, or pairing is incomplete, where only certain homologous chromosomes fail to pair, and thus univalents are formed. Asynapsis can lead to fertility problems due to uneven distribution of the chromosomes in the gametes (**Figure 2**).

Variation in Chromosome Numbers

Generally, each species has a characteristic number of chromosomes in each cell (except for gametes) referred to as the somatic number ($=2n$), which is typically diploid. Most higher organisms have one species-specific set of homologous chromosomes donated by the male (pollen) ($=n$, the gametic number which is typically haploid), and the other set by the mother (egg). Through evolutionary processes, the number of chromosomes can increase by whole sets (polyploidy) and/or increase or decrease by individual chromosomes (aneuploidy).

Polyploidy can occur in different ways, spontaneously or induced. Autopolyploids are polyploids that have occurred through chromosome doubling (*AA*–*AAAA*). Allopolyploids are created when different species (*AA* and *BB*) hybridize and the chromosome number doubles or the hybridization involves unreduced gametes (*AABB*). A segmental allopolyploid occurs when the chromosome complements of very closely related species or subspecies combine ($A_1A_1A_2A_2$).

As with polyploidy, aneuploidy can occur spontaneously or can be induced. There is a large body of terminology for individuals that have lost or gained individual chromosomes, e.g., nullosomic ($2n-2$; missing both homologs of a chromosome pair), monosomic ($2n-1$; missing one homologous chromosome), trisomic ($2n+1$; containing three homologous chromosomes).

In conifers, true polyploid coniferous species are rare, occurring only in Taxodiaceae (*Sequoia sempervirens*) and Cupressaceae (*Fitzroya cupressoides*), although individuals within Taxodiaceae, e.g., *Cryptomeria*, and Cupressaceae, e.g., *Juniperus*, are polyploid in nature. Aneuploidy is widespread in species of Podocarpaceae. In other coniferous families, however, polyploid and aneuploid individuals are generally stunted and not competitive in natural settings.

A review of Darlington and Wylie's *Chromosome Atlas of Flowering Plants* in 1955, coupled with a more recent overview by Schlarbaum in 1991, reveals a significant number of hardwood species where polyploid and aneuploid processes have been involved in the speciation process. Additionally, it is evident that there are species with polyploid races, e.g., *Fraxinus americana*, *Populus tremuloides*, and *P. tremula*. The chromosome nature of most hardwood species, however, is still unknown. While chromosome counts have been made on many species, those counts are often based on a single sample of individuals or a single individual.

Basic chromosome number (x) represents the smallest (monoploid) chromosome number in a taxon. Basic number can become variable as the taxon grouping becomes larger, e.g. *Cupressus* to Coniferales, etc. The basic chromosome number has evolutionary connotations, and there are many publications that speculate about the true basic number of different taxa, particularly those with high chromosome numbers.

Notation of chromosome number in the scientific literature is often incorrect, when the notation involves the somatic ($2n$) or gametic (n) number and basic number (x) of a species. For example, notation for somatic chromosome number of a diploid species with 24 chromosomes in somatic cells ($2n$), 12 chromosomes in haploid cells (n), and a basic number of 12 chromosomes, is written as: $2n=2x=24$. If there is a euploid (whole chromosome set) increase in chromosome number to 36, the notation would be $2n=3x=36$; not $3n=3x=36$. The notation for somatic number remains $2n$, despite the increase in chromosome number. With aneuploid changes in chromosome number, the $2n$ and $2x$ notation remains the same, but the number of chromosomes added or missing is noted, e.g., $2n-1=2x-1=23$.

Slide Preparation Methodology

Uniform Chromosome Staining

Until the mid-1970s, the majority of forestry cytogenetic studies were conducted to determine the chromosome number and karyotype by using a staining methodology that produced a uniform stain. Root-tip meristematic tissue and, to a lesser extent, terminal bud or young leaf tissues were used. Before fixing, the root tips are usually pretreated with a mitogen to inhibit spindle fiber formation in metaphase, resulting in slides with a large number of cells at the metaphase stage. In addition, the mitogens selected, e.g., colchicine, 8-hydroxyquinoline, were often used to shorten the extremely long chromosomes found in conifers, as well as to inhibit postmetaphase cell division. After fixation, usually in Farmer's or Carnoy's solutions, the sampled materials were hydrolyzed in different chemicals, e.g., $1\,\mathrm{mol\,l^{-1}}$ HCl, or later enzymes, e.g., pectinase, to secure the satisfactory separation of cells. Somatic investigations have used a variety of methods for slide preparation, including the smear and squash techniques.

Different cytological methods were described in detail by Darlington and La Cour in 1962, followed by various improvements made by many authors, depending on the species and tissue investigated. More recently, Fukui and Nakayama edited in 1996 an excellent laboratory manual describing methods for plant cytology investigations. An example of most commonly observed features of the prometaphase and metaphase chromosomes is shown in **Figure 3**.

Karyotype Analysis

The karyotype of an organism is a descriptive analysis of the chromosome complement. Each karyotype is defined numerically with statistical parameters of values based on the measurements of the chromosome's morphology. A graphic presentation is often used to give a better illustration of the chromosomes and their morphological features. Problems of comparison among studies can arise due to the lack of standardization in presenting a karyogram, graphically or numerically. An insight into this problem was published in *Forest Genetics* journal in 1996, with recommendations for standardized presentation of karyotypes for the species of the Pinaceae family. An example of the graphic presentation is shown in **Figure 4**.

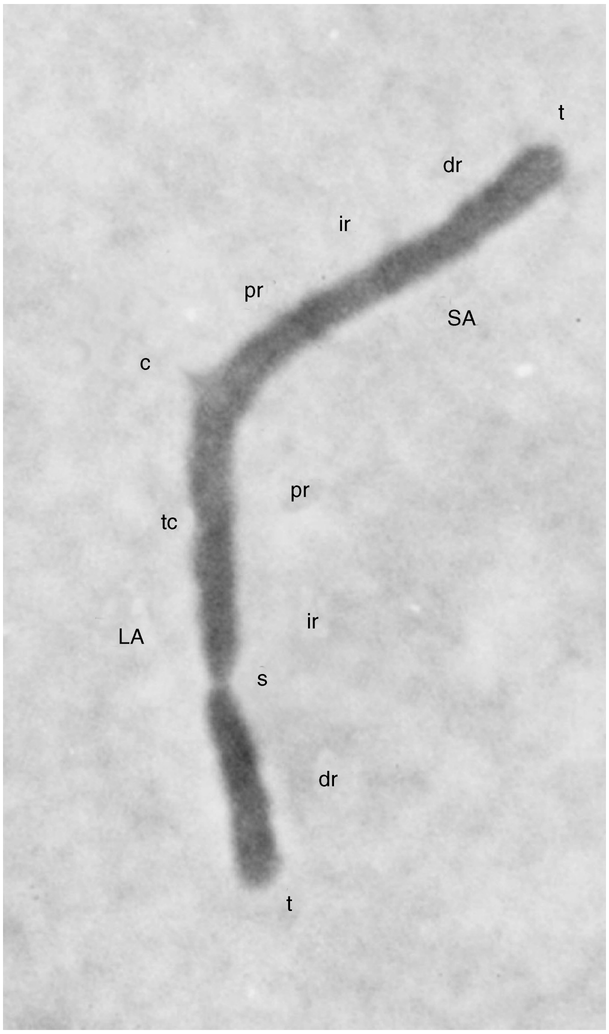

Figure 3 Chromosome terminology shown on the *Pinus nigra* metacentric chromosome V. SA, short arm; LA, long arm; t, telomere; dr, distal region; ir, interstitial region; pr, proximal region; c, centromere (primary constriction); tc, tertiary constriction; s, secondary constriction (nucleolar organization region or NOR).

Classification of chromosomes by centromere position is a basic feature of karyotype analysis. Depending on the centromere position, chromosomes can range from metacentric to telocentric. Centromeric nomenclature, however, can vary from study to study. In studies of *Pinus* species, the classification presented by Saylor's classic papers is most often used. Another classification system often cited is the nomenclature presented by Schlarbaum and Tsuchiya in 1984, which was developed according to protocols given by Levan and his coworkers in 1964. Recognizing the inconsistency in centromeric nomenclature in a wide range of studies and the need for a standard, Levan and his coworkers developed precise standards for nomenclature and devised a system for modifying the standards to allow for better distinction among chromosomes if needed. Other modifications can be used if warranted by chromosome morphology, but the modifications should be according to their protocols.

The ability for rapid communication among scientists through the internet presents an exciting possibility in sharing karyomorphological data of investigated species. An idea for consolidating data in a standardized manner in a centralized database that can be instantly analyzed and made available worldwide via the internet was presented during the Second IUFRO Cytogenetics Working Party S2.04.08 Symposium, held in Graz, in 1998.

Banding Methods

In the last quarter of the twentieth century, chromosome banding techniques began to be applied to forest tree species. These techniques allowed for better distinction between homologous chromosomes and among nonhomologous chromosomes of similar size and morphology. Chromosome banding

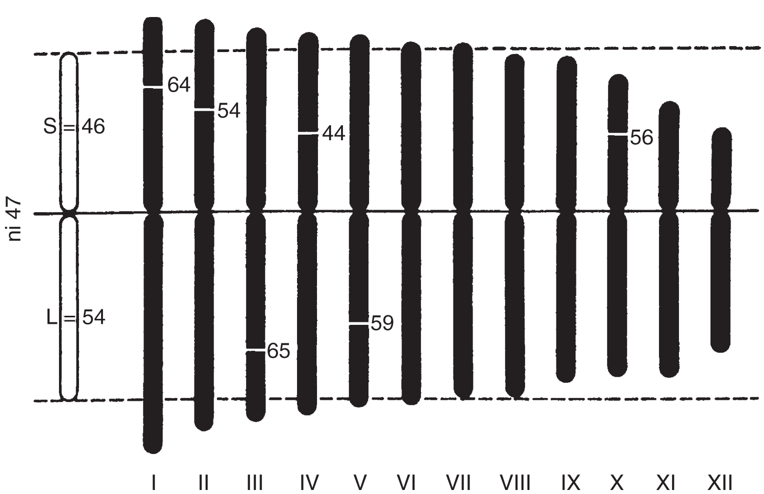

Figure 4 Graphic presentation of karyotypes shown by the idiogram of *Pinus nigra*.

is especially important in physical mapping of genes and can provide additional insight into the molecular organization of chromosomes.

Chromosome banding can be defined as a lengthwise variation in staining properties along a chromosome, induced by application of a variety of chromosome treatments by specific reagents, dyes, singly or in combination. It refers both to the process of producing banding patterns and to the patterns themselves. All of the many different banding methodologies have a common objective of accurately identifying chromosomes and parts of chromosomes. The use of banding methodology can also give insight into chromosome organization. Some banding methods have contributed greatly to both the molecular biology and cytogenetics, giving chromosome research a new and wider importance. However, successful attempts to band chromosomes of tree species using protocols for mammalian or plant species have been limited. Thus, banding of chromosomes of forest trees is currently still an enigma in terms of band numbers and/or consistency.

Important insights into chromosomal reactivity to applied reagents for revealing banding patterns was possible after Heitz in 1928 showed that certain specific chromosome segments, termed heterochromatic, do not decondense during the telophase. Constitutive heterochromatin is a permanent structural characteristic of a given chromosome pair, and is present in all cells at identical positions on both the homologous chromosomes, whereas facultative heterochromatin is heteropycnotic in special cell types or at special stages, and is related to differential gene activity, according to Brown in 1966. Constitutive heterochromatin is chromosome-specific and species-specific and can be used for chromosome identification; it is cold-sensitive, late-replicating, and genetically inert, and usually contains highly repetitive DNA sequences. After Pardue and Gall's paper in 1970 showed that Giemsa dye stained centromeres of mouse chromosomes more strongly than other chromatin, the Giemsa C-banding technique became the most widely used banding method for both animal and plant chromosomes. The first successful Giemsa C-banding of a forest tree species was on *Pinus nigra* chromosomes (**Figure 5**) by Borzan and Papeš in 1978 on haploid chromosomes in the female gametophytic tissue. Other scientists – Muratova, Tanaka and Hizume, Wochok and coworkers, and MacPherson and Filion – applied Giemsa banding to various coniferous species, mostly on root-tip meristematic tissue, and made further steps in that field. The use of Giemsa C-banding in hardwood species has been very limited. Generally, the small size of metaphase chromosomes in hardwoods limits the usefulness of this technique. An example of a Giemsa C-banding method applied to chromosomes from female gametophytic tissue of *Picea abies* is shown in **Figure 6**.

A review of Giemsa C-banding studies in conifers shows that this method successfully reveals bands of constitutive heterochromatin located in the region of the centromere, in secondary constrictions and, occasionally, in intercalary regions. In general, coniferous chromosomes contain a relatively small amount of constitutive heterochromatin. Owing to the lack of research on forest trees in this area, it is still not possible to formulate conclusions on heterochromatin distribution at the level of population, let alone of taxon.

Chromosome banding became more practical in the early 1970s, when staining protocols developed for banding chromosomes of one organism could be applied to other organisms with only minor modifications. As the use of banding protocols became more prevalent and more specific for certain chromatin or regions, classification of chromosome bands occurred as follows:

1. Heterochromatic bands, where constitutive heterochromatin (not facultative) is stained distinctively.
2. Bands occurring throughout the length of chromosome, which Sumner regarded provisionally as euchromatic bands.
3. Specific staining of the kinetochore structure.
4. Nucleolar organization region (NOR) bands.

Nomenclature of different banding methods is standardized and usually abbreviations are used to designate the method in use. In 1990 Sumner described banding nomenclature and reviewed C-banding and related methods, G-banding, R- and T-banding, Q-banding, banding with fluorochromes and methods for NOR and kinetochore staining. Fukui and Nakayama presented in 1996 banding plant chromosomes principles and detailed protocols for revealing C-bands, N-bands, fluorescent-bands 4′,6-diamidino-2-phenylindole (DAPI) for the detection of AT-rich and chromomycin A_3 (CMA) for the detection of CG-rich regions of constitutive heterochromatin in plant chromosomes, F-bands, Hy-bands, G-bands, RE-bands, and Ag-NOR-bands.

Fluorescence chromosome banding using CMA, Hoechst 33258 and DAPI has been successfully used in different coniferous species. Fluorescence *in situ* hybridization (FISH) is a technique for detecting a site of specific DNA sequences (rDNA, other classes

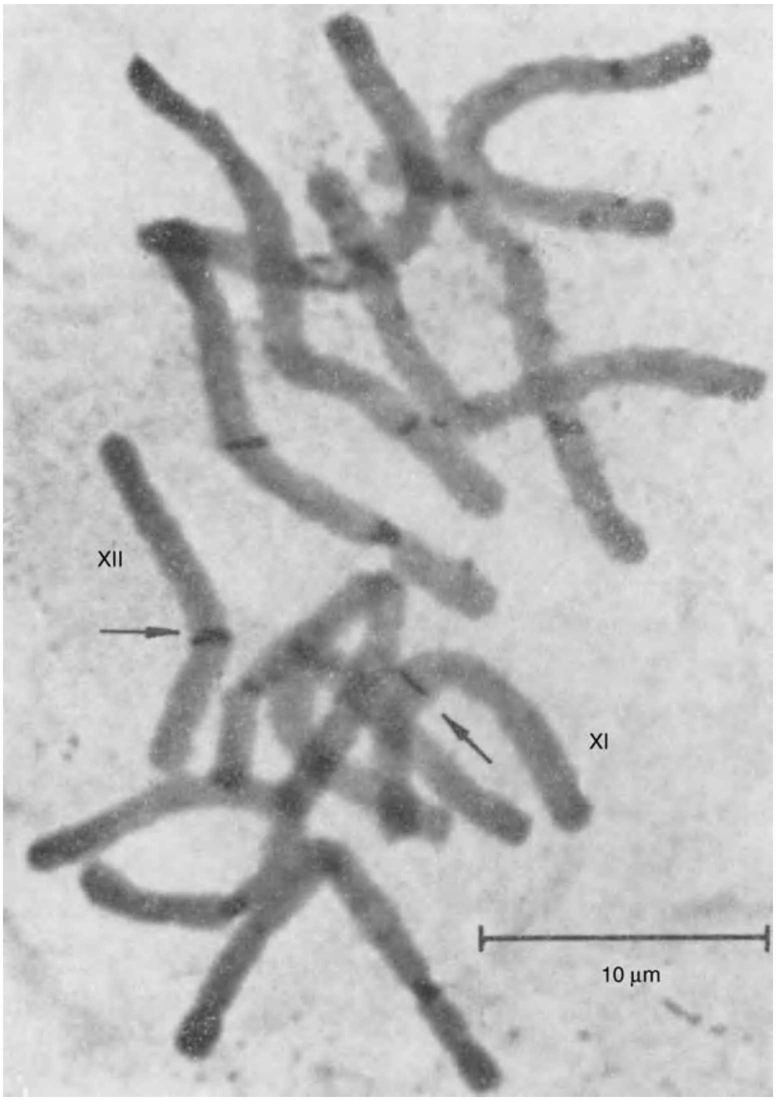

Figure 5 Giemsa C-banded chromosomes in the female gametophyte tissue of *Pinus nigra*. Arrows indicate centromeric bands on submetacentric chromosomes.

of repeated DNA, or single genes) in plant and animal chromosomes, thereby allowing physical mapping. CMA bands appearing at the secondary constrictions coincide with FISH signals when an 18S-5.8S-26S rDNA probe is used on chromosomes of coniferous and hardwood species, and in many other plant and animal species. **Figure 7** shows banded chromosomes from *Quercus pubescens* by the FISH technique, using 18S-5.8S-26S and 5S rDNA probes. Nakamura and Fukui applied in 1997 a laser dissection method to dissect specific regions of the chromosomes of giant sequoia (*Sequoiadendron giganteum*), showing that visible SAT-chromosome contains 18S rRNA genes and is the only location for those genes in the chromosome complement.

Applications of Cytogenetics to Basic Genetic Research in Forest Trees

Prior to the advent of molecular biology and *in-situ* hybridization of probes directly on chromosomes, physical gene mapping was essentially nonexistent in forest tree species. Agronomic and horticultural approaches that use chromosomal aberrations, e.g., translocations, or aneuploidy, such as monosomics or trisomics, in combination with breeding are generally not possible with coniferous species. Most conifers do not tolerate aberrations and aneuploid changes which usually affect growth and reproduction. With hardwood species, cytogenetic characterization of the different species was too limited to conduct mapping experiments. Long-term

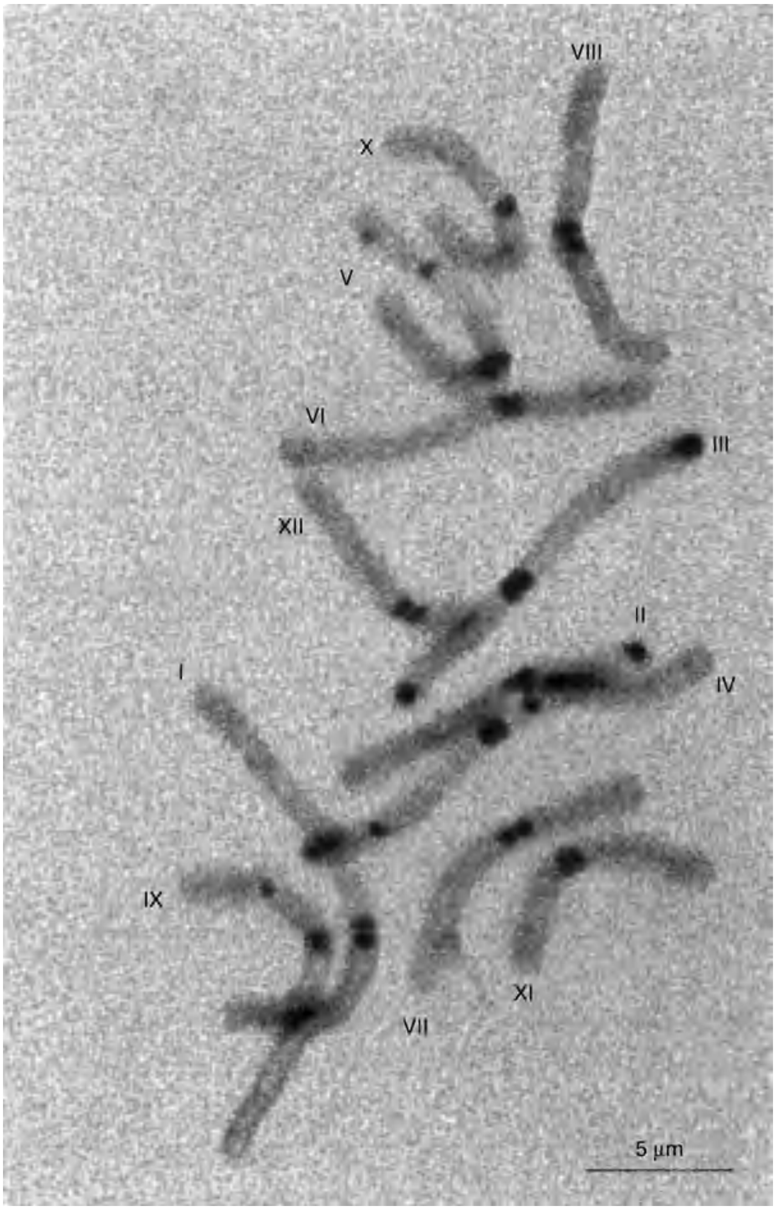

Figure 6 Giemsa C-banded chromosomes in the female gametophyte tissue of *Picea abies*.

reproductive cycles and, often, the physical size, contributed to difficulties in mapping forest tree species.

The application of chromosome banding techniques developed in the 1970s specifically to identify chromosomes was an initial step toward physical mapping. The development of chromosome imaging techniques for tree species by Fukui and by Guttenberger has also contributed to chromosome identification. *In-situ* hybridization with a variety of fluorescing probes has physically mapped gene sequences to chromosomes in a number of coniferous and some hardwood species. Nakamura and Fukui's laser microdissection of a SAT-chromosome in *Sequoiadendron* shows the potential for using a combination of cytogenetic and molecular techniques with instrumentation. Physical mapping efforts have been concentrated on coniferous species owing to their chromosome size, but advances in instrumentation from human genome projects may make studies on hardwood species more feasible.

Applications of Cytogenetics to Tree Improvement

Using a cytogenetic approach to improve a plant species usually involves breeding and/or euploid

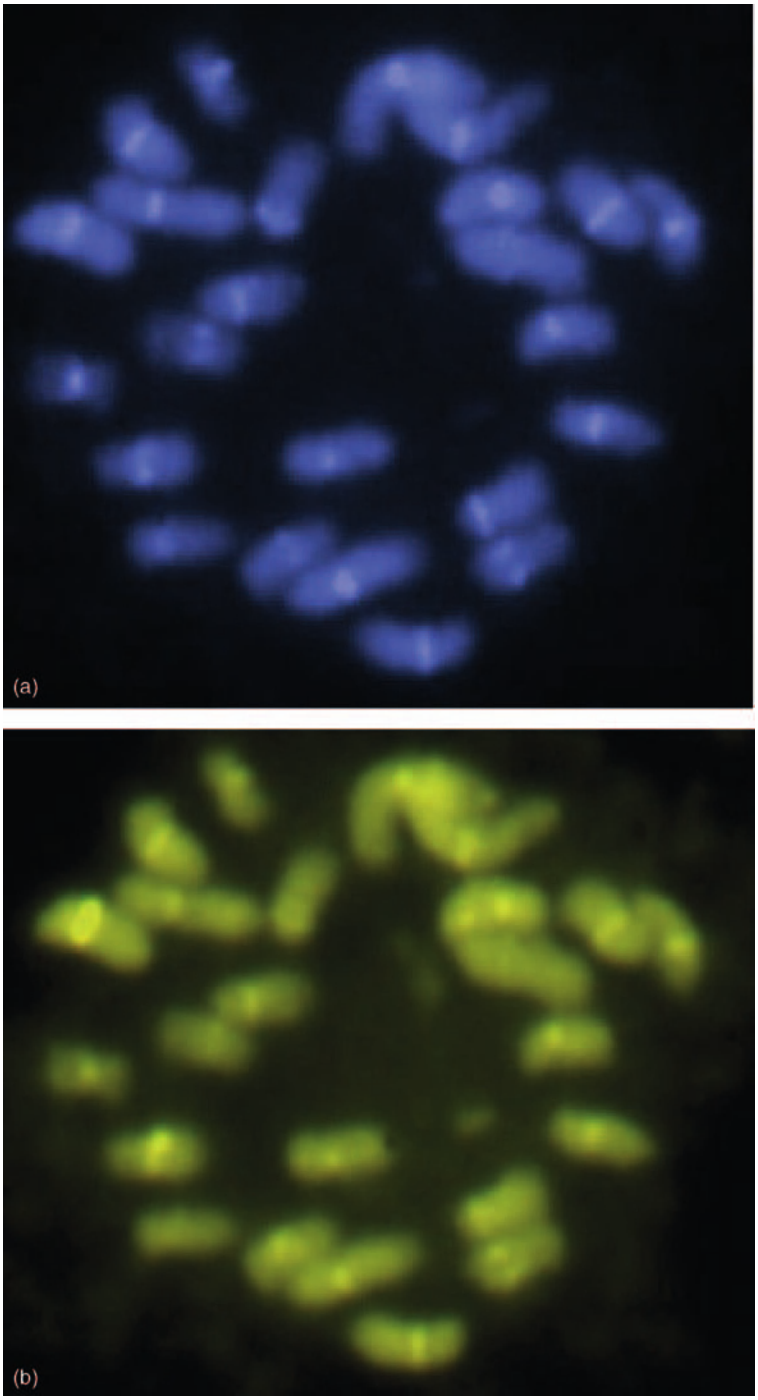

Figure 7 Banded chromosomes from the root-tip meristem tissue of *Quercus pubescens*. (a) Coloration with 4′,6-diamidino-2-phenylindole (DAPI) reveals fluorescent bands exclusively in centromeric regions of all 24 chromosomes of *Q. pubescens* complement. (b) Coloration with chromomycin A_3 (CMA) reveals fluorescent bands in all 24 chromosomes at the juxtaposition with those produced by use of DAPI. The most prominent CMA bands at the centromeric region of one metacentric pair correspond to 18S-26S rDNA sites. Note the same metaphase plate for both DAPI and CMA banding. Reproduced with permission from Zoldos V, Papes D, Cerbah M *et al.* (1999) Molecular-cytogenetic studies of ribosomal genes and heterochromatin reveal conserved genome organization among 11 *Quercus* species. *Theoretical and Applied Genetics* 99: 969–977.

increases in chromosome number. Unfortunately, the majority of cytogenetic studies of forest trees have been on coniferous species and little improvement has been made. Most species have a juvenile period that can be measured in years, which has precluded improvement via a cytogenetic approach when breeding is involved. The delay in breeding may be circumvented by using accelerated breeding techniques that have been developed for some species. Shortening the breeding cycle, however, is only a partial solution. Chromosome changes in this group of trees are not well tolerated, with the exceptions of Taxodiaceae and Cupressaceae. It is only in *Cryptomeria japonica* that euploid changes from the normal diploid state have been exploited.

Cytogenetic improvement of hardwood species shows more promise than coniferous species. Some species have relatively short juvenile periods that would not greatly inhibit an integrated cytogenetic/breeding approach to improvement. Ploidy changes, either natural or induced, are not a problem in many species, and euploid changes from the diploid state have been shown to increase yield in some species. Studies have shown that triploidy is the optimal level for growth in *Populus* and could be for some *Quercus* species. In general, cytogenetic manipulation of hardwood species is a vast reservoir of potential waiting to be explored.

Conclusion

A general conclusion on the benefits from cytogenetic studies on forest trees is somewhat problematic. Studies on forest trees are able to follow successfully the methods applied in human, animal, and plant cytogenetic studies, but usually have not been pursued in depth, e.g., in an integrated long-term breeding and cytogenetic program with tangible objectives. During the era when cytogenetics was prevalent in science and resources were available, many studies concentrated on coniferous species in Pinaceae, in which chromosome aberrations and changes in chromosome number are usually disastrous. Early efforts in studying and developing triploid aspen were successful, but diminished in the 1960s. Despite the success of the triploid aspen program, interest in cytogenetic studies did not spread to other hardwood species. Although sporadic studies on ploidy changes in some hardwood species have shown promise for increasing timber yields, corresponding tree improvement programs have generally not had a cytogenetic component. Advances in instrumentation, e.g., chromosome imaging systems and laser microdissection, coupled with wise choices for experimental material can make cytogenetics an important component of basic and applied forestry research. Therefore, it can be concluded that the contribution of cytogenetics to the forestry profession and science in general has been small, but the potential for contribution still remains significant.

Forest Management for Conservation

R Uma Shaanker, N A Aravind and K N Ganeshaiah, Ashoka Trust for Research in Ecology and the Environment, Hebbal, Bangalore, India

Introduction

Forest management for conservation is in practice different from management of forest for optimizing economic returns. It refers to the preservation of forest for the explicit functions of conserving the constituent biodiversity elements and ecosystem processes. The concept of managing forest for conservation is very old and was practiced by many traditional cultures and societies across the world. The resurgence however of the concept in the nineteenth century followed the European colonization events and thereafter more recently owing to the disproportionately large human pressure on the forest resources. Several models of forest management for conservation have emerged, both globally and locally. From very formal models such as the protected area network to completely informal models of grassroots people's movements, managing forests for conservation has gained an unparalleled momentum in the last couple of decades. In this article we trace the development of the concept of managing forests for conservation with a critique on the various models of management for conservation.

Historical Developments

Historically, forest management for conservation can be traced to two major schools, the first embedded in traditional cultures and the second emerging subsequent to European colonization of the tropical world. In both, the motive seems to have emerged from the need to prevent the overexploitation of natural resources, be it waterfowl hunting by the Egyptians or timber felling by the British in India. Ashoka, one of the illustrious Emperors of India (274–232 BC) was known for his great diligence in conserving forests. He not only passed an official promulgation forbidding the killing of a set of animals, but also decreed that forests must not be burnt. A large number of civilizations across the world, including the Greeks, Romans, Mongols, Aztecs, and Incas, developed such decrees from time to time. With the wave of exploitation of natural resources by the European powers during the eighteenth and nineteenth centuries, the need for conserving the natural resources, if only to build up the growing stocks, was acutely realized. This resulted in a number of promulgations in the European colonies from the Ivory Coast in Western Africa to Indonesia in Eastern Asia. In India, for example, the British established the Imperial Forest Department in 1864 to oversee the utilization of timber for railway crossties. By another legislation, in 1874, the British classified forests in India into three categories, viz., the reserved forests (where extraction of timber was permitted), protected forests (which were under state control and protected against extraction pressures from the local people), and village forests (apparently open to the village settlements for sourcing their needs).

In the recent past, a significant shift in the conservation ethos occurred when attention was paid to conserving or preserving species other than those that were merely economically useful. Thus, perhaps for the first time in recent history, attention was paid to the conservation of invertebrates, small plants, amphibians, and reptiles. One of the earliest milestones in this movement can be traced to the 1960s and 1970s when several countries including the USA passed national legislation on endangered species. Thus from a predominantly economic approach to forest management there was a shift in emphasis to forest management for conservation.

Models of Forest Management for Conservation

Among global models of forest management for conservation, three types can be readily identified: (1) formal models that include protected areas; (2) semiformal models that includes conservation through community participation with the state, such as sacred groves, joint forest management and extractive reserves; and (3) informal models arising from grassroots people's movements (**Figure 1**). The formal models are almost invariably controlled by the state while the semiformal approaches involve varying degrees of state and local community regulations. The informal models are mostly led by individual groups of people or institutions. In the following sections, we describe the salient features of these models with a brief commentary on the relevance of these models to conservation issues and practices.

Formal Model of Forest Management for Conservation: Protected Areas

History

According to the IVth World Congress on National Parks and Protected Areas, 1992, a protected area is

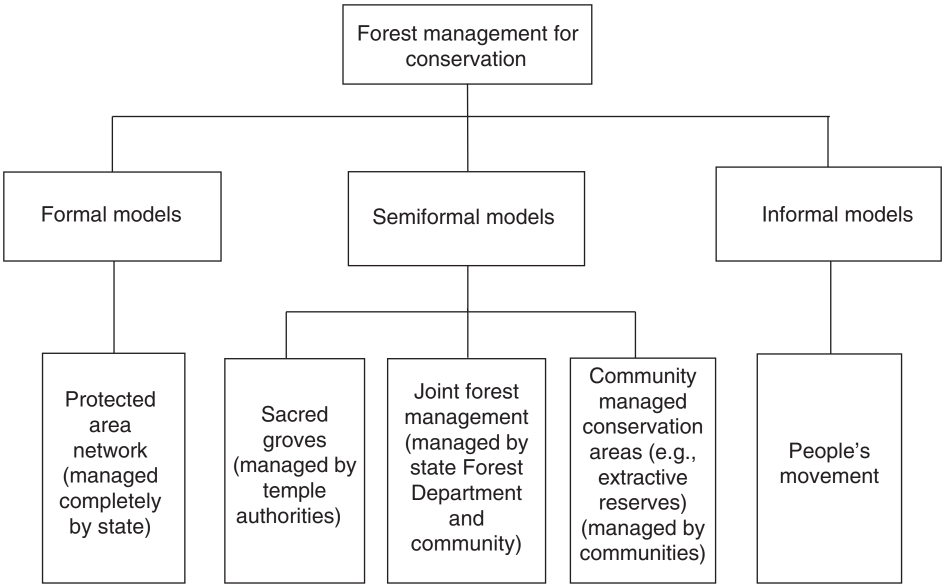

Figure 1 Schematic diagram of the various models of forest management for conservation.

defined as: An area of land and/or sea especially dedicated to the protection and maintenance of biological diversity, and of natural and associated cultural resources, and managed through legal or other effective means. The designated protected areas are usually accorded protection by the state authorities and often exclude local people and institutions from decision-making processes or procurement of direct economic benefits. By enforced exclusion of all forms of dependence, the protected area is supposed to serve the conservation goals in its purest form. Delimiting a protected area was historically used by rulers to exclude people from parks to conserve, primarily, a healthy population of wild animals for purposes of hunting. Thus among the first 'conservation areas' in Europe were the medieval hunting parks such as the New Forest established in 1079 by William I of England. In recent history, the first area protected specifically for 'the preservation of' its biodiversity and 'for the enjoyment of the people' was Yellowstone National Park, established by the US Congress in 1872, and later followed by the creation of the National Park Service in 1916. The latter was instrumental in the establishment of the network of protected areas across the USA.

Classically the protected area concept involves setting aside natural or seminatural areas with high conservation value in which genes, species, communities and even habitats are conserved. Based on the emphasis of conservation, the IUCN has categorized protected areas into several groups (**Figure 2**). With increasing international efforts to preserve biological diversity, protected areas have become central to any global strategy for conservation.

Global Network of Protected Areas

Globally there are currently 9869 protected areas (>1000 ha) covering an area of about 9 317 874 km^2, about 6.29% of the earth's land surface area (**Figure 3**). Protected area networks vary considerably from one country to another, depending on needs and priorities, and on differences in legislative, institutional, and financial support. Europe has the maximum area under protection (about 16.4% of the continent's land area) while Asia has the least, accounting for only 4.29% of the land area (**Figure 4**). The global distribution of protected areas does not necessarily reflect the underlying patterns in species richness and biological diversity. For example, in the world's 25 biodiversity hotspots, which harbour 30–40% of all earth's biodiversity, an average of less than 10% of land area is protected. Partly to rectify this discrepancy, a number of protected areas have been established in the framework of international instruments include the World Heritage Sites, designated under the 1972 Convention for the Protection of the World Cultural and Natural Heritage and the World Network of Biosphere Reserves, operated under the UNESCO's Man and Biosphere (MAB) program.

Effectiveness of Protected Areas

Critics claim that protected areas cannot serve as effective means of conservation, because often these forests are vulnerable to anthropogenic pressures. The World Bank/World Wildlife Fund (WWF) Alliance have shown that less than one-quarter of declared national parks, wildlife refuges, and other

IUCN has defined a series of eight protected area management categories, based on primary management objective. These are:

1. Strict Nature Reserve/Scientific Reserve. To protect nature and maintain natural processes in an undisturbed state in order to have ecologically representative examples of the natural environment available for scientific study, environmental monitoring, education, and for the maintenance of genetic resources in a dynamic and evolutionary state.

2. National Park. To protect outstanding natural and scenic areas of national or international significance for scientific, educational, and recreational use. These are relatively large natural areas not materially altered by human activity where extractive resource uses are not allowed.

3. Natural Monument/Natural Landmark. To protect and preserve nationally significant natural features because of their special interest or unique characteristics.These are relatively small areas focused on protection of specific features.

4. Managed Nature Reserve/Wildlife Sanctuary. To assure the natural conditions necessary to protect nationally significant species, groups of species, biotic communities, or physical features of the environment where these may require specific human manipulation for their perpetuation. Controlled harvesting of some resources can be permitted.

5. Protected Landscapes and Seascapes. To maintain nationally significant natural landscapes which are characteristic of the harmonious interaction of humans and land while providing opportunities for public enjoyment through recreation and tourism within the normal lifestyle and economic activity of these areas. These are mixed cultural/natural landscapes of high scenic value where traditional land uses are maintained.

6. Resource Reserve. To protect the natural resources of the area for future use and prevent or contain development activities that could affect the resource pending the establishment of objectives which are based upon appropriate knowledge and planning. This is a "holding" category used until a permanent classification can be determined.

7. Anthropological Reserve/Natural Biotic Area. To allow the way of life of societies living in harmony with the environment to continue undisturbed by modern technology. This category is appropriate where resource extraction by indigenous people is conducted in a traditional manner.

8. Multiple Use Management Area/Managed Resource Area. To provide for the sustained production of water, timber, wildlife, pasture, and tourism, with the conservation of nature primarily oriented to the support of the economic activities (although specific zones may also be designated within these areas to achieve specific conservation objectives).

Figure 2 IUCN system of classification of Protected Area Management Categories.

protected areas in 10 key forested countries were well managed, and many had no management at all. In other words, only 1% of the protected land area is secure from serious threats such as human settlement, agriculture, logging, hunting, mining, pollution, war, and tourism, among other pressures. However, officially designated conservation areas have been shown to be successful at reducing forest clearance and, to a lesser degree, effective at mitigating the effects of logging, hunting, fire, and grazing (**Figure 5**). Even modest increases in funding to the parks are likely to increase the ability of the parks to protect biodiversity.

Despite their shortcomings, protected areas do provide the last refugia for many species threatened with extinction. About 40 critically endangered trees are found almost exclusively within the protected areas across the world. These include *Hibisicadelphus woodii* (Malvaceae) with population fewer than 10 in the Napali Coast State Park, Hawaii; *Parsania formonsana* (Fagaceae) in the Kenting National Park, Taiwan; and *Shorea bakoensis*, in Sarawak, Malaysia. In Thailand, a large number of important timber species, which have been extensively harvested from the native forests, are today found only in protected areas. The last remaining population of the white rhinoceros (*Diceros simus*) is found in the Garamba National Park in the Democratic Republic of Congo as much as the remaining population of the Asiatic lion (*Panthera leo*) in the Gir National Park, Gujarat, India (**Table 1**).

Protected areas also serve as repositories of intraspecific genetic diversity for economically important forest species. For example, populations of sandal (*Santalum* spp.), a tree treasured for its heartwood oil in India and that has been extensively felled as a result, have higher genetic diversity in national parks and sanctuaries than outside. Protected areas also afford higher population genetic diversity for several species of bamboos and rattans. Thus in addition to species conservation, protected areas fulfil an important function in the conservation of intraspecific genetic diversity.

Deficiencies of Protected Areas

Critics also point to the fact that protected areas tend (1) to be biased towards conserving charismatic taxa

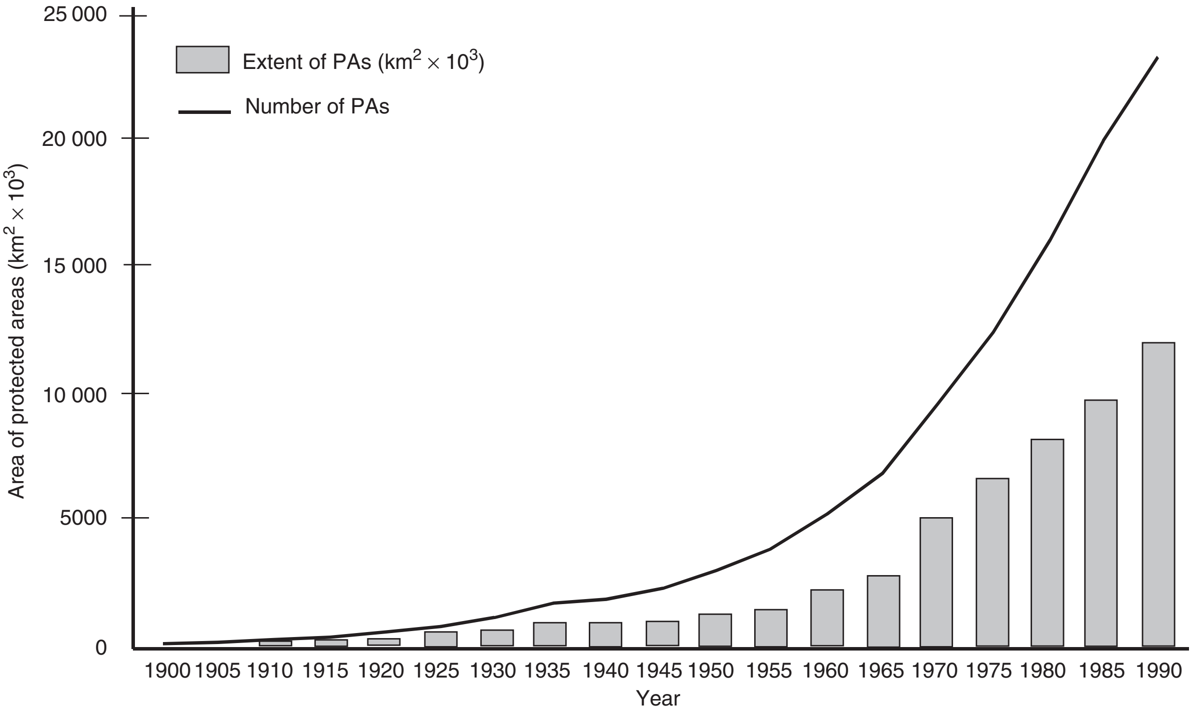

Figure 3 Cumulative area (bars) and cumulative number (line) of protected areas in the world since 1900. About 59% of the protected areas are less than 1000 ha. Redrawn from Michael JBG and Paine J (1997) State of the world's protected areas at the end of the twentieth century. In IUCN World Commission on Protected Areas *Symposium on Protected Areas in the 21st Century: From Islands to Networks*, 24–29 November 1997, Albany, Australia.

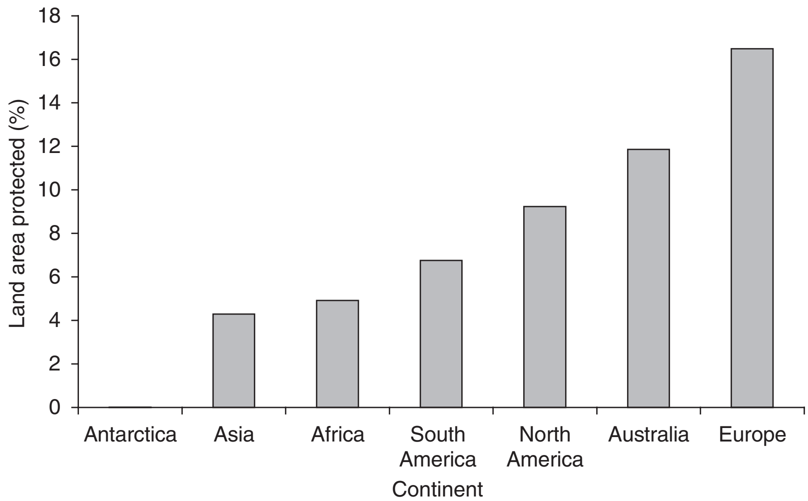

Figure 4 Percentage of land area protected in different continents.

at the expense of lesser known taxa, (2) to be too small to host viable populations, (3) to act as insular and isolated habitats that do not allow for genetic mixing across populations, and (4) to be costly and demanding in terms of logistics to secure the protected area from extraneous pressures.

Among the commonest of criticisms is that protected areas do not necessarily address the conservation needs of nontarget taxa. This is because protected areas have been generally designated on the basis of geomorphical or phytogeographic considerations or, frequently, due to the presence of charismatic large mammals (tiger and elephants in India, panda in China, grizzly bear in British Columbia, wolf in the USA, gorilla, white rhinoceros, and okapi in the Congo Basin, etc.) and not on

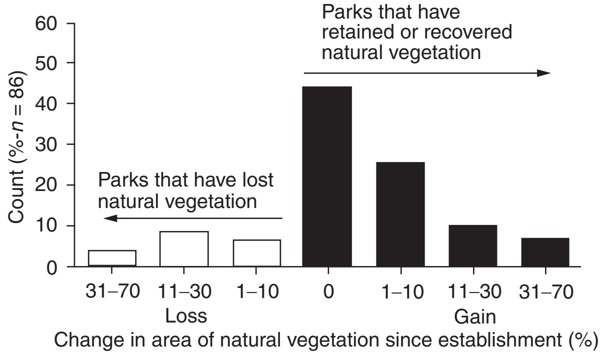

Figure 5 Effectiveness of protected areas in the world. The figure describes the change in the area of natural vegetation for 86 tropical parks. The majority of the parks have either experienced no net clearing or have actually increased natural vegetation cover. Reproduced with permission from Bruner AG, Raymond EG, Rice RE, and da Fonseca GAB (2001). Effectiveness of parks in protecting tropical biodiversity. *Science* 291: 125–128.

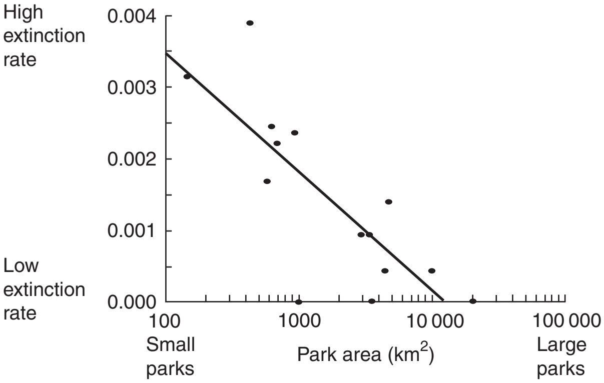

Figure 6 Extinction rates of mammals versus park size. Each dot represents the extinction rates of animal populations for a particular US national park. Mammals have higher extinction rates in smaller parks than larger ones. Reproduced with permission from Newmark WD (1995) Extinction of mammal populations in western North American national parks. *Conservation Biology* 9: 512–526.

Table 1 Protected areas as refugia for critically endangered species; the examples illustrated are those in which the concerned species is not present outside the protected areas

Species	*Protected area*
Animals	
Asiatic lion (*Panthera leo*)	Gir National Park, Gujrat, India
Javan rhinoceros (*Rhinoceros sondaicus*)	Udjung Kulon National Park, Java (Indonesia) and the Cat Tien National Park in Vietnam; it may also still exist in other locations
Hangul or Kasmir stag (*Cervus elaphus hanglu*)	Dachigam National Park, Jammu and Kasmir, India
Orangutan (*Pongo pygmaeus*)	Sepilok Forest Reserve, Malaysia
Straight-horned markhor (*Capra falconeri*)	Sheikh Buddin National Park, Pakistan
Plants	
Dypsis ovobontsira (Palmae)	Mananara Biosphere Reserve, Madagascar
Rhododendron protistum var. *giganteum* (Ericaceae)	Nature Reserve, Gaoligongshan, Yunnan Province, China
Maillardia pendula (Moraceae)	Aldabara Strict Nature Reserve, Seychelles
Hibisicadelphus woodii (Malvaceae)	Napali Coast State Park, Hawaii, USA
Parsania formonsana (Fagaceae)	Kenting National Park, Taiwan
Shorea bakoensis	Sarawak, Malaysia

a holistic basis. The disproportionate emphasis on few large mammals may divert attention from other similarly endangered taxa. Thus it is suggested that the boundaries of protected areas need to be revised to fulfil the conservation requirements of a more representative range of taxa.

The trade-off of size with number of protected areas has been the subject of considerable debate. A single large reserve allows for a wider habitat heterogeneity that is more representative of landscape complexity, and larger population sizes, particularly important for maintaining viable populations of wide ranging low-density species such as carnivores (**Figure 6**). On the other hand, several small reserves offer a degree of protection from large-scale catastrophic events, such as disease, fire, or extreme weather events that may destroy populations confined to a single reserve.

Protected areas could be made more effective by establishing them in sites known to harbor exceptionally high species diversity and/or endemism. Efforts should be made to optimize the selection of new protected areas by iterative processes that maximize the biological diversity conserved in a given area.

Semiformal Model of Forest Management for Conservation

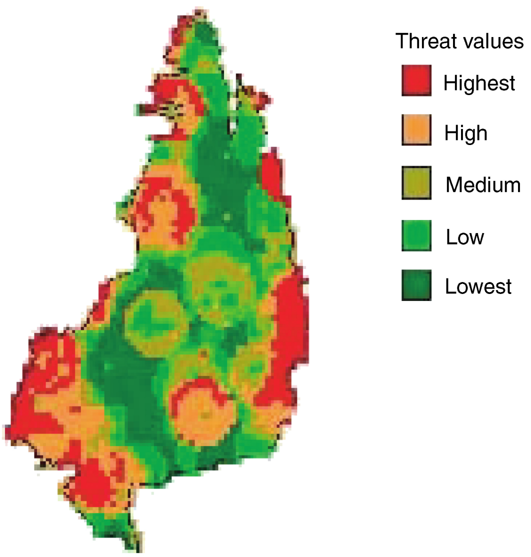
Protected areas that exclude humans alienate local people who may have traditionally depended on forest resources. A recent study estimated that 54% of protected areas considered had residents who contested the ownership of some percentage of the park area. In India, with about 572 protected areas occupying 4.58% of the geographical area, an estimated 3 million people live within the protected areas with several million more living adjacent to the parks. Rather than evicting people traditionally dependent upon forests a more pragmatic and sympathetic approach is to manage forest use and impacts in a way that maximizes conservation gains while realizing economic benefits (**Figure 7**). Community involvement in the management of protected areas, where the state and the local inhabitants work together for both conservation and basic livelihood security, is seen as a positive and necessary strategy for successful conservation programs in both tropical and temperate regions.

Semiformal methods of forest management for conservation are predominantly located in tropical countries that have a long history of association of people with the forests and that retain sufficiently large areas of forest such that these associations persist. The origin of these models can often be traced to the codification of the use of forest resources. Among the semiformal models, the predominant are the temple forest or sacred forests, joint forest management (*see* **Social and Collaborative Forestry:** Joint and Collaborative Forest Management), and extractive reserves.

Sacred Groves

Probably begun as manifestations of nature worship, sacred groves have played an important role in conserving the forest and its constituent biodiversity elements. This unique community-linked forest conservation concept is practiced in several tribal and agrarian regions of the world. A number of societies in Asia, Africa, Europe, America, and Australia have long preserved sections of their natural environment as sacred groves. The practice of sacred groves is widespread in India (**Figure 8**). About 4215 sacred groves covering an area of 39 063 ha are estimated to

In India a number of protected areas (PAs) continue to be inhabited by the tribal and indigenous communities who depend almost completely on the forests for their livelihoods and thus constitute direct threats to the PAs. It is clear that unless attempts are made to reduce these threats, the protected areas in succumb to the increasing human pressures. Unfortunately most of the threats arising from anthropogenic activities in the protected areas are not easily quantifiable as they are very dynamic and heterogeneous. Effective conservation of such protected areas demands that we evaluate the threats and accordingly formulate appropriate management plans to mitigate them. However, there is hardly any standardized methodology to evaluate the complex threats that protected areas might face.



Threat map of BRT wildlife sanctuary, south India

Ganeshaiah and his coworkers developed a protocol for measuring and mapping threats in a protected area, a wildlife sanctuary, in South India. They computed three threat values viz:

1. Settlement associated threat from human, cattle, and sheep.
2. Developmental activity associated threats due to major and minor roads.
3. Accessibility-related threats due the steepness of the terrain.

Combining all the three threat values, they derived a composite threat index for each grid over the sanctuary. The composite threat index clearly reflected the pressures on the sanctuary as evident from the strong correlation between the threat levels and the human related disturbance activities and a strong negative relation between the composite threat index of a grid andits tree diversity. Periphery of the sanctuary (in deep red) is more threatened than those in the core (green). Based on the composite threat index, Ganeshaiah and coworkers have proposed strategies to manage the forest to maximize the conservation gains.

Figure 8 A typical sacred grove in Coorg District, Western Ghats, India. Photograph by courtesy of G. Ravikanth.

be distributed in India and are located in habitats ranging from resource-rich forested landscapes, in the Western Ghats, to extremely resource-poor desert conditions, in western and central India. In Ghana, about 1.5% of the land is covered with nearly 2000 groves. Typically the local village temple authority directly manages the groves. However with passage of time, the regulations were extended to the state as well. In India, for instance, the local revenue department and the forest department have joined the temple authorities in managing the groves.

Being bound by taboo, sacred groves have been as effective as modern protected areas in conserving biological diversity and serving as a refugia for endangered species. In Coorg district along the Western Ghats of India, about 14% of tree species, 26% of bird species, and 44% of macrofungi were exclusively found in the groves. Certain species such as *Dysoxylum malabaricum*, *Anacolosa densiflora*, *Holigarna arnottiana*, *Diospyros bourdilloni*, *Poeciloneuron indicum*, and *Vateria indica,* which are in heavy demand for their commercial value, continue to survive and flourish mostly in the sacred groves. The sacred groves called 'orans' managed by the Bishnoi community of Rajasthan, India are well known for their conservation ethos of protecting the khejari trees (*Prosopis cineraria*) and the blackbuck (*Antelope cervicarpa*) (**Table 2**).

Over the years the sacred groves have been threatened from both powers within and outside. In India, from early nineteenth century, the British gained control over the use of forests of the Western Ghats including the vast network of sacred groves. At certain other places, taboos relating to the groves began to weaken. With declining forest resources outside the groves, people began to remove leaf litter and dead wood from the groves to meet the needs of the charcoal industry. Encroachment of the sacred groves, notably by forest-based plantations such as

Table 2 Sacred groves as refugia and sites of relict vegetation; the species listed below are known to occur either exclusively or predominantly in the sacred groves

Species	*Area*
Kunstleria keralensis	Southern Kerala, India
Belpharistemma membranifolia, *Buchanania lanceolata*	Kerala, India
Syzygium travancoricum, *Cinnamomum quilonensis*,	Kerala, India
Philautus sanctisilvaticus	Amarkantak, Madhya Pradesh, India

coffee, also took its toll. Between 1905 and 2000, the total area under groves in Coorg, decreased from 6277 to 2550 hectares with about 45% of the groves smaller than 0.4 ha and 80% less than 2 ha. Perhaps in large measure degradation of the groves has been associated with decreased religious rigor among the people over time. The highly fragmentary nature of the groves with their poor insularization in a matrix of grassland and forest makes them very vulnerable.

Maintaining the sacred groves might not only help in conserving the biological diversity in the forests, but also serve to be symbolic of the traditional conservation cultures associated with some of the oldest religions and faiths across the world. In the context of conserving the genetic resources, the groves act as micro-hotspots of biological diversity, and thus merit serious attention. The groves, by their nature, can complement protected areas in forming a network of forest conservation areas in the tropics.

Joint Forest Management Program in India

In a pioneering move, the government of India formulated a National Forest Policy in 1988 where it emphasized the need of people's participation in the management of forests. Specifically the policy urged the need for 'creating a massive people movement with the involvement of women, for achieving these objectives and to minimize pressure on existing forests.' In June 1990, the government of India formally unleashed a new system of forest management involving grass root institutions popularly known as 'Joint Forest Management' (JFM) (*see* **Social and Collaborative Forestry**: Joint and Collaborative Forest Management). The JFM is a tripartite body with the involvement of the Forest Department, local level institutions, and nongovernmental organizations (NGOs). The JFM characterizes a paradigm shift in forest management from a centralized management to decentralized management, from revenue orientation to resource orientation, from a production motive to a sustainability motive, from target orientation to process orientation, and from restricting people to working with people. By the year 2000, the JFM program had been launched in 22 states in India, covering an area of 10.24 million ha of forest (about 5.5% of the forested area) through 36 130 JFM committees. In the relatively short time of its existence, the JFM has had its impact in regressing the loss of forest cover in a few states such as West Bengal, Madhya Pradesh, and Andhra Pradesh. However, not all the states in the country have shown similar impacts of JFM. The failure of JFM is attributed often to the lack of coordination between state and members of a JFM initiative. More recently, JFM has been introduced in neighboring countries such as Nepal and Pakistan.

Community Managed Conservation Areas

In Brazil, as in many other tropical countries, a large number of indigenous communities continue to live within the forest where they are dependent on the forest resources for their livelihood. Declaration of protected areas and national parks in such countries have resulted in a serious social problem with either the displacement of the indigenous people or restriction of their use of the forest. Partly to address the social conflict and to maintain efforts to conserve the forest, the Brazilian government initiated the establishment of extractive reserves in the Amazon forest. Under this approach, rather than fence people away from the forest, the reserves permitted the people to manage the forest for their subsistence livelihoods, thereby providing incentives for conservation and sustainable management of the forest resources. Thus the extractive reserves have been broadly successful in preventing land clearance or logging. To date about 12 extractive reserves covering over 3 million ha have been established. However, extractive reserves have not always been successful in maintaining the balance desired between meeting the people's dependence and conserving the ecosystem. Close monitoring and reinforcement could perhaps make community managed conservation areas more effective for conservation than they actually are.

Community managed conservation areas might be highly relevant in regions that have very little forest under government control, as is the case in a number of South Pacific countries. The South Pacific Biodiversity program brought together local communities, NGOs, and governments in 14 countries in the south Pacific to conserve the biological diversity in what has been referred to as the community managed conservation area. The program provides for the sustainable use of the resources in these protected areas but ensuring that the important ecological features and processes are maintained.

Informal Model of Forest Management for Conservation: People's Movement

A number of informal people-based approaches for managing forest for conservation has been the cornerstone of conservation in many traditional cultures in the world. These approaches are essentially amorphous and have no formal structures. Often they have emerged in response to local community perceptions about how local natural resources were being exploited.

In India, there have been several important people-based movements that have made significant contributions to the way forests have been managed. One such illustration is the Chipko movement (chipko, to stick or embrace) initiated by the Bishnoi community of Rajasthan in the early eighteenth century. In this movement local people embraced trees, often at grave risk to their own lives, to prevent the trees from being felled by the King of Jodhpur (**Figure 9**). The movement has since spread to many districts of the Himalayas, in Uttar Pradesh, and Himachal Pradesh in the north, Karnataka in the south, and Bihar in the east, and to the Vindhyas in Central India, and is now realized as a popular people-led movement to conserve trees. Another notable people's movement, in the southern state of Kerala, India rescued a major evergreen forest, the Silent Valley, from being destroyed by a hydroelectric

Figure 9 Chipko movement in India (for details see text).

project. The valley was declared a national park in 1985. In Slovakia, an NGO, WOLF, has since 1993 been working to save natural forests that include large predators such as wolves. WOLF is predominantly managed by local tribes, each tribe adopting a mountain range to save the natural forest. Whether practiced in the Australian outback by the Aborigines or in Amazonia by native Indians, these movements have fought, often successfully, unscrupulous exploitation of forest resources by larger interests. Several such movements have, over time, gained sufficient strength and publicity that they have been later adopted into more formal approaches to forest management.

Conclusions and Implications

Prior to the major human settlements and advances tropical forests covered about 17 million km^2 of the earth's surface. Today, less than half of this remains. The forests lie in some of the most economically underdeveloped and heavily populated countries in the world. Consequently even these remnants face extreme pressures due to an increasing demand on the forest resources by the developing economies. It is feared that unless urgent measures are taken to conserve the remaining forest, not only will these forests be lost but there will also be an irreversible loss of the variety and performance of life functions on earth. Awareness of both threats and consequences has stimulated urgent efforts, initiated mostly at the beginning the twentieth century, to develop various approaches to managing forests in a manner that would conserve biological diversity and ecosystem processes. The establishment of protected areas has been central to these efforts, and now about 6.3% of the earth's land surface is under protection. While protected areas have their faults, there is an overriding consensus that they could be the last refugia for several scores of critically endangered species. Besides state-regulated protected areas, several semiformal approaches to managing forest for conservation also exist, such as sacred groves and people-inclusive forest management (e.g., joint forest management and community managed conservation areas). While the reach of these systems has been restricted, they have nevertheless been moderately successful in managing forest for conservation and local benefit in many developing countries. People-led movements have also been a powerful force in lobbying for improved management for conservation and sustainable development in countries such as India and Brazil, and have been precursors to some major conservation movements. It is believed that collectively the various models of conservation, from the very formal protected area networks to the informal but powerful people-led movements, will complement each other to avoid exploitative management in favor of sustainable management.

Genetic Aspects of Air Pollution and Climate Change

D F Karnosky and R C Thakur, Michigan Technological University, Houghton, MI, USA

Introduction

The first incidences of air pollution impacts on the genetic constitution of forest tree populations were those documented near point sources of sulfur dioxide (SO_2), particulates, and heavy metals. Localized extinction of forests around these point sources was documented by ecologists in the past two centuries. In North America, the most spectacular of these areas were those surrounding ore smelters in Trail, British Columbia, Sudbury, Ontario, and Copper Basin, Tennessee. In Europe, the most dramatic areas included the Black Triangle area (of eastern Germany, Poland, and the then Czechoslovakia) which was largely due to soft coal burning in power plants and numerous situations where industrial facilities were located in valleys such that toxic emissions destroyed vegetation on the surrounding hillsides. With these early pollution problems, large areas of forests have simply been replaced by grasses or other tolerant vegetation.

Around the middle of the twentieth century, another type of air pollution, smog consisting of various photochemical oxidants, including nitrogen oxides (NO_X), ozone (O_3), and peroxyacetyl nitrate (PAN), began to impact forest tree populations. The first documented consequences of photochemical oxidant on forest tree populations occurred in the San Bernardino mountains where sensitive genotypes of ponderosa pine (*Pinus ponderosa*) began to die in large numbers, being replaced in the forest by more smog-tolerant species such as white fir (*Abies concolor*). Ozone downwind of major metropolitan areas has also been implicated in the loss of sensitive individuals in eastern white pine and trembling aspen in the eastern USA. In parts of the highly polluted Ohio Valley region in the eastern USA, sensitive genotypes of eastern white pine were virtually eliminated from the breeding populations between the mid-1950s and the mid-1960s due to deadly combinations of SO_2 and O_3. Since the 1980s, O_3 has been implicated in the loss of hundreds of thousands of pines in the mountains surrounding Mexico City, where O_3 levels are among the highest in the world.

Recently, the scientific community has realized that greenhouse gases of anthropogenic origin are building up in the earth's atmosphere (**Figure 1**) and that these gases are likely contributing to the trapping of heat near the earth's surface. As a result, there is a sharply rising trend in global mean temperatures (**Figure 2**). The increasing temperatures will likely eventually lead to changes in species-richness in a given area and changes in the range of many forest tree species.

In this article, we first discuss genetic aspects of air pollution effects on forests and then examine how the changing climate may impact the genetics of forest trees. Finally, we discuss some of the remaining knowledge gaps and research needs with

respect to genetic aspects of air pollution and climate change.

Genetic Aspects of Air Pollution

For air pollution to induce natural selection, there must be variation in air pollution sensitivity, the variation must be heritable, and the pollution must be a strong enough selection force to disadvantage sensitive trees severely. According to Anthony Bradshaw, who has studied natural selection in grasses growing in the presence of heavy metals, evolutionary population change takes place in three stages:

- Stage 1: elimination of the most sensitive genotypes
- Stage 2: elimination of all genotypes except the most tolerant (note: elimination of *all* forest tree genotypes, as has occurred in many point source pollutants, results in extinction, not evolution)
- Stage 3: interbreeding of the survivors to give even more resistant genotypes which are then further selected

The rate of selection is dependent on the severity of the pollutant stress, the type of reproduction (sexual or asexual reproduction), and the level of competition between genotypes (the more intense the competition between sensitive and tolerant trees, the faster the effects occur). Finally, air pollution-induced selection can take place at the level of differentiation in survival among individual trees (viability selection) or among pollen grains on a stigmatic surface (gametic selection).

In our laboratory, we have long studied the responses of forest trees to air pollution in an attempt to gain a better understanding of the potential for air pollution to impact natural selection. It is clear from these studies that there is tremendous variability in responses of forest trees to air pollution and this is manifested as differences between species, provenances, families within provenances, and tree-to-tree within families (**Figure 3**). Furthermore, we and others have shown that variable responses to air pollutants such as heavy metals, SO_2, and O_3, are highly heritable. We have also shown that the differences in responses to air pollution can directly affect the competitive ability of trees as air pollution can dramatically affect growth, as we demonstrated with trembling aspen affected by O_3 in controlled fumigation studies done in open-top chambers (**Figure 4**) and in field plantings under naturally elevated levels of O_3 (**Figure 5**). We have also shown that the effects of air pollution in the stage 1 of natural selection can occur very rapidly, as shown in **Figure 6**, where nearly 50% of the O_3-sensitive trembling aspen (*Populus tremuloides*) were eliminated from highly competitive close-spacing trials in a high-O_3 environment after only 5 years. Similarly, we have

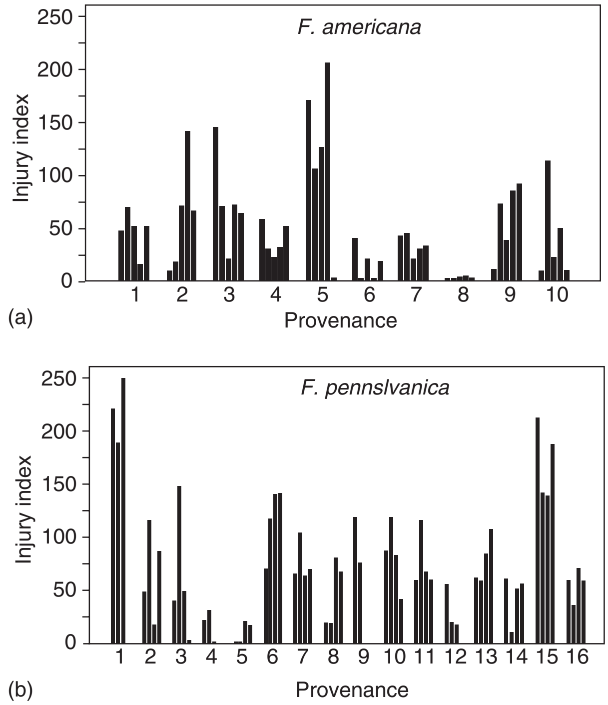

Figure 3 The average injury index for visible foliar injury after exposure of 1-year-old seedlings to 50 pphm ozone for 7.5 h. Each mean shown represents the average of five trees per family. There were either four or five half-sib families for each white ash (*Fraxinus americana*) provenance (geographic location) and either three or four families for each green ash (*F. pennsylvanica*). Reproduced with permission from the 1996 Air Quality Criteria for Ozone and Related Photochemical Oxidants. Washington, DC: US EPA Office of Resources and Development.

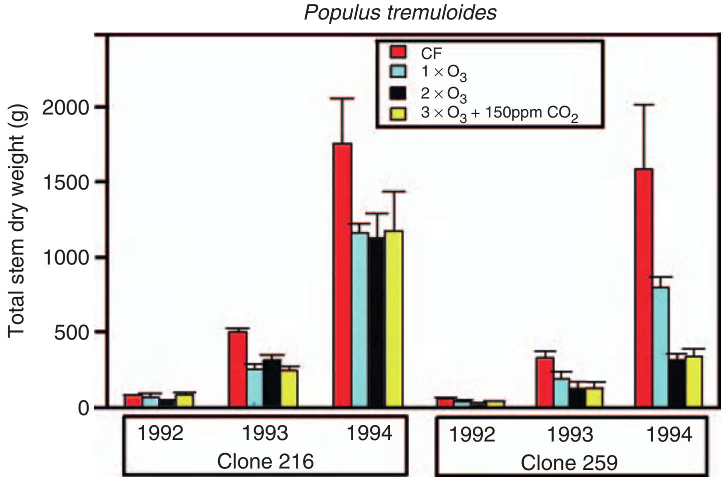

Figure 4 Total stem biomass per tree for an ozone (O_3)-tolerant (clone 216) and an O_3-sensitive (clone 259) trembling aspen (*Populus tremuloides*) clone exposed to charcoal-filtered (CF), ambient O_3 ($1 \times O_3$), twice ambient ($2 \times O_3$), or twice ambient $O_3 + CO_2$ (150 ppm over ambient) for three growing seasons in open-top chambers. The O_3-induced decreases in stem growth for the O_3-sensitive clone are particularly dramatic in year 3.

Figure 5 The effects of ambient air pollution on tree growth can be severe and is often variable due to genetic differences in sensitivity. Here is an example of three southern Wisconsin trembling aspen (*Populus tremuloides*) genotypes varying in ozone (O_3)-sensitivity in this trial in southern New York where ambient O_3 levels were quite high. The two tree plots represent 10-year-old sensitive (left), intermediate (middle), and tolerant (right) genotypes that grew at similar rates under low O_3 exposures.

documented a 10-fold increase in the mortality rate of O_3-sensitive eastern white pine trees (as compared to tolerant genotypes) in southern Wisconsin where ambient O_3 was moderately high. Thus, the evidence for stage 1 of natural selection occurring in natural forests is indisputable.

For forest trees, the final two stages of natural selection induced by air pollution are less well documented, with the exception of those populations surrounding severe point-source pollution where changes in genetic structure of polluted forest stands have been shown via studies of isozyme or molecular markers. For more subtle region-wide pollutants such as O_3, the evidence is less compelling that genetic change has occurred. Indirect evidence of these later stages of selection taking place has been presented by our laboratory in studies of 15 trembling aspen populations from across the USA. In a series of three studies, published in the late 1980s, we showed a strong negative correlation between the amount of visible foliar symptoms induced by O_3 and the maximum daily O_3 averages at the localities where the populations were collected (**Figure 7**). Additional studies are needed to verify

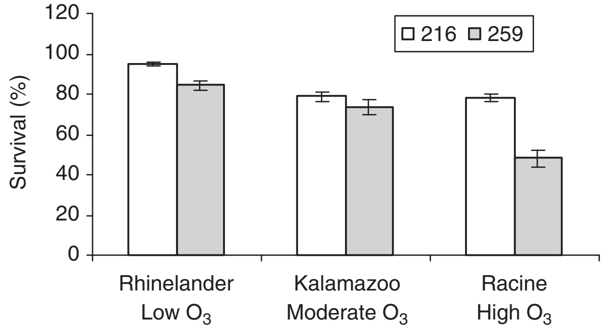

Figure 6 The rapid nature of ambient ozone (O_3) impacts on tree survival in highly competitive (tolerant and sensitive genotypes were intermixed at 0.5×0.5 m spacing) environments across a documented O_3 gradient. Survival at age 5 of two trembling aspen (*Populus tremuloides*) clones differing in O_3-tolerance (clone 216 = O_3-tolerant and clone 259 = O_3-sensitive). The three locations where this experiment was run included Rhinelander, WI = low O_3; Kalamazoo, MI = moderate O_3; and Kenosha, WI = high O_3.

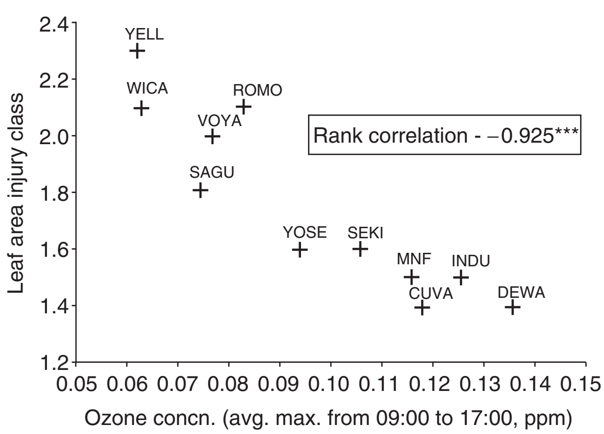

Figure 7 Scatter diagram illustrating the association between one measure of ambient ozone concentrations and one measure of foliar injury after an acute exposure to ozone for several populations of quaking aspen (*Populus tremuloides*). that the genetic structure of these populations has changed. An intriguing question remaining is whether or not valuable unique genes or germplasm are being lost with the loss of the sensitive genotypes from the polluted populations.

Genetic Aspects of Climate Change

The rapid nature of the earth's changing climate has raised concerns for the adaptability of forest trees. Long-lived and stationary, forest trees are facing unprecedented changes in the levels of greenhouse gases (especially CO_2; see **Figure 1**) and in the temperature (**Figure 2**). The rapid rates of climatic change anticipated to occur in the near future, coupled with land use changes that impede gene flow, can be expected to disrupt the interplay of adaptation and migration. Implications of these changes for the genetic stability of forest tree populations are not yet fully understood. While ecologists have predicted large changes in the ranges of species over the next 100 years (**Figure 8**), geneticists counter that most tree species have rather large amounts of natural variation and that the changes may be more subtle than those modeled predictions. What is highly likely is that the northward shift of species ranges in the northern hemisphere will proceed with differing rhythms for various species. Species with limited genetic variability to start with, however, such as red pine (*Pinus resinosa*) and red spruce (*Picea rubens*) in North America and silver fir (*Abies alba*) in Europe, will be the first true test of how severe the competitive ability changes may become, how rapidly local populations will be lost, and how great the changes in species ranges may be.

Tree breeding and genetic selection have generally involved either plus tree selection followed by progeny testing or provenance testing followed by progeny testing of superior phenotypes. Then, seed orchards have been established and rogued (further selected on the basis of progeny test information) to provide the seed for the next generation. This process has continued with advanced generation selection and breeding in a few commercially important tree species. In all facets of these programs, selection is done based on the conditions prior to selection and for the most part these selections are not done on the basis of predicted pollution and climate scenarios that will be in place during the rotation of the commercial forest. Screening and selection of genotypes suitable for future pollution and climate scenarios are generally thought to be nearly impossible because of the complexity and cost of such programs. Thus, an alternative strategy in which a wider genetic base is maintained in our breeding population is essential for developing future forests. Maintaining large amounts of genetic diversity will increase the probability that adequate adaptability is maintained to meet rapidly changing environmental conditions.

Alternative strategies are also needed to insure that *in situ* and *ex situ* conservation methods such

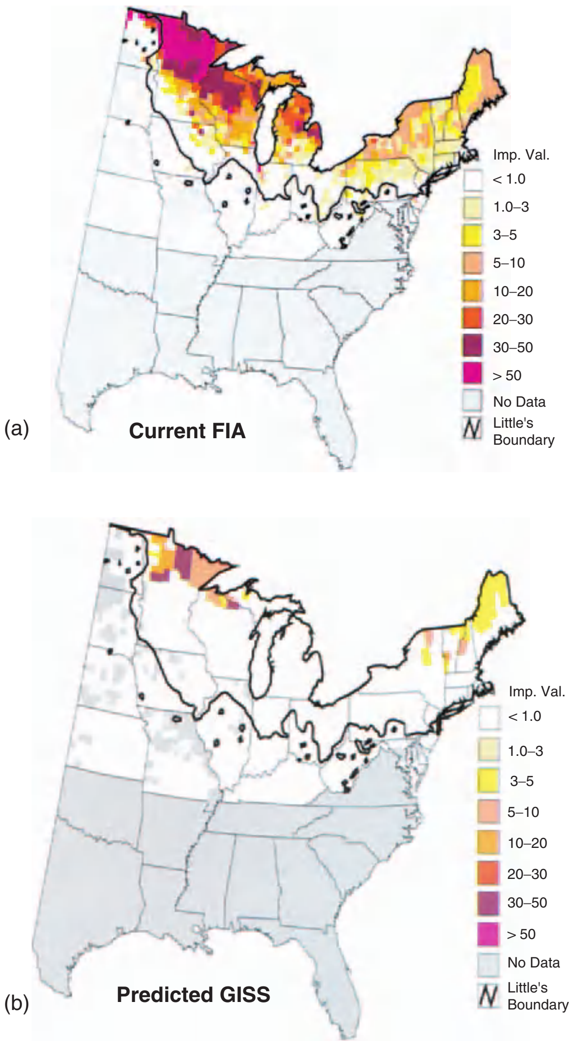

Figure 8 The projected impact of global warming on tree species richness and range is shown in these two figures. (a) Current range and importance values of trembling aspen (*Populus tremuloides*) versus the predicted range and importance value of the same species under a doubled-CO_2 climate (b). as gene banks, clone banks, seed zones, or seed collection areas are maintained in several locations such that the changing pollution and/or climate scenarios will not result in the loss of such collections from single vulnerable test sites. Given the past several decades of 'laissez-faire' attitude towards traditional genetic field trials and field conservation efforts, this need to conserve forest genetic resources in multiple amounts may help genetics regain prominence amongst the forestry community.

Knowledge Gaps and Research Needs

Restoration of forests destroyed by severe air pollution (as in the region of the Black Triangle in Europe) remains a great challenge today, and there are currently no methods available to guide these restoration projects to recreate previous genetic diversity and genetic structure. Furthermore, reforestation under today's climate (light, temperatures, phenology, and moisture) and soil conditions (many former severely degraded areas by air pollution still have acidic soils or soils contaminated with heavy metals) may preclude simple replanting with single species. Furthermore, data may not be readily available as to what the stand structure, and genetic diversity were before the areas were affected by air pollution.

The questions of whether or not regional air pollutants such as O_3 have subtly affected the genetic structure of forest tree populations, and if rare alleles have been lost as sensitive genotypes are being lost, needs to be further studied. Recollections of previously sampled populations, as have been done in evolutionary studies of grasses, have been recommended to document selection over time. Also, intensive population sampling with newly developed molecular tools such as microsatellites, single nucleotide polymorphisms (SNPs), amplified fragment length polymorphisms, or restriction fragment length polymorphisms, could determine if population changes have occurred. Studies along sharp pollution gradients would also be useful in this argument.

Exploration of ways to induce more variability in genetically disparate species, such as red pine and white fir, could be beneficial in creating new opportunities for these species to adapt to future climate change. These could include studies of interspecific hybridization, intraspecific provenance hybridization, or insertion of stress tolerance genes isolated from other species via genetic engineering.

Understanding how climate change and related changes in greenhouse gases, such as CO_2 and O_3, will impact intra- and interspecific competition will help us better predict impacts of climate change on forest tree populations. Since these changes are rapid (from a historical viewpoint) but still long-term (from a research project duration viewpoint), long-term studies of population dynamics and competition will need to be done under realistic future climate scenarios. The extensive sets of provenance trials established in the twentieth century around the world should also prove useful in addressing questions related to adaptation to warming temperatures.

It is well known that trees grow at different rates and that they are also variable in how they allocate carbon to various above- and below-ground components. This information could be used to make genetic selections for trees to optimize carbon sequestration. Selections of trees with rapid growth rates, strong allocation to root systems, and inherent resistance to decay could be done for various environmental conditions in the major tree-growing regions of the world. Likely, such selections will include use of exotic species, hybrids of local and exotic species, or genetically engineered trees with altered carbon allocation patterns.

In contrast to long-term evolutionary trends for which local populations are well adapted, the rapid change in stresses of anthropogenic origin suggests that genetic management of forests will be essential. Methods to link tree breeding for utility benefits with gene conservation to facilitate sustainable forestry should be given a high priority. The importance of maintaining high levels of genetic diversity in breeding populations and in plantations cannot be overstated.

Recent development in understanding mechanisms of stress tolerance suggest a commonality of oxidative stress from diverse factors such as air pollutants, herbicides, temperature extremes, toxic salts, and drought. This finding may lead to an increased understanding of the antioxidant tolerance mechanisms and, eventually, to the possibility of selecting for stress tolerance. This could be particularly valuable for developing forest trees for unpredictable future stresses.

Air pollution, climate change, forest trees, natural selection, biodiversity, adaptation, trembling aspen, red pine, silver fir, tree breeding.

Introduction

Transformation and Regeneration

In order to genetically engineer a plant, one must be able to insert a gene into the genome of an individual plant cell and then cause that cell to differentiate into a whole plant. The former process is referred to as transformation; the latter, regeneration.

The most common way of transforming cells exploits the ability of *Agrobacterium tumefaciens*, the causative agent of a common plant disease known as ‘crown gall.’ *Agrobacterium* contains a closed-circular piece of double-stranded DNA called the tumor-inducing (Ti) plasmid. During infection, *Agrobacterium* inserts a segment of the Ti plasmid, called T-DNA (transferred DNA), into the plant’s nuclear genome. This T-DNA contains genes encoding enzymes that catalyze the synthesis of plant growth regulators (cytokinin and auxin) which together control cell proliferation. This results in the formation of a tumor, within which the bacterium resides. The T-DNA also contains genes encoding enzymes that catalyze the synthesis of unique amino acids that the plant cannot utilize, and that serve as a carbon source for the bacterium.

Agrobacterium does not select specific genes to be shuttled into the plant. The T-DNA is defined by specific border sequences; thus, any genes located between these borders will be transferred. Plant genetic engineers isolate the Ti plasmid, excise the genes responsible for pathogenesis, and replace them with genes of interest. A minimum of two genes generally is inserted between the T-DNA borders: the target gene (e.g., insect or disease resistance) and a selectable marker. After the modified plasmid is reinserted into *Agrobacterium*, a piece of plant tissue (explant) is co-cultivated in a suspension of bacterial cells containing this modified Ti plasmid. However, not all of the explant cells will be transformed by the bacterium.

Selection helps determine how successful transformation was. The most commonly used selectable marker gene is *NPTII*, which imparts resistance to kanamycin. Untransformed plant cells ordinarily die when exposed to this antibiotic. When co-cultivated explants are plated on a solid medium containing kanamycin, only cells transformed with *NPTII* survive. Because the selectable marker gene is directly linked to the gene of interest (transgene), it too should be present in the transformed cell.

Another DNA delivery system, biolistics, involves coating microscopic beads (usually gold or tungsten) with DNA. These beads are propelled at an explant, usually with a burst of compressed air as the driving force. Once inside the cell, DNA that sloughs off the bead can recombine with a plant chromosome. Biolistics is often less efficient than *Agrobacterium*-mediated transformation because of cellular damage from the impact of the beads, digestion of the transgene by cytosolic enzymes (nucleases), and the need for recombination. The selection process for cells transformed biolistically is as that described above.

Transformed cells that survive selection are used to regenerate a whole plant. The two main routes for *in vitro* regeneration are embryogenesis and organogenesis. In the former, cells are coaxed to differentiate into an embryo, similar to what is contained within a plant's seed. Organogenesis, on the other hand, is the process by which cells differentiate directly into specific organ types (e.g., shoots and roots). Both means of regeneration are done by successive transfers of the co-cultivated explants to media containing the proper type and concentration of plant growth regulators, mainly cytokinin and auxin. Varying the cytokinin : auxin ratio will result in callus formation, shoot organogenesis, or root initiation.

Recombinant DNA Techniques

The expression of a gene's coding sequence (i.e., transcription and processing to produce mRNA and translation of mRNA into protein) is carefully regulated by adjacent control sequences. Promoters are upstream elements that direct the timing, location, and extent of a gene's expression. Constitutive promoters allow for high levels of expression, in (nearly) all tissues, all of the time. The most commonly used constitutive promoter is derived from the cauliflower mosaic virus (CaMV) *35S* gene. Other promoters can be activated through treatment with a specific inductive agent, or may allow for tissue- and/or temporal-predominant expression. Enhancers are the portion of a promoter that can elevate a gene's expression level, and can act in *trans*. There are also downstream elements, terminators, which signal the end of transcription.

Once a gene is transcribed, its message undergoes processing. In some cases interspersed sequences, called introns, are cut out of the mRNA at well-defined sites. The remaining sequences, termed exons, are then spliced together.

It is possible to enzymatically reverse-transcribe single-stranded mRNA to reproduce the double-stranded DNA from which the message was derived. This product is called complementary DNA (cDNA). Complementary DNA does not contain introns that may have been present in the corresponding genomic DNA. A cDNA library is a collection of sequences from only those genes that were being actively transcribed at the time the mRNA was extracted. Partial sequence information derived from the cDNAs in a given library is called an expressed sequence tag (EST) library.

Restriction enzymes are proteins that catalyze the cleavage of DNA at very specific recognition sites, usually about four to eight base pairs in length. Another enzyme, called ligase, fuses the ends of DNA that have been cut by the same restriction enzyme. This pair of enzyme types allows molecular biologists to mix and match various coding sequences and promoters.

Reporter genes allow one to visualize a promoter's expression pattern. The most common reporter gene, β-glucuronidase (GUS), encodes an enzyme that catalyzes the conversion of a colorless substrate to an insoluble, blue-colored product that precipitates in cells expressing the gene encoding it.

Polymerase chain reaction (PCR) is a technique that allows for amplification of a specific piece of

DNA. Short pieces of DNA (usually about 15 to 30 nucleotides in length), referred to as primers, are designed to complement sites on opposite strands of the target DNA. These primers are mixed with a DNA sample containing the fragment to be amplified, along with a complete set of nucleotides (i.e., dATP, dCTP, dGTP, and dTTP) and thermostable DNA polymerase. The mixture is heated to 94°C for approximately 1 min to separate the two strands of DNA (denature). Subsequent cooling of the mixture allows complementary strands to anneal to each other; the optimal annealing temperature depends on the length and composition of the primer (usually about 55–60°C). Because the primer DNA is of a much higher concentration than the template, it is much more likely to find its partner. The mixture is then heated to a temperature that is optimal for the polymerase to extend the primers using the genomic DNA as a template (72°C). Successive rounds of denaturation, annealing, and elongation result in a geometric increase (up to 4×10^6 times in 25 cycles) in the accumulation of product. Reaction mixtures are contained in tubes that are inserted in the aluminum block of a thermocycler. This machine can rapidly heat and cool liquid that is circulated through the interior of the block, and has a microprocessor that can be programmed to maintain different temperatures for various lengths of time.

Nucleic acids (e.g., restricted genomic DNA, PCR-amplified product, RNA, etc.) can be separated via electrophoresis and visualized. A dilute ($\sim$0.8%), heated solution of agarose (a polysaccharide) is poured into a form and allowed to solidify (as a gel). A ‘comb’ is inserted into the solution before it cools to create depressions (wells) in the gel, where DNA samples can be loaded. A strong electrical current is passed through the gel matrix, allowing the nucleic acids (which are charged molecules) to be separated based on their molecular weights. A standard, containing a mixture of nucleic acid fragments of known size, is run in a parallel lane on the gel, for estimating the size of nucleic acid fragments contained within the sample. To visualize the separated DNA fragments, the gel is stained with a dye, such as ethidium bromide, which binds to nucleic acids and fluoresces an orange color under ultraviolet light.

Platforms for Studying Tree Biology

Marker-Aided Selection

Marker-aided selection (MAS) involves the identification of individuals based on the presence of DNA markers in offspring derived from parents whose genomes have already been mapped. DNA markers are usually random nucleotide sequences that do not encode a functional gene; they are frequently amplified via PCR and are visualized on a gel. The position of the markers on a chromosome is mapped by determining the frequency of their mutual recombination when haploid gametes are formed in a given individual. To accomplish this, one needs a pedigree (a population in which gamete contribution from specific individuals can be traced to their offspring). Target genetic traits, that show extremes in variation, can be identified in a segregating population at an early stage in plant growth, based on linked markers. Traits of interest that are measured on a quantitative (linear) scale are referred to as QTLs (quantitative trait loci). These traits are typically affected by more than one gene. Examples include wood density, stem form, and frost resistance.

The potential impact of MAS on traditional breeding is tremendous. Once breeders know which bands on the gels indicate extremes for the traits of interest, screening can be conducted at a very early age, and selected individuals can be clonally propagated. Conducting this work in a laboratory obviates the need for expensive field trials, and forest managers will realize the additional genetic gain soon after crossing the selections from the previous generation. Sexual reproduction following MAS is possible, but gains will be fewer and greatly delayed relative to the clonal propagation. This is because juvenile selections must reach maturity, and the planting stock will not be genetically identical to the parents. However, wide-scale adoption of MAS for tree improvement has not been realized. Various problems impede the application of MAS, including the lack of cost-effective, high-throughput marker systems and lack of linkage disequilibrium. The latter is said to occur when the observed frequencies of haplotypes (a set of closely linked genetic markers present on one chromosome, which tend to be inherited together) in a population do not agree with haplotype frequencies predicted by multiplying the frequency of individual genetic markers in each haplotype.

Gene-Tagging Methods

Because of the ease with which it can be transformed, poplar (*Populus*) is a convenient model system for discovering tree genes of potential commercial value. Using gene tagging, a new gene or regulatory element is inserted into the genome as a probe for determining the function or expression pattern of genes adjacent to the insertion site. With gene-trap tagging, a reporter gene (e.g., GUS) is used to visualize the expression pattern of a nearby gene (**Figure 1**). In another tagging method, activation tagging, a strong

Figure 1 Staining of a poplar gene-trap line. The blue color demonstrates that GUS expression was limited to the vascular tissue in this leaf. Photograph supplied by Andrew Groover, Institute of Forest Genetics, US Forestry Service, Davis, CA, USA.

enhancer that is effective some distance from a native promoter is randomly inserted in the genome. Elevated expression of the nearby gene may result in an aberrant phenotype. Alterations that yield desired phenotypic changes, such as early flowering, modifications in crown form, or root development, are then analyzed for the causative gene (**Figure 2**). Overexpression of some native genes (e.g., those affecting wood quality) may not give rise to a visually apparent change. In this case, other, high-throughput analyses are needed for screening a population of transgenics (see below).

Both gene-trapping and activation tagging are a form of 'gene discovery' because the genes identified may be functionally unknown. Nevertheless, the unique nature of the inserted sequences (tags) permits the affected gene to be easily identified and isolated.

Poplar Genome Sequence and Informatics

The US Department of Energy has committed $28 million to producing a 6 × draft sequence (on average, every gene is sequenced six times) for the entire *Populus* genome by the end of 2003. As a result,

Figure 2 A GA 2-oxidase (GA2ox) mutant isolated via activation tagging. The GA2ox gene encodes an enzyme that degrades biologically active forms of gibberellic acid, a plant growth regulator involved in controlling various aspects of plant growth and development (e.g., seed germination, flower initiation, fruit development, stem elongation, wood formation, leaf expansion). Mutant (left) and wild-type (right) plants are the same age and were grown under the same conditions. Photograph supplied by Victor Busov, Forest Science Department, Oregon State University, Corvallis, OR, USA.

poplar is only the third plant species for which the entire genome sequence is available.

To maximize its utility, a genomic sequence must be annotated. Genome annotation, one aspect of the rapidly evolving field of informatics, has two components. The first is structural, involving the identification of hypothetical genes, termed open reading frames (ORFs), in the DNA sequence using computational gene-discovery algorithms. The second component focuses on assigning function to the predicted genes by searching databases for genes of known function that have similar sequences. For complex eukaryotic genomes, the main problem lies in the structural component of annotation. In eukaryotic genomes, a gene is defined as a locus of cotranscribed exons, which may give rise to several splice variants and, hence, multiple protein products with multiple functions. The structural identification of genes depends heavily on the use of homologous cDNA/EST or protein sequences. Algorithms for coding-sequence recognition exhibit performance trade-offs between increasing sensitivity (ability to detect true positives) and decreasing selectivity (ability to exclude false positives). The identification of intron–exon boundaries and splice sites is of further importance. Genes not represented by homologous DNA or protein sequences must be identified by *de novo* methods, which remains a serious impediment to genome annotation (described below).

Transformation to Confirm Gene Functionality

Transformation is an important tool for analyzing gene functionality. Through constitutive or conditional up- or down-regulation (knock-in/knock-out, KI/KO) of a target gene, important information about its function and downstream targets can be obtained. To date, tree genetic engineering has largely been performed using strong constitutive promoters, the aim being to obtain maximum levels of expression and, consequently, maximal effect. Such a strategy may be useful for imparting certain commercial traits (e.g., insect resistance or herbicide tolerance), but is not practical when the goal is to alter the expression of an endogenous gene. In fact, numerous cases of gene silencing have resulted from this approach. Moreover, altering the expression of key genes, such as transcription factors or other regulators, may have lethal or at least strong negative effects on plant development. In the future, an important application of genetic engineering will be large-scale evaluation of gene function via KI/KO strategies. Without a reliable system for conditional transgene expression, it may be impossible to produce transgenic plants with altered expression of numerous genes vital to growth and development. It is imperative for the inducer to be highly specific to the target promoter and to lack phytotoxicity. The target promoter must also be tightly regulated (i.e., no 'leaky' expression), with high-level expression being conferred upon induction.

High-Throughput Analyses

Gene expression Microarray technology can be used to study the simultaneous expression patterns of thousands of genes (**Figure 3**). Here, unique sequences of DNA (either oligonucleotides or cDNA) sequences are anchored to a glass slide in neatly arrayed microscopic spots (the probe). Spotting is done using very fine needles and robotics. Messenger RNA (the target) is isolated from both control and treated plants; each RNA sample is labeled with a different color fluorescent dye. The labeled RNA is allowed to hybridize to its complementary single-stranded DNA probe before the microarray is scanned. A laser then excites each fluorescent dye at a specific wavelength, and emissions are captured digitally. The fluorescent images for the control and treated samples are superimposed and the resulting color of each spot reveals whether a given gene is differentially expressed in the two samples.

Chemical characterization If the forward genomics approaches described above do not result in a visual phenotype, one must have a way to quickly screen large populations of independent transgenic lines. Techniques have been developed for using near-infrared (NIR) spectra to obtain quantitative measurements of lignin, cellulose, other carbohydrates, and extractives from plants. The accuracy and precision of these techniques is equal to conventional chemical methods. Similar success has been reported with descriptions of physical properties (e.g., density, microfibril angle, modulus of rupture, and tensile stress), making it possible to use NIR data to infer mechanical properties of wood. Samples showing atypical NIR phenotypes can be further subjected to mass spectral analyses for more detailed insights into the biosynthetic networks that have been perturbed.

Applied Technology

Recent Progress

Trees have already been transformed with genes that impart a variety of commercially useful traits, including insect resistance (**Figures 4** and **5**), herbicide tolerance, modified lignin and cellulose, altered metabolism, phytoremediation, and hormone biosynthesis.

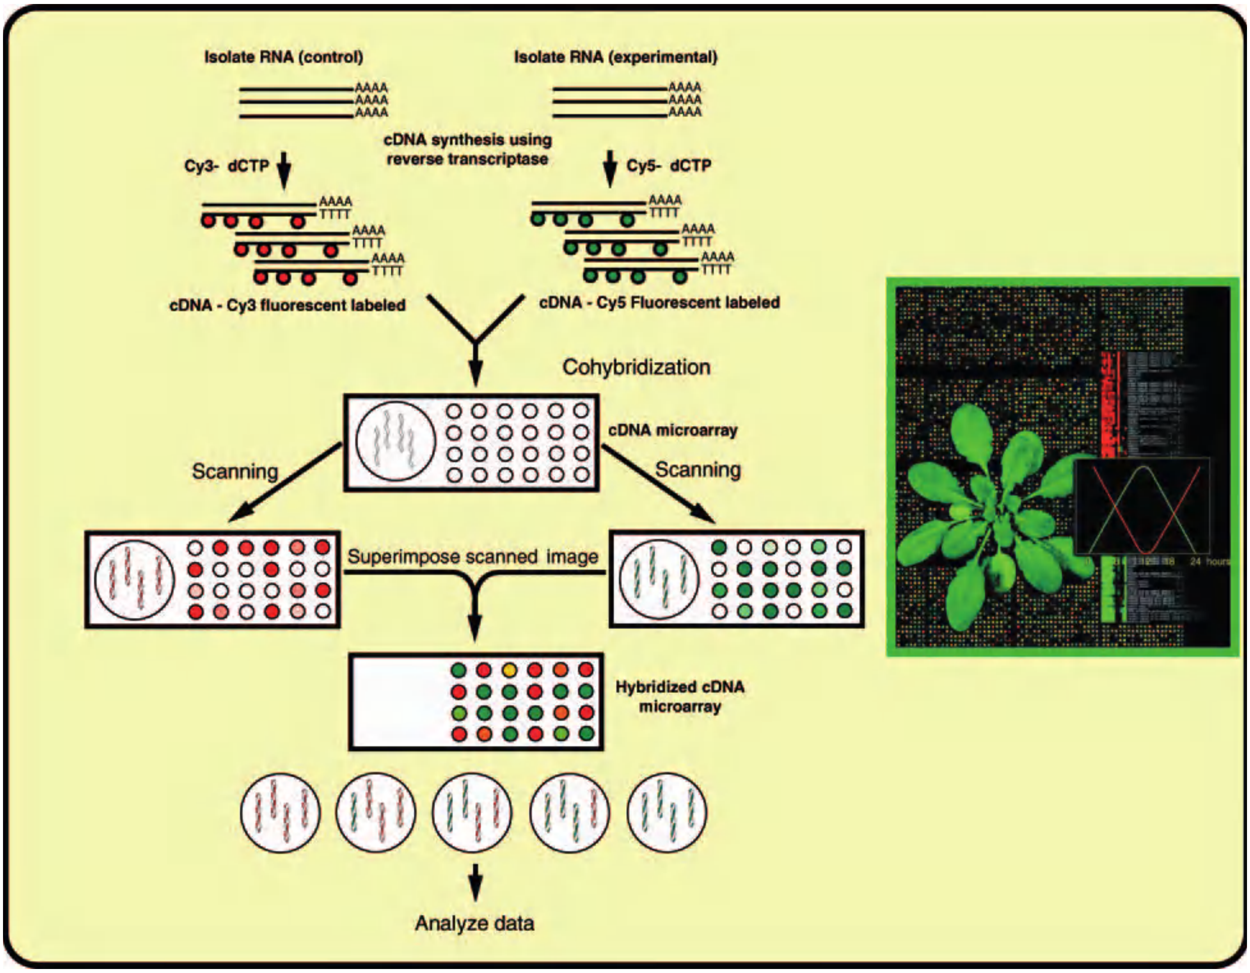

Figure 3 Experimental approach for labeling, hybridization, and scanning cDNA microarray. RNA is isolated (from control and experimental conditions) and labeled separately using two distinct fluorescent dyes (Cy3-dCTP and Cy5-dCTP) using reverse transcriptase. Both the labeled samples are cohybridized to the microarray. After hybridization and washing, the microarray is scanned using a confocal laser scanner at specific wavelengths, 543 nm (Cy3-dCTP) and 633 nm (Cy5-dCTP), respectively, for the two fluorescent dyes. The two fluorescent images are superimposed, and the data is analyzed for gene expression, using bioinformatics and image processing software. Fluorescent spots that are either red or green indicate the gene represented in the spot is expressed under one condition but not in the other. Spots carrying yellow/purple grades indicate that the gene represented in the spot is differentially expressed between the control and experimental conditions. Arabidopsis Microarray insert reproduced with permission from Wisman and Ohlrogge (2000) *Plant Physiology* 124: 1468–1471.

Plants are now being used as bioreactors to produce recombinant proteins for commercial purposes in a rapidly emerging field of biotechnology known as 'molecular farming' (or 'biopharming'). However, recent incidents (e.g., StarLink and Prodigene) have stirred public uneasiness regarding the potential for contaminating the food supply with genetically modified crops that are expressing biologically active molecules. Therefore, the use of non-food crops, such as poplar or other tree species, may alleviate public and regulatory concerns about utilizing plants as 'factories' to produce anything from biodegradable plastics and industrial enzymes to antibodies and other pharmaceuticals. It is possible to effect the production of these compounds in transgenic trees, as a way of adding value to the crop. Transgenes can be placed under the control of an inducible, leaf-specific promoter so that there is no metabolic drag during the life of the plant, and so the transgene is not expressed in the bole of the tree.

Public Concern

Genetic engineering has been used to introduce novel, commercially valuable traits into a variety of agronomic crops. Although the potential benefit of these traits has also been demonstrated in transgenic trees, no such trees are currently being grown in the USA for commercial purposes.

Figure 4 Field-grown insect-resistant poplars. The tree depicted in the left-hand panel was transformed with the *Cry3A* gene from *Bacillus thuringiensis*. The tree on the right is a nontransgenic control. Damage is the result of feeding by larvae of the cottonwood leaf beetle (*Chrysomela scripta*).

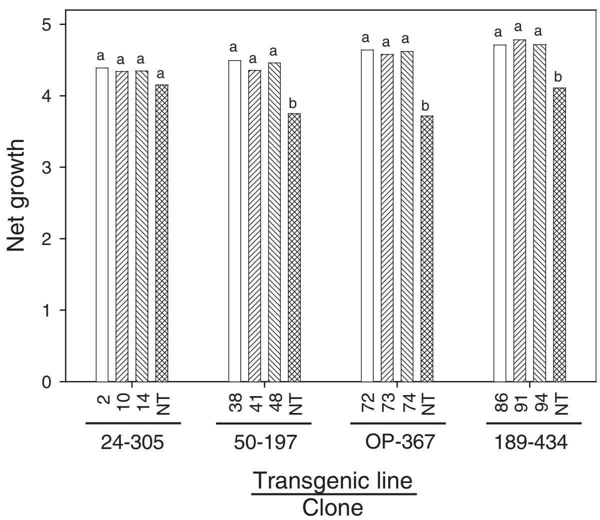

Figure 5 Growth of insect-resistant transgenic poplar trees. The first three bars in each cluster represent mean growth of 10 independent transgenic lines containing the *Cry3A* gene; black bars are for nontransformed controls (NT). Bars labeled with the same letter are not significantly different from each other. On average, nontransgenics grew 24% slower than the transgenic lines. Slower growth is presumably the result of having less photosynthetic capacity, as a result of insect feeding.

Agronomic crops generally are herbaceous annuals that are highly domesticated and have few, if any, wild relatives. Most tree plantations are established in close proximity to wild or feral relatives, increasing the probability of transgene spread. Thus, a major concern over the use of transgenic trees is the potential for extensive transgene dispersal through pollen and seeds. Because the issues surrounding the commercial deployment of transgenic woody perennials are more complex, federal regulatory agencies are now deciding what additional safeguards need to be put in place. Key areas of concern include: increased invasiveness, horizontal transfer, and development of resistance by the pest to the transgene product.

Flowering Control

Before transgenic trees can be grown for commercial purposes it is imperative to have a system for mitigating the spread of transgenes to interfertile wild relatives. Sterility is the most effective way of accomplishing this objective, as well as maintaining rapid growth. Normally, after trees undergo the transition to maturity, photosynthate is diverted away from vegetative growth and used to produce reproductive structures. Blocking flowering will likely result in preserving juvenile growth rates and preventing the formation of unwanted reproductive structures (e.g., seed pods, cotton, pollen, etc.). Finally, sterility will help curb genetic pollution. Trees such as poplar, which can be vegetatively propagated, are often grown in intensively managed plantations. In some cases, a single genotype is planted across thousands of acres. Because these trees are clonally propagated, all of their cells, including their pollen, contain exactly the same DNA. This monotypic pollen can travel considerable distances and fertilize flowers on compatible wild trees, which could affect genetic diversity in the wild. Flowering control has the potential to reduce the likelihood of this occurring.

Methods for Engineering Reproductive Sterility

One common way to engineer sterility is to ablate cells by expressing a cytotoxin gene in a tissue-specific manner. Floral promoters can be fused to one of a variety of cytotoxin genes that lead to rapid and early death of the cells within which the gene expressed. One of the more popular ways to engineer sterility in herbaceous plants employs an RNase gene, the product of which degrades messenger RNA.

A second way to genetically engineer flowering control is through the use of dominant negative mutations (DNMs). DNM genes encode mutant proteins that suppress the activity of coexisting wild-type proteins. Inhibition can occur by a variety of means, including formation of an inactive heterodimer, sequestration of protein cofactors, sequestration of metabolites, or stable binding to a DNA regulatory motif. Overexpression of floral regulatory genes that encode proteins with altered amino acid in the highly conserved domains can result in mutant floral phenotypes. Similar changes can also eliminate the encoded protein's ability to bind DNA. A potentially powerful alternative approach is to introduce a transgene encoding what is called a 'zinc finger' protein, which is specifically designed to block transcription of the target gene.

A third technique to control flowering involves gene silencing. In a variety of eukaryotic organisms, double-stranded RNA is an inducer of homology-dependent gene silencing; use of double-stranded RNA to induce silencing has been termed RNA interference. Studies in plants have shown that strong silencing can be achieved by introducing a transgene containing an inverted repeat of a sequence that corresponds to part of the transcribed region of the endogenous gene targeted for silencing. Such transgenes induce posttranscriptional gene silencing (PTGS) by triggering RNA degradation. Although this approach appears to provide a reliable means for engineering stable suppression of gene activity in plants, whether PTGS will be effective practically is uncertain, due in part to the ability of plant viruses to suppress PTGS. An alternative is to use a transgene containing an inverted repeat of a target gene's promoter region; this has been shown to induce *de novo* DNA methylation and transcriptional gene silencing (TGS). Unlike PTGS, TGS is not susceptible to viral suppression; however, it is unclear whether all endogenous plant promoters can be silenced by this method.

All of these approaches rely on the use of genes that control floral development, either through the use of floral-specific promoters or coding sequences with high homology to native genes that are targeted for suppression/silencing. In addition, flowering-time genes provide a means of advancing or retarding the onset of reproductive growth. The former can facilitate more rapid progress through conventional breeding; the latter can, depending on the rotation of the crop, serve as a transgene confinement strategy.

The Need for Transgene Stability

Stability of transgene expression is especially important for trees, which undergo numerous dormancy cycles and are often exposed to extreme environmental changes during their long lives. Unstable expression has taken on greater significance given recent reports that environmental changes and dormancy can trigger transgene silencing. Sexual reproduction may also affect the stability of transgene expression. To date, little evidence exists for somaclonal variation or transgene instability in poplar, but these characteristics will need to be evaluated over several years and in a variety of settings for any transgenic tree that is to be commercialized.

Propagation Technology for Forest Trees

W J Libby, University of California Forest Products Laboratory, Berkeley, CA, USA

Introduction

There are six major kinds of propagules now available for the reproduction of forest trees: seeds, sprouts, grafts, cuttings, tissue-culture plantlets, and somatic embryos. Each has two or more subclasses, and each has increasingly understood advantages, disadvantages, and uses. For several of these kinds of propagule, the maturation state and physiological condition of the starting material can vary substantially, with important consequences. These two concepts are discussed in general and with respect to each kind of propagule. The terminology currently in use is not always clear, and is sometimes conflicting. Alternative terminology is noted where such confusion is common.

Some Terminology for Propagule Stages

With the exception of sprouts, each of the other five kinds of propagule has terminology associated with stages suitable for storage; its early intensive-care stage; and its stage as a propagule ready for outplanting in field conditions. The 'seedling–steckling–plantling–embling' parallel terminology for field-ready propagules was formally adopted at the 1983 Second Meeting of the International Conifer Tissue Culture Work Group in Federal Way, Washington, and by 1986 had been accepted by the Genetics and Tree-improvement Working Group of the Society of American Foresters. However, these terms have not been widely or uniformly adopted. These and other commonly used terms are summarized in **Table 1**.

Seeds

The most common form of propagule in natural forests, and for artificial regeneration of forests, has been and is the seed. Most forest-tree seeds result from sexual reproduction, and thus the seeds from a given tree differ genetically from their parent(s) and from each other, providing for diversity and ongoing evolution. A typical seed consists of one or more embryos; surrounding nutritive tissue, which also contributes various enzymes, hormones, and other growth regulators that influence development and germination; and enclosing seed-coat tissue. Given the right environmental conditions, the seed germinates. The germinant grows and develops through juvenile seedling and adolescent sapling stages to become a mature tree.

Natural Regeneration

In pre-Neolithic times, all forest regeneration was natural, with (usually) seeds regenerating extant forests and colonizing new areas without purposeful help from humans. Neolithic behavior began to impact many species of plants and animals several thousand years ago, as humans began domestication of those species and replaced hunting-and-gathering cultures with agriculture. Except for clearing forests for agriculture and housing, human Neolithic behavior was much later in impacting most forest-tree species. Substantial forest planting began barely a thousand years ago, and conscious domestication

Table 1 Terminology for storage and early development

Propagule Type	Storage stage	Intensive-care stage	Field-ready stage: Traditional	Field-ready stage: SAF[a]
Seeds	Seed	Germinant[b]	Seedling	Seedling
Grafts	Scion	Wrapped graft	Graft	Grafted plant
Cuttings				
Rooted	Cutting or hedge or stool	Rooted cutting	Cutting or plantling	Steckling
Unrooted	or mother plant	None[b]	Set or offset or cutting	Cutting
Tissue cultures	Culture	Plantlet	Plantling	Plantling
Somatic embryos				
Encapsulated embryos	Synthetic seed	Germinant	Somatic seedling	Somatic seedling
Naked embryos	Embryogenic tissue or dehydrated embryo	Germinant	Somatic seedling	Embling

[a] Terminology accepted by Society of American Foresters' (SAF) Genetics and Tree-improvement Working Group as of 1986.
[b] Unrooted cuttings set, and seeds scattered or planted, directly on the forest site have no controlled intensive-care stage but, for the first months after setting, scattering, or planting in the field, they are fragile until well rooted.

(often called 'tree improvement') did not become common until the second half of the twentieth century.

Natural regeneration remains typical and appropriate for most parks and reserves. It is also relied on in many harvested forests, and there the harvest practices may have large and sometimes unintended consequences. Species composition of the subsequent forest is strongly influenced by harvest practices, for example, clearcutting or selective harvesting favoring or disfavoring light-demanding or shade-tolerant species. Where some sort of selective harvest system is employed within a species, the parents that are left strongly influence the quality of that species in the subsequent forest. When the more useful trees are harvested (high-grading or creaming), the forest becomes decreasingly useful for later harvests. When the more useful trees are retained to become parents of succeeding generations, the usefulness of the forest for harvest may be increased in the long run at substantial short-term opportunity cost.

Artificial Regeneration

Artificial regeneration is employed to augment an extant forest, to replace the previous forest, or to establish a new forest. In some cases, seeds are scattered or planted directly on the intended site, but more commonly they are germinated in nurseries and seedlings are planted. As humans have increasingly employed artificial regeneration of forests, there has frequently been a progression from (1) collecting conveniently gathered seeds to (2) selecting the mothers (seed-parents), then (3) selecting both mothers and fathers (pollen-parents), then (4) testing to determine the better families, and finally (5) selecting the better offspring within tested families. Seeds have generally been employed in steps 1–4, while various clonal techniques are employed for step 5.

Most species have seeds that are relatively inexpensive to collect, handle, and store. However, nursery propagation is difficult for several forest species whose seeds are expensive to collect; and/or have very short storage lives; and/or have complicated requirements for germination; and/or germinate erratically over long periods of time.

Wild seeds During forestry's equivalent of the early Neolithic, wild seeds were generally collected near to where they would be used. While early data from seed-source (provenance) tests frequently indicate that nonlocal populations are outperforming local populations, longer-term studies often show that the locals are best over periods of several decades. As communication and transportation improved in the nineteenth and twentieth centuries, seeds were often collected at greater distances from their intended planting sites. This practice has frequently proved to be a serious or even disastrous mistake, as these nonlocal populations encountered environmental events, pests, and pathogens to which they were not well-adapted. Whether local or distant, seed collectors often collected from trees that were malformed, or had produced unusually abundant seeds, or had been felled in early thinning; in other words, from mother trees that had undesired qualities. In some forestry programs, those early-Neolithic practices still persist in the twenty-first century.

As the importance of the genetic quality of forest-tree seeds became understood, it became common practice to collect seeds from the better trees in natural stands and plantations. This was sometimes accomplished by felling the select trees during good seed-years, or by climbing them. In some programs, seed-production areas were designated in natural stands or plantations. In these, the quantity, weight, and germinative vigor of the seeds were improved by thinning, fertilizer use, and protection from seed-destroying pests. If the poorer trees were removed during thinning, the average genetic qualities of both the seed-parents and pollen-parents were upgraded.

Orchard seeds Genetic merit is further upgraded by concentrating selected parents in seed orchards. Seed quantity, weight, and germinative vigor are often increased by locating the orchards on warm, dry sites; fertilizer use; irrigation (or water deprivation); and pest exclusion. Genetic control is further increased by augmenting the pollen naturally delivered to the female organs with select pollen, and fully obtained by controlled pollination to produce pedigreed full-sib families. At this level, the parents have usually been further characterized and selected by testing of their progeny, and inbreeding can be avoided by mating unrelated parents (**Figures 1–6**).

Sprouts

Some forest-tree species naturally sprout at or near the root collar when the top is killed, from the stump when cut, or from roots. When applied on purpose, this regeneration technique is called coppicing (or pollarding if the stem is cut 2–3 m above ground). It results in maintaining many of the same (usually well-adapted) genotypes in the subsequent forest. Root-sprouting results in spreading the clone over short distances, and it can be stimulated by ripping the soil to cut up the root systems, or by otherwise damaging the roots.

Sprouts can also serve as good sources of cuttings or tissues for subsequent cloning to other sites. They are particularly effective because traits of the mature tree can be evaluated, and because the sprouts are usually at a juvenile or early adolescent maturation state.

Physiological Condition and Maturation State

A propagule's physiological condition depends on its supply of photosynthates and mineral nutrients, and on the interaction of its growth regulators (such as hormones and inhibitors) with its recent and current environment. The propagule's physiological condition strongly affects its performance during its growth and development. Physiological condition can be influenced to produce more juvenile-appearing or more mature-appearing propagules by the husbandry of the donor plants and during propagation.

Figure 1 *Pinus radiata* full-sib seedlings hedged to produce much larger numbers of cuttings of select full-sib families. The stecklings thus produced from this hedge-orchard will be almost fully juvenile by virtue of the hedges being maintained close to ground level. Courtesy of New Zealand Forest Research Institute.

While the maturation state of most germinating seeds is early juvenile, it is clear that the maturation state of graft scions, cuttings, and tissue-culture plantlets of many forest-tree species varies substantially and importantly. For most species, this variation is reasonably predictable by the chronological age of the donor plant and the part of the plant used as a cutting or tissue donor; most important is the current maturation state of the cutting or tissue when it is donated.

Maturation can be understood as a developmental genetic process, proceeding more or less continuously from embryonic through various juvenile, adolescent, and mature stages, to a late-mature stage when systems are likely to fail. Different parts of a large tree are typically at different maturation states, with the more juvenile (usually early adolescent) states being found low in the tree or in the roots, and the most mature occurring in the terminal meristem(s). One useful indicator of likely maturation state of the donated part is its cumulative distance along the stem from the position of the seedling's cotyledons. Thus, a propagator can influence the maturation state of propagules not only by choosing

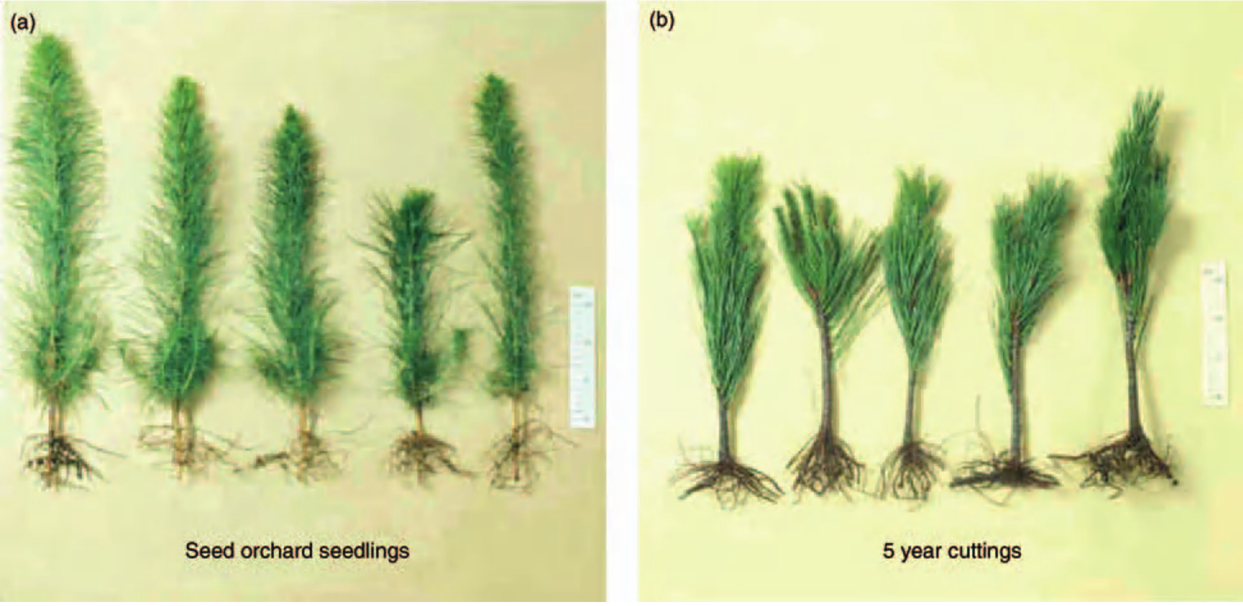

Figure 2 Propagules of *Pinus radiata*, 3 months after planting, comparing habit and vigor of (a) seedings with paler foliage and green apical tufts and (b) stecklings from 6-year-old trees with deeper green foliage and sealed buds (concealed by foliage). Courtesy of New Zealand Forest Research Institute.

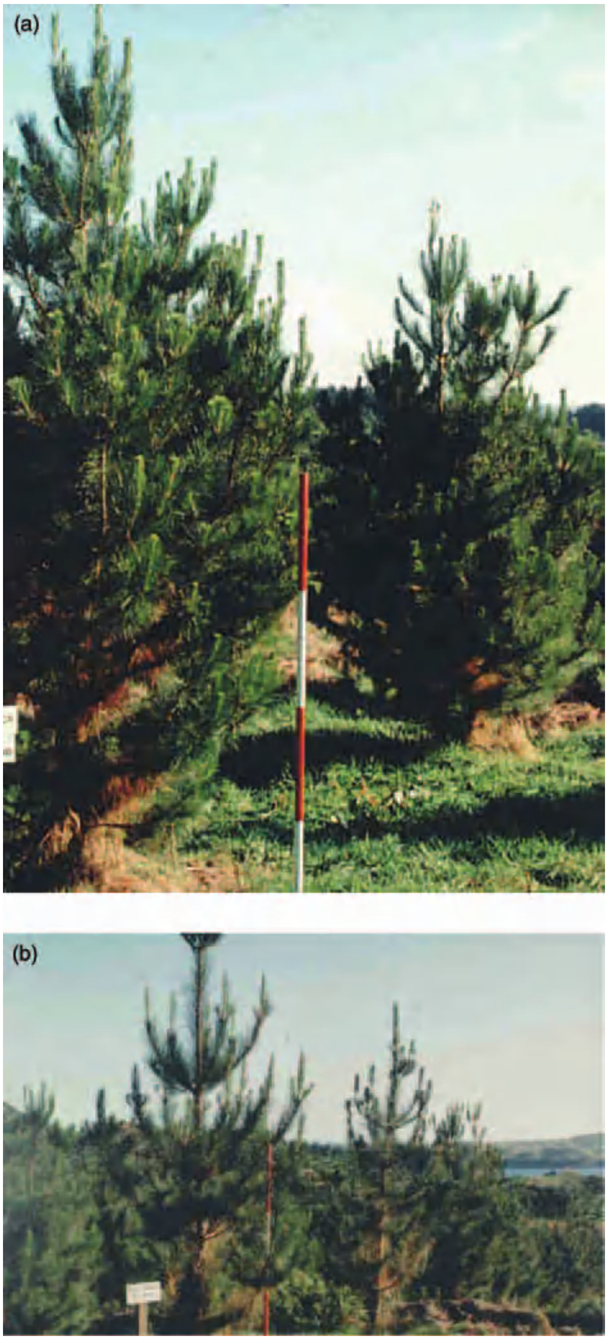

Figure 3 Contrast in *Pinus radiata* between (left) juvenile habit of seedling planting stock, with paler foliage and green apical tufts, and (right) stecklings (rooted cuttings) from 5-year-old trees with deeper green foliage and sealed buds (concealed by foliage). Stecklings from first-year seedlings or stool beds resemble the seedlings. Those taken from progressively older seedlings become more difficult and costly to produce, and make slower growth. Figure 5 Harvested somatic embryo shoots of *Pinus radiata*, transferred to a germination medium, where the hypocotyl and epicotyl elongate and develop green chlorophyll. Courtesy of New Zealand Forest Research Institute.

While the maturation of a clonal line can be slowed by techniques such as low-hedging of donor plants or rapid serial propagation, it is less clear whether the maturation state of tissue or other propagule material can be reversed. It is clear that elements of maturation affecting vegetative propagation proceed rapidly in some species (such as sugar pine, *Pinus lambertiana*) and are long persistent in the juvenile state in others (such as willows, *Salix*).

The effects of maturation state on the performance of propagules can be anticipated by considering the performance of the part of the tree whose terminal meristem is or was at that maturation state. Thus, in an example typical of many conifer species, a propagule produced at a mature maturation state

Figure 6 Somatic embryo shoots of *Pinus radiata* transferred into a rooting medium. In this variation of the somatic embryogenesis technique, the basal part of the hypocotyl initiates roots in a manner similar to that of shoots from organ culture. Following sufficient root development, the developing germinant then hardens off to become a field-ready embling. Courtesy of New Zealand Forest Research Institute.

will develop the lower-bole form, branch architecture, and thinner bark typical of the upper bole; the wood of its lower bole will have, for a given ring number from the pith, the longer tracheids, lower (steeper) microfibril angle, and lower specific gravity typical of upper-bole wood; and its growing shoots will have greater resistance to juvenile diseases, greater susceptibility to browsing, and will more quickly exhibit sexual competence.

Seedlings are normally juvenile when they germinate and their subsequent development is considered to be the norm. Several terms are associated with the concepts and effects of physiological condition and maturation state of other kinds of propagule, and they are most applicable to the scion portion of grafted plants, to cuttings and stecklings, and to a lesser extent to tissue cultures and plantlings. ‘Cyclophysis’ refers to the maturation state of the terminal meristem and the effects of that on propagation and subsequent development. ‘Topophysis’ has elements of cyclophysis, but adds an effect of the additional differentiation that occurs after lateral meristems are produced and grow into a branch hierarchy, plus the different physiological conditions of branches in different parts of the tree. ‘Periphysis,’ less used, refers to the effects of the operational environment of the donor plant on the physiological condition of the parts sampled from the donor. ‘Plagiotropism’ indicates that the main stem of the growing propagule develops at an angle and rather like a branch (often with bilateral symmetry), as contrasted to vertical, radially symmetric ‘orthotropic’ growth typical of seedlings and other juvenile propagules.

Grafts

Grafted plants, often simply called grafts, are compound organisms. In its simplest form, a grafted plant consists of a rootstock (which may be a clonal propagule or a seedling) and a scion, usually a twig or bud from the desired donor plant. Sometimes interstock stems from a third plant are grafted between the rootstock and the scion. The rootstock becomes the root system and sometimes the basal part of the bole, while the scion becomes the upper part of the tree. Many techniques are available for grafting, with a unifying principle of matching the cambium of the scion to the cambium of the rootstock to promote early fusion and healing.

Grafting is commonly used to produce highly uniform clones of fruit or nut trees, and for some forest-tree species to be planted in urban and amenity settings. However, it has not gained wide acceptance as a means of producing planting stock for forests. This is largely due to its higher cost, compared to seedlings, cuttings, and stecklings. It is also due to the frequent occurrence of incompatibility between the scion and the rootstock, which can result in sickening and then death of the grafted plant years or even decades after planting.

Rootstocks are generally of the same species as the scion, although successful grafts are advantageously made using scions of species different from the rootstock (for example, *Juglans regia* scions on *J. hindsii* rootstocks). Using seedling sibs of the grafted scions as rootstocks or rootstock clones selected for general compatibility is sometimes successful in reducing or eliminating a stock–scion incompatibility problem.

Seed Orchards and Breeding Orchards

Seed orchards and breeding orchards concentrate desired genotypes in one place for more effective production of improved planting stock. While some seed orchards and breeding orchards are established with stecklings or pedigreed seedlings, most employ grafts. Twigs that are sufficiently mature to be sexually competent are used as scions, thus usually producing pollen and/or seeds earlier and on smaller trees than if seedlings were used. Severe top-pruning, or dwarfing rootstocks, sometimes help keep the trees small for easier-controlled pollination and collection of seeds

Cuttings

Cuttings are usually twigs detached from the donor plant. In some species, stem sections, root sections, and/or sprouts can also serve as cuttings. In many tree species, the maturation state of the cutting is of great importance. Juvenile cuttings typically root easily and grow well, but mature cuttings root with difficulty, grow weakly, and often maintain branch form for several or even many years.

Unrooted Cuttings

In some species, such as willows (*Salix*) and poplars (*Populus*), it is common to plant unrooted dormant cuttings (sometimes called ‘sets’ or ‘offsets,’ terms commonly used when planting such dormant clonal propagules as onion bulbs, potato tubers, and gladioli corms) directly into the forest site. In some areas, poplar cuttings (poles) 6 m or more long are inserted into planting holes so that their bases reach reliable moisture, where they root and then grow. Some riparian species naturally reproduce when twigs broken off during flood conditions are partially buried downstream and root after the water recedes. Unrooted cuttings of upland species such as radiata pine (*Pinus radiata*) are sometimes planted in soils where young trees are prone to toppling. Given favorable conditions, a high percentage of such cuttings root on site and they are more windfirm than planted seedlings, stecklings, or plantlings on such sites.

Stecklings

There is confusion of terminology in practice and in the literature, with well-rooted propagules originating as cuttings also being called cuttings (Table 1). Nursery-produced well-rooted cuttings, called stecklings, are a common form of cloned propagule for many forest-tree species.

Either dormant or actively growing twigs, sprouts, or root sections may be taken as cuttings. The dormant cuttings may be stored for weeks or even months before setting, and they frequently suffer fewer pathogenic problems than do cuttings taken during the growing season. However, if pathogens are controlled, cuttings that were actively growing and are immediately set frequently root more quickly than do cuttings that are dormant when set. When the cuttings used are root sections, steckling production is fairly straightforward; it involves stimulating shoots to develop and grow from the root section, which also produces new roots.

In established clonal programs, donor plants are often maintained as low-pruned hedges, sometimes called ‘stool beds’ or ‘mother plants.’ A hedge orchard allows a large number of clones and variable numbers of donor plants per clone to be maintained and managed in a relatively small area, under conditions that produce cuttings in a physiological condition favorable for rooting and subsequent growth.

Depending on species and conditions, rooting of cuttings may be done in an outdoor nursery or in enclosed structures ranging from small cold-frames to elaborate greenhouses and growth chambers. Since a cutting has no roots, moisture loss must be reduced by high humidity or periodic misting. Root initiation can often be speeded and root system quality improved by application of auxins such as indole-acetic acid or analogs of that naturally occurring hormone. Stem-rotting pathogens must be avoided or controlled until roots develop and rapid growth resumes. For many species, the quality of the root system is important and can be improved in the nursery by root-pruning, by lifting and loosening the soil (wrenching), or by growing the recently rooted cutting in an appropriate container with internal structure that guides the developing roots. The rooted cutting becomes a field-ready steckling when it attains a size and physiological condition appropriate for outplanting. As with seedlings, nursery practice to foster the appropriate physiological condition often involves a change in fertilizer formulation, moisture stress, and cold soil, all of which combine to produce roots ready to resume active growth immediately following transplanting to the field.

Tissue Culture

‘Tissue culture’ is a generic term that includes *in vitro* growth and proliferation of relatively unorganized cells (cell culture), of callus (callus culture), of particular tissues, and of organized organs such as shoots or roots (organ culture). Organ culture is the form of tissue culture most commonly used to propagate forest trees.

Plantling Production

Cultures may be initiated using cells, tissues, or organs from various parts of the donor plant, including leaves, terminal meristems, stem sections, root sections, and excised embryos. The physical, nutrient, and growth-regulator composition of the culture media are crucial, as are the removal and subsequent exclusion of most or all fungi, bacteria, viruses, and other organisms that would thrive on the culture media and/or infect the growing tissue. Sterile procedures are followed in producing the culture media, preparing the culture containers, and during preparation and handling of the plant material as cultures are initiated and then multiplied.

A major advantage of tissue culture as a mass-propagation technique is the rapid exponential proliferation of material producing plantlets. Another major advantage is the ability to store small numbers of cultures from each clone in a slowly growing or dormant condition while the clones are being tested, and then rapidly multiply those clones that are selected. A problem with many species is that the cultures slowly mature, and/or physiologically degrade, thus changing the performance of the cultures and subsequent propagules.

Adventitious plantlets When cultures are grown as cells or callus tissue, and then shoots develop when the conditions and composition of the culture medium are changed, or if shoots develop from other than shoot meristems during organ culture, these shoots and the resulting plantlets that develop when they root are called 'adventitious.' Multiplication rates are generally very high in such cultures. However, there is some evidence that within-clone variation is also higher in such cultures, apparently resulting from higher mutation rates, lower ability to repair such mutations, and/or persistent (epigenetic) effects that are maintained within clonal sublines but not subsequently inherited following sexual reproduction. Other anomalies may occur when tissues developing on some different pathway incompletely change to become shoot meristems. Thus, there has been a shift away from these adventitious forms of tissue culture.

Axillary plantlets When cultures are initiated using explants including the terminal meristems of embryos or shoots, these meristems then continue to grow shoots of increasing length. These shoots are harvested, cut into stem sections, and the stem sections are used to initiate new cultures. The stem sections usually contain one or more suppressed meristems in the axils of their leaves and, upon release from the inhibition of hormones from the terminal meristem, these axillary meristems then initiate long-shoot growth. Extension growth of the shoot organs and production of new stem-section explants are repeated through several or many cycles. When the culture medium is formulated to stimulate root production instead of shoot growth, the rooted shoots are termed axillary plantlets.

Plantlet Care and Development

Whether axillary or adventitious, newly rooted plantlets are fragile and need intensive care. They must be slowly acclimatized to nonsterile ambient conditions. This is commonly done by moving the growing plantlets through a series of nonsterile environments with increasingly greater variation in temperature and humidity. When able to cope with ambient conditions, the plantlets are transferred to a normal greenhouse or open-air nursery, with nursery practices similar to those for rooted cuttings. When the plantlets reach a size and physiological condition suitable for outplanting, they are called plantlings. As with stecklings, the maturation state of the plantlings may not be fully juvenile, and their maturation state will affect their subsequent growth and development when outplanted.

Somatic Embryogenesis

It has recently become possible to produce embryos from somatic cells, rather than from fused gametes. Thus, the normal genetic recombination that results in no two zygotes being identical can be avoided, and clones can be produced by somatic embryogenesis. As of the early twenty-first century, somatic embryogenesis has become available technology for a few species, for example yellow poplar (*Liriodendron tulipifera*) and several species of spruce (*Picea*), while the techniques are proving to be difficult for several other species. Somatic embryogenesis has not yet been intensively attempted with most species of forest trees.

Explants appropriate for initiating embryo-producing (embryogenic) cultures are commonly obtained from tissues such as suspensor organs connecting normal zygotic (sexually produced) embryos to surrounding nutritive tissue. In some species, embryogenic tissue has also been induced in cultures of such things as pith tissue obtained from mature plants. This latter approach allows the substantial advantage of cloning from donors that have developed to an advanced maturation state, an advantage not available when cultures are initiated from embryonic tissues associated with (or part of) new embryos following sexual recombination.

As with organ culture, the embryogenic tissue proliferates rapidly, and very large numbers of embryos can be induced to develop with a change in culture conditions and media composition.

While it is relatively easy to advance the maturation state of a clonal line, a clonal line's maturation state has been difficult, if not impossible, to reduce. A major advantage of somatic embryogenesis is that embryogenic tissue can be cryogenically stored at very low temperature. Later, clonal propagation can be resumed at an embryonic maturation state when the clone has been adequately tested for confident deployment, or when it is needed for special or unusual purposes.

A second possible advantage is the insertion of foreign genes into the cells of embryogenic tissue, followed by identification and testing of the genetically engineered miniclones (lines that differ by only one or a few genes from otherwise identical lines of the original clone). The identified miniclones can be cryogenically stored, and those genetically modified

Table 2 Comparative advantages and 2003 status

	Seeds	*Grafts*	*Cuttings*	*Cultures*	*Embryogenesis*
Cost	Very low	Moderate	Low	High	Potentially low

[b] Lag time from selection to substantial propagule production. Seed production following selection of parents varies from immediate to several decades.
[c] Multiplication rate once propagule production begins.
[d] Graft scions are likely to be used at a mature state, while cuttings and cultures may be initiated at early-juvenile to mid-adolescent maturation states, balancing advantages and disadvantages.
[e] The research and development status of the technology.

miniclones that prove to be acceptable can later be mass-produced.

Emblings

When embryo development is stimulated in embryogenic tissue, the embryos can be harvested and 'converted' (germinated) immediately, or they can be dehydrated, stored, and germinated later. In either case, these naked embryos need favorable conditions for their germination and early growth. As with plantlets, after the somatic embryo germinants have been acclimatized to ambient conditions, they can be grown in a normal greenhouse or outdoor nursery. When they reach a size and physiological condition suitable for outplanting, they are called emblings.

Somatic Seedlings

Harvested embryos can also be encapsulated. In this procedure, each embryo is surrounded with a gel containing nutrients and growth regulators, all contained within a hard coating. This coating can be color-coded, with clone name or number, organization logo, and other information printed on it. These synthetic seeds can be handled with the equipment and procedures well developed for seedling nurseries. Because the materials encapsulated with the embryos will affect their germination, growth, and development, it is useful to differentiate these propagules from those developing from naked somatic embryos. Thus, when field-ready, they are called 'somatic seedlings' rather than either emblings or seedlings.

Relative Properties and Status of Propagule Types

Table 2 summarizes some of the advantages and disadvantages of the various types of propagule discussed above.

Forest Operations in the Tropics, Reduced Impact Logging

R Heinrich and U Arzberger, Food and Agriculture Organization, Rome, Italy

Introduction

In recent years considerable efforts have been made in introducing improved forest harvesting practices to tropical forests to support sustainable forest management. However, only a small proportion of forests in the tropics is actually being managed on a sustainable basis. Environmental groups and, increasingly, the general public have called for refined harvesting systems and techniques so as to utilize wisely forest resources, thereby maintaining biodiversity and keeping forest stands intact in order to provide forest goods and services for the present as well as for future generations. The application of reduced impact logging (RIL) systems and techniques seems to have gained increasing importance in meeting environmental challenges and providing economic and social benefits.

Forest Operations in the Tropics

In tropical countries, harvesting operations are fundamentally different from those applied in temperate zones. Stand densities in temperate forests are considerably higher than in the tropics, generating much higher potentials for commercial timber volumes per hectare. There is less diversity of tree species in temperate zones, and the utilization of commercial tree species permits simplified forest operations. Due to the application of both selective and clear-cutting as well as the higher standing timber volumes per hectare, harvesting densities in general greatly exceed those in the tropics. Directional felling is easier to carry out in temperate zones due to the usually smaller-sized trees and crowns; and soil conditions are better for skidding operations. In spite of varying seasons, climatic conditions allow the appropriate implementation of harvesting operations throughout the whole year.

In the tropics, forest operations are generally more complex to organize and implement than in temperate zones. Natural forests in the tropics are characterized by a higher abundance of different species with many diverse sizes of timber and ample stand densities with only a few species of commercial interest. The harvestable wood volumes per hectare vary considerably depending on the occurrence of commercial tree species. The situations that most often complicate harvesting operations are the following:

- large trees with large crowns
- low carrying capacity and high vulnerability of forest soils
- extensive variety of timber sizes
- high precipitation rates, which often contribute to soil erosion
- lack of forest road and skid trail infrastructure
- long transport distances on poorly paved roads due to scarcity of appropriate road construction material.

Preharvest Planning

The main objectives of preharvest planning are to optimize harvesting operations and to minimize environmental impacts. A harvest plan should consist of a written description of the planned operation and a detailed topographic map of the harvesting operation area. Preharvest plans should also include information on harvestable tree species, as well as data on other factors to be taken into consideration in harvesting planning, such as soil and terrain conditions or existence of watercourses. Detailed information about specific working equipment and the workforce involved plus careful attention to the integration of local communities in the projected operation are additionally preconditions for well-planned harvesting operations.

Forest Road Engineering

The goal of forest road engineering is to provide reliable access to the forest for management purposes and for silvicultural and harvesting operations. It involves specifying design standards and field layout, followed by construction and maintenance of forest roads including setting of skid trails, location and layout of landings as well as constructing subsidiary structures, such as bridges and culverts.

Forest roads are unquestionably the most environmentally problematic feature of timber harvesting operations, since a major part of the total soil erosion can be attributed directly to them because of inadequate design and construction standards, as well as poor maintenance practices.

Tree Felling and Cutting

Tree felling and cutting includes all activities from felling the standing tree to its preparation into logs for wood extraction. These activities include the felling process itself, cutting off tree crowns and limbs, crosscutting stems into logs and sometimes debarking of logs.

In tropical regions, trees may be large and heavy with huge crowns and might be connected by strong vines to each other. They fall with a tremendous force which can uproot neighboring trees; and stems may shatter, bounce, and roll uncontrollably. Therefore felling operations are both the most hazardous part of harvesting operations for the labor force. They are also a major cause of damage to the forest stand and result in the generation of a large amount of wood waste.

Wood Extraction

Extraction of wood is the process of moving trees or logs from the felling site to a landing or roadside. Extraction practices can be distinguished by the system used and the harvesting equipment employed (**Table 1**). Regardless of the type of logging system used, extraction can inflict substantial damage on forest ecosystems.

In the tropics the most common method of wood extraction is the ground-skidding system. A conventional set of ground-skidding equipment consists of ground-dependent machines, which may consist of either crawler tractors, wheeled or tracked skidders, or a combination of them. They are generally equipped with winches.

The use of draft animals, such as elephants, oxen, horses, or water buffaloes, can be economically attractive, particularly in remote areas. They are often used by local communities in small-scale operations and in forest stands with smaller-sized trees.

Cable systems are a preferred method for wood extraction in hilly to steep terrain. With this method, logs are transported either partially (as in ground and high lead operations), where logs may drag on the ground causing soil disturbance, or fully suspended in the air (as in skyline operations). Ordinarily, the

Table 1 Advantages and disadvantages of different extraction systems

Extraction system	*Advantage*	*Disadvantage*
Ground skidding	Low cost extraction system Short training requirement Simple technology	Tendency to cause the greatest environmental problems High density of skid trails Limited by slope gradient and soil conditions
Draft animals	Low soil and stand damage Extremely narrow skidding paths Low investment and maintenance costs	Limited extraction distances Mostly limited to small timber sizes and small-scale operations
Cable	Low density of roads No skid trails Very low environmental impact when properly done	High investment costs Laborious assembly and disassembly of the cable system
Helicopter	High production rates Low density of forest roads Very low environmental impact	Very expensive Thorough planning and precise organization needed Extremely highly skilled team of workers needed
Manpower	Narrow skid trails Necessary equipment very simple Cheap	Hard and slow work Limited extraction distances

timber is transported by carriages which are moving on a cable. The power source – a winching machine, also called a yarder – is located either at the top or the lower station, depending on the type of system used.

Helicopter systems are the most productive as measured by cubic meters of timber produced per hour or day and yet are the most expensive wood extraction system. Helicopters are only used in difficult and steep terrain where high-value tree species are extracted and where intensive forest road development would be too expensive and not appropriate.

With the introduction of the crawler tractor, log skidding by manpower has almost disappeared in tropical Africa. However, it is still being used in Asia and in the Pacific region where it is called kuda-kuda. Short wooden wedges, driven into the sides of the log, give the men a hold to control and push the log lengthwise over wooden cross-skids. Skidding distances may exceed 1 km where there are no alternative methods of extraction.

Landing Operations

Work on landings include all activities in connection with sorting, storing, and preparing the extracted stems or logs for further transportation to the processing facility or any other final production destination. Landings are always connected to roads so as to provide access to the stored timber by transport vehicles.

Transport Operations

At present the most common form of log transport in the tropics is by means of logging trucks. In remote areas, however, often a combination of land and water transport is used: hauling timber from the landing to an embarkation point by trucks, where the journey is continued by water transport, using barges or rafts. In some rare cases, railways are an alternative means of transport.

Harvesting Intensity

Harvesting intensity is a decisive criterion that influences the degree of impact on forests. Generally the total standing timber volume may range from 50 to over 200 $m^3 ha^{-1}$ in the tropics. Harvesting intensity in tropical forests varies considerably between regions, countries, and even within countries. In Africa a low logging intensity forest operation is usually practiced with a mean extracted timber volume of 8–25 $m^3 ha^{-1}$. Medium and moderately high logging intensity operations as practiced in South America often reach 10–50 $m^3 ha^{-1}$ of harvested timber. In Asia and the Pacific region, logging intensity is higher than in the other two regions, reaching about 40–100 $m^3 ha^{-1}$.

Reduced Impact Logging

Definition of Reduced Impact Logging and Conventional Logging

Reduced impact logging (RIL) may be defined as an intensively planned and carefully controlled implementation of harvesting operations used in order to minimize impact on forest stands and soils, usually in cutting individually selected trees. In contrast to RIL, conventional logging systems are carried out without much concern about possible environmental impacts to the forest stand and soils and the sustainable utilization of forest products and services.

The aim of RIL is to introduce environmentally sound forest operations and to avoid negative impacts that could occur in conventional logging systems. Besides following the forest operation suggestions described above, other improvements can be obtained by applying RIL techniques in order to decrease impacts and increase benefits. The main characteristics of RIL are shown in **Table 2** and described below.

The idea behind RIL is not a new one. It is actually a collection of environmentally sound forest practices already used in some temperate and tropical forests. Techniques such as preharvest inventory, worker training, directional felling, prescribed skidding or advanced road construction are well-established practices in a number of countries. Additional practices specific to tropical forests are, for example, mapping of individual crop trees and preharvest cutting of vines.

Stand Entries at Predetermined Cutting Cycle

In order to provide sufficient time for the regeneration of remaining forest stands and to guarantee a sufficient amount of timber for future harvesting operations, a predetermined cutting cycle for stand entries should be defined and observed. This is a

Table 2 Main characteristics of reduced impact logging techniques

Stand entries at predetermined cutting cycle
Worker and supervisor training
Safety regulations
Favorable working conditions
Preharvest operational inventory, including tree marking and location mapping of potential crop trees
Vine cutting when required
Advanced road construction
Minimize extraction trails
Directional felling
Maximum utilization of all trees felled
Landings planned
Damage to residual stand minimized
Postharvest assessment
Rehabilitation of sites of negative impacts

major aim of sustainable forest management. A minimum interval has to be determined by silviculturists based on knowledge of local growth rates and an assessment of the degree of damage caused to the residual stand by the harvesting operation.

Worker and Supervisor Training

Forest workers are in many cases underpaid and poorly skilled. This fact results in negative environmental impacts and economic losses. Forest companies often involve local communities in the workforce for harvesting operations, because they are the only available workers in remote forest areas.

The implementation of training programs for logging and supervisory personnel at all levels is essential to improve the working conditions. Perhaps the lack of skilled workers is one of the main reasons why a successful application of RIL in tropical forests has failed to materialize on a large scale so far.

Safety Regulations

Training programs for workers, protective clothing, and properly serviced equipment contribute to significantly improved labor safety and health conditions. Safety has tended to be neglected due to economic difficulties. Accidents occur mainly during the felling process. Often, forest management does not know the real costs of accidents: many of the indirect costs resulting from inadequate safety regulations are difficult to determine, but they can be up to six times higher than the direct costs.

Favorable Working Conditions

Environmentally sound forest operations can only be carried out under favorable weather and soil conditions. Wet soils and heavy rainfall considerably hamper the use of ground-dependent machinery, and cause substantial soil disturbance and compaction. Preharvest plans need to consider alternative systems, should forest operations be hampered by weather, soil, and terrain conditions in a specific area.

Preharvest Operational Inventory

A preharvest operational inventory should estimate the timber volume and its distribution over the forest production unit as well as the number and the condition of potential crop trees. In tropical forests identification, marking, and mapping of each individual crop tree is essential to ensure efficient location of crop trees so as to increase the productivity of harvesting operations and to protect potential future crop trees.

Vine Cutting

Vine cutting, when required and properly implemented, can be an effective measure for improving the safety of the workforce during felling and for reducing crown damage to remaining trees. It generally should be done far enough in advance of felling to ensure that the vines have died and fully decomposed. Otherwise, safety may be compromised by vine cutting that has not been properly carried out.

Advanced Road Construction

The objective of advanced road construction is to minimize the clearing width, while at the same time ensuring that the width is adequate to permit the expected traffic to operate safely. In areas of high precipitation it is common to clear an area of forest alongside the road to allow sunlight to penetrate so that it can dry out the road surface after rainfall. The amount of roadside clearing can be reduced if appropriate drainage systems are used and properly maintained.

Minimizing Extraction Trails

In conventional skidding operations, uncontrolled driving to each harvestable tree or log due to the lack of skid trails can cause substantial soil disturbance and compaction. A system of skid trails, predetermined in the planning phase, should be adopted to minimize soil compaction by forest machines. Tracked and wheeled wood-extraction machines should stay on those skid trails. When using wheeled skidders the use of low-pressure and high-flotation tires further helps to minimize soil compaction.

Directional Felling

Directional felling is a specific tree-felling technique in which the direction of fall is determined by the operator prior to cutting. Where possible, trees should be felled in the direction of existing canopy gaps in order to reduce damage to nearby standing timber. In general, trees should be felled either towards or away from skid trails, preferably at an oblique angle to the skidding direction. Felling away from the skid trail will reduce problems for the extraction crew when tree crowns are large, whereas felling towards the skid trail can reduce the extraction distance substantially.

Maximum Utilization of Trees Felled

Most of the logging waste in forest operations occurs in both felling and cutting operations; some also occurs in skidding operations. Appropriate felling and cutting techniques include directional felling, cutting stumps low to the ground, and optimal crosscutting of stems into logs. Following RIL practices, such as mapping of felled trees and controlled skidding, wood waste due to lost logs very seldom occurs in skidding operations.

Landings

The location and design of landings should be done at the same time as road location and design. In many places, a small clearing at the side of the road is used for the landing rather than creating an entire landing structure.

Postharvest Assessment

Postharvest assessments can serve as an operational feedback for forest managers, technicians, and workers to determine the degree to which the objectives of RIL guidelines have been achieved, and to obtain information on how to improve forest operations in future. These include evaluation of stand and soil damages, as well as an assessment of costs and productivity of harvesting operations.

Minimizing Damage to the Residual Stand

Impacts on soil and forest stands arise inevitably from the use of heavy-duty machinery in forest operations. By following RIL practices and through proper implementation of harvesting operations, such damages can be minimized, thus leaving residual stands in better condition regarding future forest operations.

Rehabilitating Forests after Negative Impacts

Observation of the operating areas disturbed by roads, landings and skid trails, and also of the degree of soil disturbance, will provide an indication of whether rehabilitation is needed. If necessary, the areas with exposed soil should be revegetated with grass or other ground cover to prevent soil erosion. When harvesting only a few tree species, enrichment planting is often needed to guarantee diversity of species.

Benefits of RIL

Although a considerable number of studies on environmental impact assessment have already been carried out in tropical forests, many authorities have called for more comprehensive knowledge and information on the environmental, social, and economic benefits of forest operations. Unquestionably it has been proved that RIL significantly reduces damages to the remaining stand, soil, and watercourses. It has also been shown that RIL increases profitability on a larger scale, and considerably improves efficiency, recovery rates of timber, and safety standards for workers. Since higher recovery rates of felled timber generally can be achieved in RIL as compared to conventional logging systems, smaller areas of natural forest are subsequently affected by harvesting operations while at the same time the same amount of timber is recovered (**Table 3**).

RIL reduces the percentage of wood waste, thus increasing productivity and the economic return of operations. Minimized road length subsequently lowers maintenance and transportation costs, and contributes to a reduction in harvesting operation expenses, thus increasing financial benefits. Moreover, RIL has less impact on the residual stand and site, which enhances regeneration, allowing earlier re-entries with higher recovery rates in wood volume in m^3 in second cuts. However, overall costs for forest operations increase due to the expensive and comprehensive planning activities, which cost less in conventional logging systems. Overall, it is assumed that RIL practices are generally worthwhile (**Table 3**), but concerning specific financial benefits, the evidence of RIL experts is inconclusive.

Future Outlook

At present RIL is used by only a small number of forest companies and operators in the natural forests

Table 3 Mean values for various parameters in conventional and reduced impact logging systems obtained from examples in the scientific literature from the last 30 years

Parameter	*Unit*	*Conventional logging*	*Reduced impact logging*
Logging intensity	$m^3 ha^{-1}$	45	37
Logging intensity	trees ha^{-1}	8	8
Logging cycle	years	35	34
Costs			
Planning	\$US m^{-3}	1.44	1.72
Felling	\$US m^{-3}	0.60	1.16
Skidding	\$US m^{-3}	4.64	4.46
Damage			
Residual stand	% of residuals	49	29
Stand	trees/trees felled	22	9
Site	% of area	18	8
Canopy opening	% of area	25	16
Lost timber	% of removals	25	15
Utilization rate	% of felled timber	47	60

There are still many unknown aspects concerning RIL, and the major obstacle to the implementation of RIL is the common lack of knowledge about its benefits. The belief that RIL is more expensive is one of these obstacles.

Despite the research, data collection, and field studies that have been done so far, more effort needs to be dedicated to emphasizing the importance of RIL. Forest managers have expressed the need for research on a larger scale so as to provide reliable information concerning the benefits of RIL, especially the financial benefits. Comparative studies on RIL and conventional harvesting systems are necessary in order to acquire adequate data that would demonstrate, with examples, to forest companies and logging operators the numerous advantages of RIL. Consequent implementation of training programs for forest personnel at all levels and the availability of technical assistance are additional inducements for spreading the acceptance of RIL.

Through the application of RIL techniques, at least one source of negative impact on tropical forests from logging pressures could be partly reduced. Sustainable tropical forest management has to secure the existence and the continuity of the tropical forest ecosystems. RIL is a very important contribution to this end.

Harvesting of Thinnings

R Spinelli, National Council for Research – Timber and Tree Institute, Florence, Italy

Introduction

When thinning a forest, loggers operate under such peculiar conditions that special techniques and equipment are required. In principle, thinning teams face two main constraints: the low value of the harvest and the permanence of a residual stand that hinders machine movements. Of course, the impact of these factors largely depends on thinning type. The first thinning is most critical, because it yields very small trees and releases the densest residual stand. In contrast, the second and third thinnings are somewhat easier to implement: harvest trees are larger and may yield valuable products, while the residual stand is not excessively dense and offers more space for maneuvering. In fact, one often speaks of commercial thinning and precommercial thinning, according to whether the operation is sustainable from a commercial viewpoint or not. In precommercial thinning, the value of the harvest does not cover the overall harvesting cost, and the operation configures as a subsidized activity, performed with the aim of increasing future profit and improving forest stability. The first thinning is more likely to be conducted on a precommercial basis, whereas later thinning can offer some profit. At any rate, such profit is much inferior to that obtained from the final harvest, because the value of the harvest is lower and the harvesting cost higher – often twice as high.

Good Reasons for Thinning

Why thinning, then? There are several reasons. First, appropriate thinning allows released trees to grow healthier and larger than if they were left to compete with the removed trees, which increases the value of the final harvest. Second, by improving forest stability, thinning increases the chances for such a final harvest to occur in due time – and not be ruined by disease, windstorm, or fire. After thinning, released trees grow stronger and may better resist all kind of adversities, parasites and storms included. Furthermore, thinning implies the removal of any fuel build-up and decreases fire hazard, especially if the thinning breaks all 'fire ladders' – i.e., the dominated layer that connects the understory to the crowns of dominant trees, which may transform a litter fire into a catastrophic event.

These are 'strategic' benefits that accrue in the medium and long run. Other benefits have a more contingent nature, but at times they can be stronger motivators than any strategic goal, because they work in the short run – the here and now where we live. In general, any commercial thinning can be regarded as an anticipation of revenue that can be cashed in moments of need. Therefore, commercial thinning is a way to obtain quick cash when the business needs it. On a similar line, commercial thinning can help face demand peaks for certain products, or bridge age-class gaps in the available harvest: an intense thinning plan can supply pulp factories with significant amounts of pulpwood, if the volumes obtained from maturity cuts are not sufficient to cover the demand.

Whatever the reason for thinning, there are some crucial requirements that must be satisfied. First, it is imperative that the thinning improves the stand, or at least that it does not decrease its stability and value. This requirement stands even when the thinning is performed as a mere commercial operation, aimed at obtaining an anticipation of the projected revenue: no sound business would seek immediate cash at the expense of jeopardizing its capital base. Therefore, all thinning must be implemented in such a way that residual tree damage and soil disturbance are kept below the risk threshold, beyond which stand decline can be expected. Furthermore, as in any other economic activity, profit should be maximized – or losses kept to the absolute minimum – always within the limits allowed by sound forest practice. This is a very difficult task, since thinning is often a "borderline" activity from the financial viewpoint. Much research has been devoted to improving the economics of thinning, and more is in progress. Today, a number of alternative strategies are available to forest managers to apply a sound thinning plan effectively, while new machinery has been designed that can aid in the endeavor. Of course, the choice of any strategy and equipment must reckon with the working conditions typical for each case.

Working Method

Thinning crews can resort to any of the three classic working methods: shortwood, tree length, and full tree. The shortwood method implies delimbing and bucking felled trees at the stump site, before extraction. When applied to thinning, this method offers the great advantage of reducing the bulk of the wood being handled, which is particularly important when operating amidst a dense residual stand that hinders maneuvering. With the tree length method, felled trees are delimbed at the stump site, but they are bucked into logs only after they reach the landing. Therefore, they are extracted as full-length stems, which requires very careful planning if damage to the residual stand is to be kept within acceptable limits. Finally, harvesting by the full tree method implies extracting full trees to a landing, where they can be processed into a number of products. Here, handling is the most difficult, and the trade-off is in the total recovery of all available biomass – or the complete removal of dangerous fuel, depending on viewpoint.

In principle, the shortwood method is best applied to the second and third thinning, when removed trees have reached such a size to provide a few merchantable logs. In contrast, the full tree method seems ideally suited to the first thinning, which generally yields a crop of small trees that can hardly offer one good log. In this case, mass handling and whole-tree chipping are the most effective solutions (**Figure 1**).

The implementation of any harvesting method varies greatly with local conditions, and especially with the scale of the forest economy. Small-scale forestry and industrial forestry are two worlds apart, each with its own constraints and opportunities. In general, a business operating in a small-scale forestry environment enjoys better flexibility and is spared part

Figure 1 Moving on the corridors, a chip forwarder picks up whole-tree bunches, chips them on site, and takes the chip to a landing.

Figure 2 The integral harvester–forwarder is a new machine being introduced to thinning operations.

of the fierce global competition endured by the industrial company, but it also lacks the capital to acquire state-of-the-art technology. On the other hand, the industrial company can buy cutting-edge equipment, but it must deploy such equipment according to a very careful plan, if it wants to reach the efficiency required to match competition (**Figure 2**).

Translated into harvesting practice, this means that nonindustrial operations generally resort to low-productivity, low-investment equipment, such as the chainsaw and the adapted farm tractor (**Figure 3**). These two machines can be used to implement any of the harvesting methods described above. When applying the shortwood method, trees are felled, delimbed, and bucked with a chainsaw, and the logs are forwarded to the landing with a farm tractor, coupled to a dedicated forestry trailer. Tree-length and full-tree harvesting also rely on the chainsaw for felling–delimbing or felling respectively, while skidding can be performed by a farm tractor equipped with a log grapple or a forestry winch, depending on terrain conditions. As an alternative, extraction can be delegated to cheap second-hand skidders and forwarders, once industrial users have shifted to new, more productive models.

On the other hand, advanced mechanization is the pillar of industrial forestry operations. Here, the shortwood method is applied by the harvester–forwarder team, which is almost a symbol of Nordic forest technology. These two machines can carry out the whole task: the former felling, delimbing, and bucking the trees, the latter forwarding the logs to the landing and stacking them into neat piles. Although they work together, the two machines act independently with the advantage of simple logistics and easy planning. The alternative is to use a feller–buncher and a skidder to harvest full trees (**Figure 4**). These are cut and grouped in bunches with the feller–buncher, and dragged to the landing by a grapple

Figure 3 Felling with a frame-mounted chainsaw in a first thinning.

Figure 4 Compact feller–buncher in a late thinning.

skidder – or by a cable skidder, if terrain conditions prevent direct access to the bunches. Mechanized tree-length harvesting would require adding a delimber to this basic team, but this is comparatively rare. Today, most delimbers can also buck, and if one introduces such machines, then shortwood production is more likely to occur, which in turn will favor the adoption of the simpler harvester–forwarder team. On the other hand, one can always process the trees at the landing, which allows their tops and branches to be recovered for conversion into energy chips or mulch.

Whatever the system adopted, modern machinery is very expensive and can only be used if the value of their output will match their operating cost. When thinning, the value of the harvest is rather low: due to the limited size of removal trees, most thinning jobs only yield pulpwood and small sawlogs, which bear very low price-tags. Therefore, productivity must be high enough to compensate for the low value of the product. But this is difficult to achieve, because thinning does not offer favorable working conditions to mechanical equipment. In fact, productivity is proportional to the size of the harvested tree and to the ease with which the machine can move around, and we have just seen that thinning offers small-size trees and confined work space.

The Effect of Stem Size

Stem size governs the productivity of logging teams more than any other single factor (**Figure 5**). For each situation one may eventually identify a minimum stem size that makes harvesting economical: below such size, productivity does not reach the required level and the value of the harvest fails to match the machine's operating cost.

Stem size limits are particularly binding when harvesting shortwood, as today's harvesters can only treat one tree at a time. On the contrary, most feller–bunchers have accumulating capacity, so that they can cut more than one tree per cycle. This is crucial to compensating stem-size limitations. It is true that the time spent accumulating grows proportionally with the number of trees accumulated, but accumulation is only one stage of the felling cycle: the others – such as positioning the machine, moving the accumulation to the selected dump site, and dumping it to the ground – remain more or less constant, whatever the size of the accumulation. Therefore, even if the overall time consumption per cycle does grow with the number of trees accumulated in a cycle, its total value is always below the sum of the individual cycle times recorded if those trees were felled one at a time. That is why mass handling dampens the effect of decreasing stem size and allows its threshold value to be lowered. When harvesting with the shortwood method is no longer profitable, one may always resort to the full-tree method, which enjoys all the benefits of mass handling. The ultimate application of this concept is exemplified by whole-tree chipping, where tree bunches are fed to a chipper stationed at the landing. Under this scheme, trees are handled individually only when an accumulation is formed: this accomplished, they travel as a bunch through all the harvesting process. Whole-tree chipping is indeed the method of choice for early thinning, even though a low chip price occasionally drives loggers away from it.

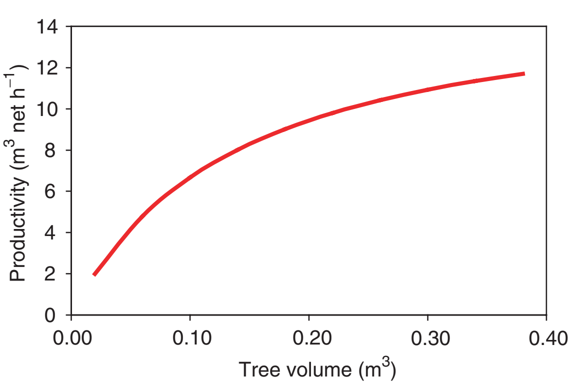

Figure 5 The effect of stem size on the productivity of a thinning harvester.

In fact, attempts have been made to develop shortwood harvesters capable of handling more than one tree per cycle. Results have been good, but not as conclusive as hoped. Some machines can really handle several trees per cycle, but the quality of processing often falls below the commercial standard, so that more development work is still needed.

Stem size limitations can also be tackled from another side, that of silviculture. Thinning is often conducted with the intent of facilitating natural selection: dominated trees are removed to leave more space for the dominant to grow. It is therefore no wonder that the size of the harvest trees so often falls below the economical threshold. Today, an increasing number of foresters support 'thinning from above' – a thinning concept that turns the conventional approach upside-down. They believe that if the small trees are healthy and well formed, they can be released with no prejudice to the future development of the forest. In turn, this allows the largest trees in the stand to be harvested, and this increases both the value of the harvest and the productivity of the harvesting teams. Several studies seem to indicate the viability of this thinning strategy, often dubbed as 'quality thinning.'

Manipulating Work Space

If stem size limitations can be partially solved through mass handling, other technical constraints must be faced in different ways. Confined work space is the second limiting factor that is peculiarly associated with thinning. The intensity of a thinning is determined by silvicultural considerations that integrate harvesting needs only to a limited extent. As a result, the total space available for maneuvering is a given value that loggers cannot alter too much, if they want to perform a good job: the density of the residual stand must reflect the growing conditions of the forest and guarantee its optimum future development.

However, if density remains a somewhat rigid parameter, spatial distribution may prove more flexible and it can be manipulated to a larger extent. From this consideration come the different thinning designs: row, row and selection, and group. These can all be regarded as adaptations to machine traffic of the original 'pure selection' design, which can be perfect from a silvicultural viewpoint, but gives results which are totally impractical for the harvesting crews. The ideal spacing job that leaves equally distant trees can only be applied to late thinning, when the density of the residual stand is so low that machines can sneak around leave-trees. Otherwise, one must open access corridors for machine traffic – removing entire tree rows in a geometric pattern. Selection thinning can be applied to the forest between two corridors (**Figure 6**). If all the work is conducted with mechanical equipment moving on the corridors, corridor spacing must not exceed twice the reach of the felling machines. If a larger spacing is adopted, trees must be felled towards the corridor using chainsaws, so that one may profit from the additional length of the stems. In this case, a processor can catch the felled trees by their tops and drag them to the corridor for processing. Corridor spacing can be increased even further if one is ready to take the felled trees to the corridors using a winch, a small tractor, or a draught animal. Moving corridors further apart is motivated by a desire to reduce the unproductive area represented by the corridors, which bear no trees. However, we have seen that increased corridor spacing often results in additional manual handling, and this can penalize industrial operations that must reach a high productivity if they are to remain profitable.

Figure 6 In early thinning, harvesters generally move along corridors, selectively thinning the stand on both sides.

Recently, compact harvesters have appeared that can move freely inside the stand, felling the trees and moving them to the corridors for extraction (**Figure 7**). They allow forest managers to increase corridor spacing without resorting to manual handling. However, the profitability of small-size thinning harvesters is questioned by many. Thinning harvesters can only handle thinning-size stems and lack the flexibility of large standard units, which can be deployed in both thinning and maturity cuts. Flexibility is an important asset in the logging business, where long-term planning is rare and a contractor can bid for a number of different jobs over a period of time. Furthermore, maturity cuts offer better profits than thinning, which is considered as a second choice by many. Today, the general trend is to acquire a standard harvester and adapt it to the occasional thinning jobs (**Figure 8**). In fact, it is the thinning that more often adapts to the harvester: moving from individual selection to group selection is another way to manipulate work space for

Figure 7 Dedicated thinning harvester in a row plantation.

Figure 8 Standard harvesters can be used in thinning operations as well as in maturity cuts.

Figure 9 Stem and soil damage in a badly managed thinning.

providing in-stand access to mechanical equipment. In addition, group selection contributes to increasing the size of harvest trees, with a similar effect to quality thinning. Group thinning also offers a number of silvicultural benefits, such as better resistance to wind and snow damage.

Managing the Impacts

For better or for worse, machines lend us extra power and increase our ability to impact the environment. In many cases, mechanized operations have indeed resulted in extensive environmental damage and there is a wealth of studies documenting the most common impacts. Large machines are especially prone to causing severe soil disturbance and widespread tree wounding, both of which can result in substantial yield losses (**Figure 9**). Worse than that, they can jeopardize the stability of the stand, making it more vulnerable to adversities: extensive tree wounding invites insect attacks, while soil disturbance can reduce tree stability and increase sensitivity to windblown.

Fortunately, mechanized thinning does not ordinarily result in extensive tree damage. Awareness of impact has informed the development of 'environmentally friendly' machinery: to some extent, the design of all forestry equipment produced today incorporates environmental concern, so that modern machinery generates increasingly less impact. As tolerance for impact keeps decreasing, manufacturers have to face the new trend in a proactive way. Some have transformed this constraint into a marketing tool, and they offer new machines that are specifically designed to create minimal disturbance. Compact shape, reduced size, and light weight are especially compatible with in-stand traffic, although not all opinions converge on its specific mode (**Figure 10**). Thinning harvesters can sneak between trees and

Figure 10 Specifically designed for thinning, this small forwarder can sneak into the residual stand without damaging the trees.

leave a very shallow footprint – to the point that the trails they tread are often known as 'ghost trails.' These machines exert a very low ground pressure: often below 50 kPa, which most soils can bear without suffering compaction. Experts suggest that such equipment should be allowed unrestrained circulation in the stand and not confined to corridors. The point they make is that such machines are so light that they hardly disturb the soil if they travel just once over the same spot. Confining the machine to predefined tracks would increase the number of passes over the same spot, thus forfeiting the benefit of low ground pressure. Of course, not all foresters agree on this matter, and the opportunity of allowing unrestrained stand traffic is still an open question.

Another feature of environmentally friendly mechanization is the use of biodegradable oils, especially hydraulic oil. Modern machines incorporate a good deal of hydraulics and carry large amounts of hydraulic oil. Leaks are very common and occur in a number of cases, including breakdowns and ordinary maintenance. The best way to

Figure 11 Self-leveling thinning harvester for steep-terrain operations.

prevent soil pollution is to use biodegradable oils. Much has been written on the performance of such oils, as well as on their real environmental compatibility – but nobody doubts that they are less harmful than mineral oils and perform almost as well. Their main drawback is a higher price and the fact that they occasionally cause allergic reactions in sensitive individuals.

Of course, 'environmentally friendly' technology is not the only way to reduce environmental impact. Operator training is crucial to low-impact silviculture, as well as to work safety and to the social promotion of forest labor. A number of studies have shown that the level of residual tree damage largely depends on operator skill and that this can be improved by appropriate training.

The availability of infrastructure is another requisite for effective, low-impact thinning. The case of mountain forests is typical (**Figure 11**). While experts highlight the environmental advantages of cable yarders, the lack of a suitable landing space often prevents the use of such equipment. In fact, the problem is general: fast technological progress implies that one often deals with obsolete infrastructures that need upgrading. Of course, such upgrading must follow appropriate rules to avoid generating more impact than the new technologies will avoid.

Concluding Remarks

Thinning has become one of the main preoccupations of forest managers, especially when artificially created forests are concerned. One assumes that the development of seminatural stands needs a certain amount of tending, which translates into a more or less intense thinning program. As thinning becomes increasingly expensive to implement, foresters worry about their ability to apply appropriate silviculture to their stands.

Any decisions about thinning revolve around three main considerations: (1) the cultural need for a thinning; (2) the economical performance of the operation; and (3) the possibility to mitigate its impact. Once the decision is taken, the logging manager will have to struggle against the low value of the harvest, the impact of limited stem size on machine productivity, and the constraints of restricted work space. Under these conditions the manager will try to make some profit or at least minimize losses.

A number of strategies are available to this end, in particular, selecting the most appropriate working method, employing the right equipment, and manipulating thinning design. The same strategies must be followed to keep the environmental impact within acceptable limits and make the operation a success.

Roading and Transport Operations

A E Akay, Kahramanmaras Sutcu Imam University, Kahramanmaras, Turkey
J Sessions, Oregon State University, Corvallis, OR, USA

Introduction

Forest roads connect forested lands to primary roads to provide access for timber extraction and management, fish and wildlife habitat improvement, fire control, and recreational activities. Road location and design is a complex engineering problem involving economic and environmental requirements. Due to low traffic volumes, construction and maintenance costs are the largest components in the total cost of forest harvesting operations. Inadequate road construction and poor road maintenance have potential to cause more environmental damage than any other operation associated with forest management. Thus, forest roads must be located, designed, and constructed in such a way as to minimize construction and maintenance costs, satisfy geometric design specifications, and control environmental impacts.

Route Location

Road location is a cost optimization problem. The road location should achieve minimum total road cost, while protecting soil, water resources, and wildlife. The alignment should provide driver safety, reduce visual impacts, and improve the recreation potential of the forest. The systematic road location process consists of four phases: (1) office planning, (2) field reconnaissance, (3) selection of the final alignment, and (4) locating the alignment on the ground.

Office Planning

The first step involves study of the terrain using available data including topographical maps, air photo, orthophotos, digital elevation model (DEM), and soil and hydrologic reports. The designer studies the essential features of the land identifying the difficult places, such as swamps, rocky places, and steep or unstable slopes. The advantageous parts of the terrain, stream crossings suitable for bridges, saddles on ridges, suitable sites for curves, and gentle slopes, are also noted. If a logging plan is involved, the designer marks the suitable sites for log landings.

The road location must be economical for construction and feasible for hauling logs. The road should efficiently connect the main road to the secondary branches. At the end of this phase, the designer determines alternate feasible road corridors to be examined in the field reconnaissance. Office planning is the least expensive, yet the most important decisions of road design are made during this phase.

Field Reconnaissance

Each essential feature of the terrain (difficult and advantageous places) is examined in a detailed reconnaissance. To provide feedback for the earthwork operation, the designer should examine the terrain for limits of seasonal swamps, loose ground, rocky areas, and potential construction material. This phase is best done during the rainy season so that soil characteristics and the limits of wet places can be observed.

It is more convenient to start the fieldwork from the highest point of the road section to see the terrain easily by looking toward the bottom of the slope. In field reconnaissance, it is necessary to use appropriate survey instruments. At the end of field reconnaissance, one particular corridor is selected as the best corridor based on gradient, haul distance, ground condition, sources of road-building material, and stream crossing obstacles.

Selection of the Final Alignment

Following selection of the best corridor, the next step is to locate the final alignment. The party chief considers a number of strategies:

- On uniform terrain, building the road on a ridge minimizes the earthwork, provides good drainage, and reduces the number of culverts.
- On a side hill, keeping a constant gradient provides a balanced cut and fill section. If the side hill is steep, a full bench cross-section can be used to avoid overloading the slope below the road.
- In a valley, the route should be kept as low as possible, but above the floodplain. Proper choice of stream crossings and stream crossing angle minimizes bridge length.
- Cut bank heights should be kept low, because excessive earthwork increases construction and maintenance costs, increases potential for landslides, and requires special construction for drainage.

Laying Out the Alignment on the Ground

On uniform terrain the final location line is marked on the ground by centerline stakes with 15–20-m intervals. The road edges should be calculated on both sides from the centerline. On difficult and irregular terrain, the centerline and excavation and embankment limits should also be marked. The method for identifying the centerline and limits on a straight alignment varies with the method used for a horizontal curve.

On uniform terrain, a straight alignment is generally laid out by eye, using posts in three at a time. On uneven terrain, the grade line is carried forward in a series of incremental steps to preserve the gradient. The methods used for laying out a horizontal curve are aided using design tables. Several methods are used. The deflection angle method is described here. First, the deflection angle is defined, depending on the specified radius and a chord length (**Table 1**). Then, points on the curve are identified by turning chord deflections and pacing the chord distance (**Figure 1**). Several trials are generated from different starting points on the tangent, when a curve point of intersections is inaccessible.

Cost Control in Forest Road Design

The total cost of a road section consists of the construction cost, maintenance cost, and transportation cost.

Construction and Maintenance Costs

Road construction and maintenance costs are generally calculated using the 'engineer's' method. In this method, quantities of required material used are estimated and then multiplied by the unit costs for the items (i.e., cost per meter, square meter, or cubic meter). The road construction cost is the total cost of the road construction activities: construction staking, clearing and grubbing, earthwork, drainage, surfacing, and seeding and mulching. The maintenance activities involve rock replacement, grading, culvert and ditch maintenance, and brush clearing. Detailed information regarding formulae and tables to calculate the costs of these activities can be obtained from the references given in the Further Reading section.

Transportation Costs

Transportation costs depend upon the traffic, cost of vehicle operation, and vehicle speed. Traffic volumes should consider the immediate and longer-term road use. Vehicle speed is a function of road width, alignment, gradient, surface type, and traffic volume.

Selection of Most Economical Road Standard

Forest road design involves simultaneous consideration of and trade-offs between construction costs, road maintenance, vehicle performance, and environmental effects. The trade-offs are not always obvious and vary depending upon local availability of construction materials, road standards, and topography. Based on these factors, the designer should be able to select the best road standard. It is important to know as much as possible about the future performance of a selected road standard so that adequate roads can be designed and built at minimum expense. If forest roads are planned for use during spring thaw conditions, road designers should take extra care in constructing the roads to reduce the road deformation.

Geometric Design Specifications

In order to ensure driver safety, smooth traffic, and efficient and economic movement of the trucks, the road alignment must satisfy certain geometric design specifications. The main elements of geometric design specifications are stopping sight distance, middle ordinate distance, vehicle off-tracking requirements, road gradient, horizontal curves, and vertical curves.

Stopping Sight Distance

The objective in determining the stopping sight distance (SSD) is to provide a sufficient sight distance for the drivers to safely stop their vehicles before reaching objects obstructing their forward motion. The SSD (in meters) for two-lane roads is computed in eqn [1]:

$$\mathrm{SSD} = \frac{V^2}{254(f \pm g)} + 0.278 V t_r \qquad (1)$$

where V is the design speed (km h^{-1}), t_r is perception/reaction time of the driver in seconds (generally 2.5 s), f is the coefficient of vehicle braking friction, and g is the road grade in decimal percent. On two-directional one-lane roads, the SSD is approximately twice the stopping distance for a two-lane road.

Middle Ordinate Distance

The middle ordinate distance must be visually clear, so that the available SSD is sufficient for the driver's line of sight (**Figure 2**). Experience has shown that a driver should be able to see from an eye height of 1070 mm and stop before hitting an object of 150 mm height at the mid-ordinate. On forest roads, 600 mm of object height at the middle ordinate point is generally used. Middle ordinate distance in meters is computed as follows:

$$M = R\left[1 - \cos\left(28.6\,\frac{\mathrm{SSD}}{R}\right)\right] \qquad (2)$$

where R is the radius of horizontal curve (in meters). It is a straightforward task to compute M, once the R and SSD have been determined.

Off-tracking

When traveling around the horizontal curve, the rear wheels of the vehicles do not track in the same path as the front wheels, which is called off-tracking. To accommodate the off-tracking of the rear wheels,

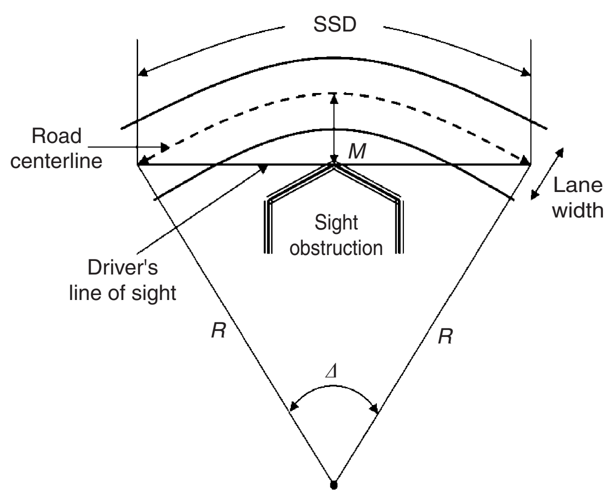

Figure 2 Middle ordinate distance (M) around a horizontal curve. SSD, stopping sight distance; R, radius; Δ, central angle of curve.

extra road width is required on the inside of the curve (**Figure 3**). The required curve widening depends on various factors such as vehicle dimensions, curve radius, and the central angle of the curve (Δ). To predict off-tracking (OT), an empirical method, providing the designers with quick, easy, and relatively accurate results, is generally employed.

$$\mathrm{OT} = (R - \sqrt{R^2 - L^2})[1 - e^{(-0.015\Delta\frac{R}{L}+0.216)}] \quad (3)$$

where L is computed for a stinger-steered trailer as:

$$L = \sqrt{L_1^2 - L_2^2 + L_3^2} \quad (4)$$

where L_1 is wheelbase of the tractor, L_2 is the length of the stinger measured from the middle of the tractor rear duals to the end of the stinger, and L_3 is bunk-to-bunk distance minus the length of the stinger. For a low boy or conventional trailer:

$$L = \sqrt{L_1^2 + L_2^2 + L_3^2} \quad (5)$$

where L_1 is wheelbase of the tractor, L_2 is the distance from the fifth wheel to the middle of the rear duals for the first trailer, and L_3 is the distance from the fifth wheel to the middle of the rear duals for the second trailer.

Road Gradient

Road gradient (%) is calculated in units of vertical rise divided by the horizontal distance. The minimum road gradient is limited by the minimum acceptable road grade to provide proper drainage. Having minimum 1–2% longitudinal gradient along the road section helps avoiding the ponding of water on the surface. The maximum road gradient is determined based on the design vehicle. A list of recommended truck gradients for low light trucks is shown in **Table 2**. Since trucks lose speed rapidly when climbing a grade, and ultimately reach an equilibrium speed, the vehicle performance should be taken into account to minimize overall transportation cost. In current vehicle performance models, the road alignment and surface type are taken as inputs, and alignment-specific results (ground speed, engine speed, gear shifting requirements, fuel consumption, and roundtrip time) are determined. Detailed information on these models can be obtained from the references in the Further Reading section.

Horizontal Curves

On low-volume forest roads, a circular horizontal curve is generally used to provide a transition between two tangents (**Figure 4**). To design a feasible horizontal curve, the designer considers the minimum curve radius, acceptable road grade on the horizontal curve, and minimum safe stopping distance.

Having high centers of gravity and narrow track width (the distance between the outside faces of the wheels at opposite ends of an axle), logging trucks may overturn due to an inadequate radius. Design

speed, lateral acceleration, and vehicle weight must be considered (**Table 3**).

The maximum gradient permitted on the horizontal curve should be kept lower than that on a tangent because: (1) off-tracking of the vehicle creates a higher 'effective' grade for both the truck and the trailer, (2) the truck incurs additional forces required to turn the tandem axles around the curve, and (3) the powered wheels may have unbalanced normal loads due to a combination of centrifugal force, super elevation, and angle of the trailer. The effects of these factors are increased as the radius decreases.

The safe stopping distance is computed using eqn [1] in which the limiting speed of the vehicle around the horizontal curve, V (in km h^{-1}), can be formulated considering vehicle weight, side friction force, centrifugal force, curve radius, side friction coefficient, and super elevation.

$$V = 11.27\sqrt{R(f_s + e)} \quad (6)$$

where f_s is the coefficient of side friction, R is the radius of horizontal curve in meters, and e (%) is the super elevation of the horizontal curve if it exists.

Vertical Curves

Forest road engineers customarily use parabolic vertical curves (**Figure 5**) with a constant rate of change of gradient, because: (1) they result in alignments comfortable to drive, (2) they are easy to lay out, and (3) the SSD is constant along the curve. The vertical curves should have a sufficient curve length to permit a log truck to pass a curve without bottoming out in the sag or breeching the crest and provides SSD.

In determining a feasible curve length, crest and sag vertical curves are considered separately based on the assumption that whether the curve length is greater or less than the SSD. Equations [7] and [8] indicate the formulation for length of the crest vertical curve in meters. If SSD is greater than the curve length (**Figure 6**):

$$Lv = 2SSD - \frac{200(\sqrt{h_1} + \sqrt{h_2})^2}{A^2} \quad (7)$$

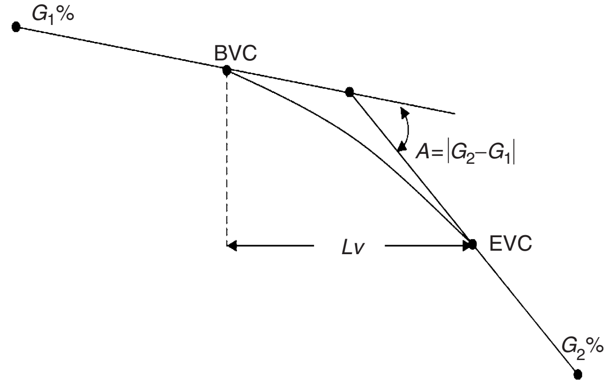

Figure 5 Geometry of a crest vertical curve (symmetrical). BVC, beginning point of the curve; EVC, ending point of the curve; Lv, curve length; G_1, initial tangent grade; G_2, final tangent grade; A, absolute difference between grades.

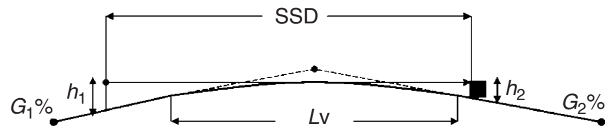

Figure 6 Stopping sight distance (SSD) is greater than the length of a vertical curve. G_1, initial tangent grade; G_2, final tangent grade; Lv, curve length; h_1, distance from road surface to level of driver's eye; h_2, height of object on road.

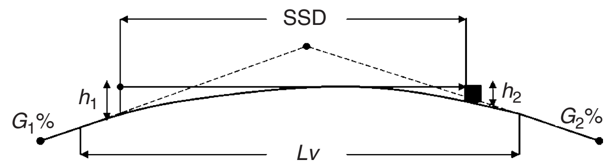

Figure 7 Stopping sight distance (SSD) is less than the length of a vertical curve. G_1, initial tangent grade; G_2, final tangent grade; Lv, curve length; h_1, distance from road surface to level of driver's eye; h_2, height of object on road.

where h_1 is the distance from road surface to level of the driver's eye, h_2 is the height of the object on road, and A is absolute value of the difference between gradients. If SSD is less than the curve length (**Figure 7**):

$$Lv = \frac{SSD^2 A}{200(\sqrt{h_1} + \sqrt{h_2})^2} \quad (8)$$

The length of a sag curve, for a required SSD, is formulated in eqns [9] and [10]. If SSD is greater than the curve length:

$$Lv = 2SSD - \frac{200(h_3 + SSD \tan \alpha)}{A} \quad (9)$$

where h_3 is the distance from road surface to level of the vehicle headlights and α is angle of the headlight beam above axis of the vehicle. If SSD is less than the curve length:

$$Lv = \frac{SSD^2 A}{200(h_3 + SSD \tan \alpha)} \qquad (10)$$

Forest Road Construction

Clearing and Grubbing

The road centerline, the cut and fill limits, and the clearing limit should be marked on the ground prior to clearing. The clearing limit is the width that the trees, stumps, and organic debris are to be cleared across the future roadway. The terminology of a forest road on a cut and fill type cross-section, which generally applies to most road types, is indicated in **Figure 8**.

The methods used for the clearing and grubbing should be consistent with good safety and environmental practices while keeping construction costs to a minimum. The hazardous snags and unsafe trees adjacent to the clearing limit should be felled and removed from within the road prism. Merchantable timber should be piled on the decking areas so as to not interfere with the construction of the road or turnouts. Unmerchantable material and stumps should be disposed of with care to prevent any hazard during the logging operation.

Earthwork

On gentle terrain, the bulldozer proceeds from both sides of the road to construct an embankment that will keep the road structure dry. In difficult terrain hydraulic excavators combined with advanced drilling and blasting technology are the best solutions both environmentally and economically. The features of the hydraulic excavator and advanced drilling and blasting technique in road construction are:

- The excavator operates by digging, swinging, and dumping of excavation.
- The excavator works from the fixed position and does not require additional road width for maneuvering.
- Using buckets and attachments increases the excavator's versatility to do ripping, trenching, loading, compacting, and hydraulic hammering.
- The high breakout force of the excavator reduces the need for blasting.
- The hydraulic drilling units attached to the excavator optimize blasting by performing vertical as well as horizontal drilling.
- Soft blasting techniques avoid loosening of fractured rock, and control the rock size.

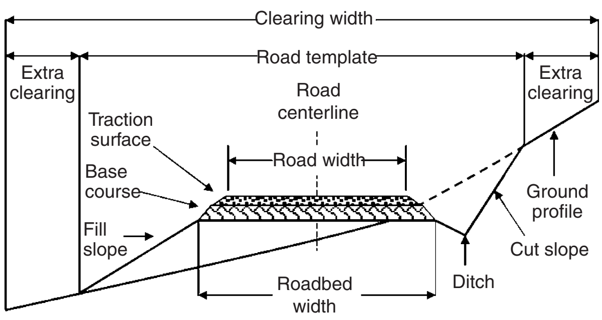

Figure 8 Road elements on the cross-section.

Building the desired cut and fill slope steepness is critical during the earthwork operation. If the operator constructs a steeper cut slope, this will require further excavation, increase construction cost, and may cause slope failure. Therefore, road cut and fill banks should be constructed to the slope angles that minimize slope failure and erosion. Cut and fill slopes are constructed depending on the available soil and rock types (**Table 4**).

Embankments are commonly used on stream drainages, swamps, flat ground, and are used as waste areas. The common methods used for embankment are: (1) end haul dumping where cut material is hauled to a fill area, and (2) side casting where cut material is pushed from a road cut to a close fill location. In both methods, material should be layer-placed and compacted to minimize future maintenance, soil erosion, and road failure. On deep fills and roads with heavy traffic, a mechanical roller can be used for effective compaction.

The economic distribution of cut and fill quantities in forest roads is traditionally determined using the mass diagram method. However, its capability is limited where soil characteristics vary along the roadway. To overcome the limitation of the mass diagram, linear programming has been used to plan the movement of earthwork during road construction.

Surfacing

Native-soil surfacing can be used when harvest operations are conducted during the dry season. However, road operations in the wet season require aggregate surfacing (crushed rock) to increase the strength of the

Table 4 Cut and fill slope types for various soil and rock types

Soil type	*Cut*	*Fill*
Common soil	1 : 1	1.5 : 1
Clayey soil	2 : 1–3 : 1	Not used
Solid rock	0.5 : 1	Not used
Fractured rock	0.75 : 1	1.25 : 1

forest road surface to support vehicle traffic (**Figure 8**). Aggregate surfacing also provides increased wheel traction and relatively smooth traveling surface that reduces the subsequent road maintenance, and extends the life of the subgrade by reducing road surface ruts and erosion. The rock size and the depth of the aggregate surfacing are determined based on the type of the subgrade soil along the roadway, road gradient, traffic density, season of road use, availability of the aggregate, and cost. A traction surface can be placed over the base rock to increase traction and to provide a smooth durable traveling surface.

The hardness, durability, wearability, and shape of the aggregate affect the quality of the road surfacing. The surfacing rock should be tested in the field in terms of its hardness, shape, and durability. If there is doubt regarding its compatibility, it should be directed to laboratory tests. The Los Angeles Abrasion Test is one of the standard laboratory tests that is used to examine the wearability of the rock.

On wet ground or soils that do not compact well, geotextile material is added on top of the subgrade to provide additional strength to the subgrade, keep soil moisture from surfacing, and prevent intermixing of soil and surface aggregate layer (**Figure 9**). This also reduces the depth of surface rock. The road engineer should determine the trade-off in terms of cost and effectiveness between reducing the rock depth and extra cost of laying down the geotextile. The best practice for using geotextiles involves:

- Spreading out the geotextile in short stages to allow rock placement to follow closely.
- Securing the top of the geotextile to avoid slippage.
- Placing the geotextile free of tears and wrinkles and join the rolls with overlapped joints.

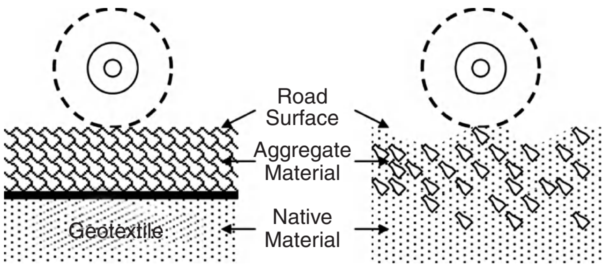

Figure 9 Geotextile material provides support and separation.

Drainage

When constructing a road, the road surface must be sloped to eliminate the tendency of surface runoff water to break up the road under heavy loads. There are three basic types of roadway templates (**Figure 10**):

- Crowned: half of the water is carried to the ditch and half to the outside shoulder.
- Insloped: water is carried to the ditch and ditch relief pipe culverts to the streams.
- Outsloped: road surface sheds runoff to the outside.

Ditched roads (crowned and insloped) require more excavation cost for the ditch and additional cost for relief culverts. Ditch water runoff should be intercepted periodically by relief culverts to carry roadway runoff from the ditch, transport it beneath the road, and discharge the water from the road (**Figure 11**). A catch basin is built in the ditch to channel the water from the ditch to the culvert inlet. Plastic relief culvert is widely used in forest roads because one person can handle plastic culvert installation and it is easy to cut to length for fabrication. The determination of culvert size depends on conditions of the precipitation, topography, soil, and vegetation types. Smaller diameter culverts

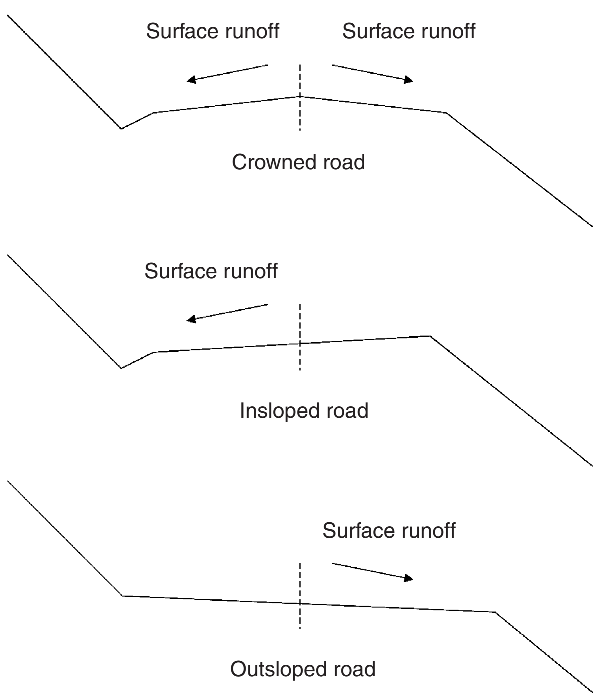

Figure 10 Ditched and outsloped roadway templates.

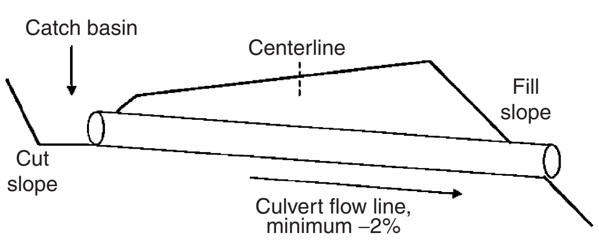

Figure 11 Geometry of a ditch relief culvert.

are inexpensive and easy to install. However, they are difficult to clean out and carry less water. Culvert spacing is generally determined based on its location on the hill, local rainfall intensity, soil erosion classes, road grade, and culvert size. Open-top culverts are also effective in controlling surface water. They offer land managers an alternative to crowning and ditching roadbeds for water control. The cost is comparable to that of a gravel broad-based dip. Installation of the culvert can be done manually or with the use of a small dozer. Open-top culverts must be cleaned regularly to remove sediment, gravel, and logging debris to allow normal function of structure.

Outsloped roads have reduced construction and maintenance costs and lessened environmental impacts due to their type of drainage. They also yield less erosion than a ditched road on the same location. Outsloped roads are not ideal for every condition. On wet or frozen surfaces, trucks slide to the outside of the roadway on steep grades. This lowers vehicle speed and in some conditions is unsafe. To enhance the effectiveness of outsloped roads, drain dips and water bars are used. Drain dips should be built considering adequate truck passage and road grade (2–8%). On road grades greater that 8%, water bars are often constructed to catch runoff water.

Seeding and Mulching

Bare cut and fill slopes, resulting from road construction on sloping terrain, increase soil erosion and stream sedimentation. Seeding and mulching can provide quick stabilization and enhance the beauty of the area. The best time for seeding is usually spring or autumn, but results will depend on local weather conditions. The seed mixture should be easy to plant, readily available, and adaptable to soil conditions (drainage, soil depth, aspect, drought tolerance, and climate conditions).

The use of mulch is considered to prevent erosion, keep seed on steeper slopes, reduce seedling mortality, and preserve soil moisture. Straw is the most commonly used mulch material. To increase the effectiveness of mulch, straw can be used in combination with other bank erosion control measures.

Forest Road Maintenance

Road maintenance protects the road investment, provides for safe and reliable vehicle operation, and controls environmental impacts. Road maintenance generally consists of road surface maintenance, roadway drainage maintenance, and ditch and culverts maintenance. Removing brush from both cut and upper fill slopes is also considered to maintain visibility.

Road Surface Maintenance

The forest road surface deforms under vehicle wheel loads and develops ruts over time if the subgrade is not constructed adequately. If the wheel load is excessive for the existing road surface conditions, shear failure occurs. Failure can also occur where the subgrade becomes saturated from standing water and the wheel load on this saturated subgrade causes damage. Ditches should be kept free of obstruction and ruts should be removed to avoid this type of damage. The forward and downward motion of wheels on the surface causes a corrugation called washboarding. To correct this, the surface rock should be reshaped to restore the camber of the road.

To decrease the road construction and maintenance costs, variable tire inflation technology is increasingly being considered for low speed operation. Central tire inflation (CTI) systems enable the driver to change and monitor the vehicle's individual tire pressures while driving. As tire pressure decreases, the tire footprint increases, primarily in the longitudinal direction. This reduces the stress applied to the road surface through a greater contact area and lower dynamic loads. Traction capability, related to tire contact length is also increased. Test studies have shown that reduction in stress reduces surface maintenance, sediment production, tire damage, and improves vehicle mobility, the ride quality, and traction on snow, ice, and loose sand.

Roadway Drainage Maintenance

Maintenance of the drainage system is also one of the key factors to preserve structural integrity and travel quality. Poor drainage can cause deterioration and weaken the road structure. To prevent this, rain and snowmelt must be quickly removed from the road surface before moisture soaks through the surface into the subgrade.

Ditch and Culvert Maintenance

Culvert maintenance involves removing debris, leaves, mud, and gravel from the culvert, the inlet, the outlet, and the catch basin. Plugged culverts cause significant ditch and roadbed erosion into the subgrade. To prevent catastrophic damage on the road, inspection and hand cleaning of culverts should be done during wet weather. Ditches should be kept free of obstructions with a shovel, a backhoe, motor grader, or loader. To stabilize the soil in ditches and to reduce the force of water, the ditch can be armored with rock, grass can be grown in the ditch bottom, and culverts should be installed at more frequent intervals.

Crossings Wetlands and Streams

Some of the planning and design considerations on wetland and stream crossings are:

- Limit the number, length and width of roads and skid trails.
- Locate roads outside riparian management zones except at stream crossings.
- Road fill must be bridged, culverted, or otherwise designed to prevent restriction of expected flood flows.
- Properly maintain road fill during and after road construction to prevent erosion.
- Correctly design, construct and maintain wetland road crossings to avoid disrupting the migration or movement of fish and other aquatic life.

Wetland Crossings

Wetland crossing methods include wood mats, wood panels, wood pallets, expanded metal grating, plastic roads, corduroy, and wood aggregate. Geotextiles can be also used to solve drainage problems in wetlands. Wood mats are individual cants or logs cabled together to make a single-layer crossing. Wood panels are constructed by nailing parallel wood planks to several perpendicular wood planks where the vehicle's tires will pass. Wood pallets are three-layered pallets similar to those used for shipping and storage, specifically designed to support traffic. They are easy to install, replace, and interconnect. Machine weight can be distributed over a broader area by placing a metal grating on top of a geotextile.

The grating is relatively light, inexpensive, and also it provides sufficient traction. Plastic roads, made of PVC and HDPE pipe mats, are portable, reusable, and provide lightweight corduroy type crossing. Using pipes generate a conduit for water to move through the crossing without further wetting the area. One method of building temporary roads across wetlands is the use of corduroy where brush and small logs are laid perpendicular or parallel to direction of travel. Nonwoven geotextile is recommended to separate the brush, logs, or mill slabs from the underlying soil. Wood aggregate (wood particles ranging in size from chips to chunks) can also be used as a fill material for crossing soft soils. Important advantages of using wood particles are they are relatively light and biodegradable. Geotextiles are used to provide subgrade restraint over areas of low bearing pressure. They are occasionally placed over buried corduroy to cross wet holes.

Stream Crossings

When the streams are shallow, inexpensive stream crossings can be constructed using drifts or fords (**Figure 12**). On shallow sandy rivers, stone-surfaced drifts are used when the fall is gentle. A higher-elevated concrete drift is used when the water flow is strong. Culvert drifts are also built in small rivers with heavy currents.

Open-bottom structures such as open-bottom arches and box culverts are also used for stream

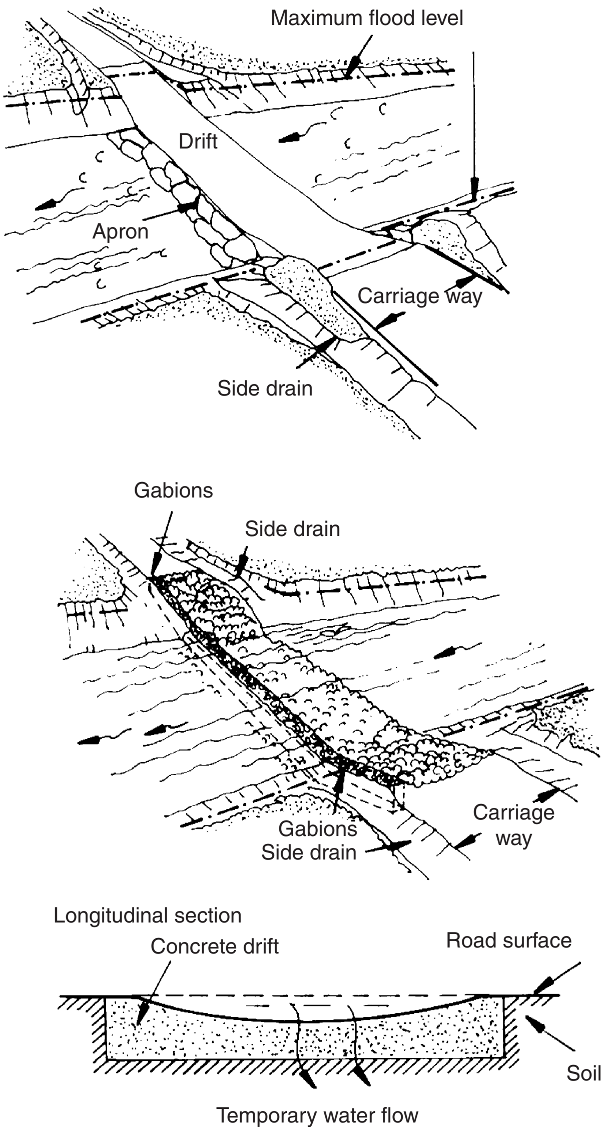

Figure 12 Examples of drifts. Reproduced with permission from Kantola M and Harstella P (1986) *Forest Harvesting Handbook on Appropriate Technology for Forest Operations in Developing Countries*. FTP Publication 19(2) pp. 79–81, National Board of Vocation Education of Finland.

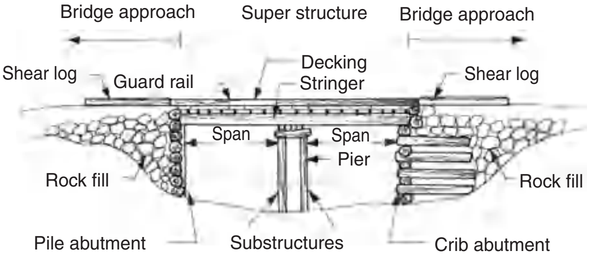

Figure 14 Log stringer bridge. Reproduced with permission from Kantola M and Harstella P (1986) *Forest Harvesting Handbook on Appropriate Technology for Forest Operations in Developing Countries*. FTP Publication 19(2) pp. 79–81, National Board of Vocation Education of Finland.

crossings. Their footings are installed on bedrock to prevent scouring (**Figure 13**). If they installed on an erodible foundation, the entire area should be ripraped between the footings. The size of the riprap material depends on water depth and flow velocity. Open-bottom culverts provide more natural conditions for fish passage than culverts.

Bridges must be built for deeper crossings. Construction cost of the bridges is high because they should be elevated sufficiently above maximum flood level, and be strong enough to carry the heavy traffic. When crossing a stream is inevitable, selecting the right structure is critical to ensure suitable and cost effective crossing, and minimum pollution of the stream.

Permanent bridges The most common type of permanent bridge is the stringer bridge where a deck is placed on top of the stringers to support the vehicle loads. Stringers can be logs, sawn timbers, and steel beams. Decking is placed perpendicular to the stringers and can consist of sawn lumber planks, timber deck panels, or concrete panels. Basic components of a log stringer bridge are indicated in **Figure 14**. The size of the stringer depends on the unsupported length of the span and loading. Stringers should be debarked, mortised, and anchored by wooden poles in the ground. The deck logs should be placed on the stringers perpendicularly, transversely, or diagonally.

Portable bridges When permanent access to a site is not needed, portable bridges are used and then removed after operations are finished. They have been used in military applications for many years, but use in forestry applications is more recent. In the past, the lower cost approaches to temporary stream crossings (log crossings, fords, and culverts) were used over portable bridges due to high initial cost of the bridges. However, these low-cost approaches frequently involve the use of large amount of fill in the stream crossing and may result in excessive erosion and sedimentation of the stream. Portable bridges cause less impact on water quality. Portable bridges can be made of steel or concrete panels and timber mats. A relatively new type of engineered design is the glulam bridge that can be moved from site to site relatively quickly and easily. To simplify the installation, the glulam panels are not connected to each other instead; they are set in place on site. Abutments to support the bridge ends are not required since the panels can be placed on a mud sill. The use of a portable bridge has been shown to be an environmentally sensitive method since it minimizes site disturbance and sedimentation in the stream.

Environmental Considerations

There are a number of actions that can be done during road construction and maintenance to protect the environment. Some of them are listed below:

- Earthwork operations should be scheduled for dry seasons.
- Steep grades should be avoided through soils that erode easily.
- Ditches and culverts should be constructed properly.
- Stream crossings should be located where minimum soil disturbance may occur.
- Stream crossing angles should be close to perpendicular.
- Seeding should be applied on cut banks and fill slopes to reduce erosion.
- Bridges and culverts should be constructed to handle the maximum water flow, and they should allow appropriate fish passage.
- Aggregate should be replaced to preserve structural integrity of the road.

- Grading and other maintenance activities, cleaning culverts and cleaning ditches, should be performed regularly.
- Excessive sediment delivered to streams has a dramatic effect on water quality and aquatic life; therefore, roads must be designed to minimize sediment production.
- The road segments with a high potential for delivering sediment can be identified using sediment prediction models.

Wood Delivery

P M O Owende, Institute of Technology Blanchardstown, Dublin, Ireland

Introduction

Cost-efficient forest harvesting operations are key to economic timber production and overall competitiveness of the global wood production sector. Consequently, efforts have been made towards the enhancement of operational efficiency through:

1. Rationalization of forest harvesting techniques and work methods, including stand establishment, harvesting operations, wood delivery, ergonomic concerns, automation of machine functions, and the control of environmental impacts.
2. Improved wood supply logistics, including supply chain and information chain management, and harvesting and transport planning.
3. Maximization of raw material utilization including log value optimization, and use of unmerchantable material and forest residues as alternative fuel sources.
4. Development of the forest industry through customer focused production, quality control in the delivered wood, and work safety.

The efforts outlined above are aimed at the optimization of forest production on a sustainable basis. The rationalization of forest harvesting techniques and improvement of wood supply logistics can be implemented relatively quickly (i.e., over a short time span), hence wood delivery is a crucial issue in optimization of the entire wood supply chain. Wood delivery in the context of this article refers to the chain of operations related to the extraction and transport of different categories of timber and by-products of forest harvesting, including wood chips and forest residue materials that are used for energy. The forest residue is transported as compacted residue or slash logs.

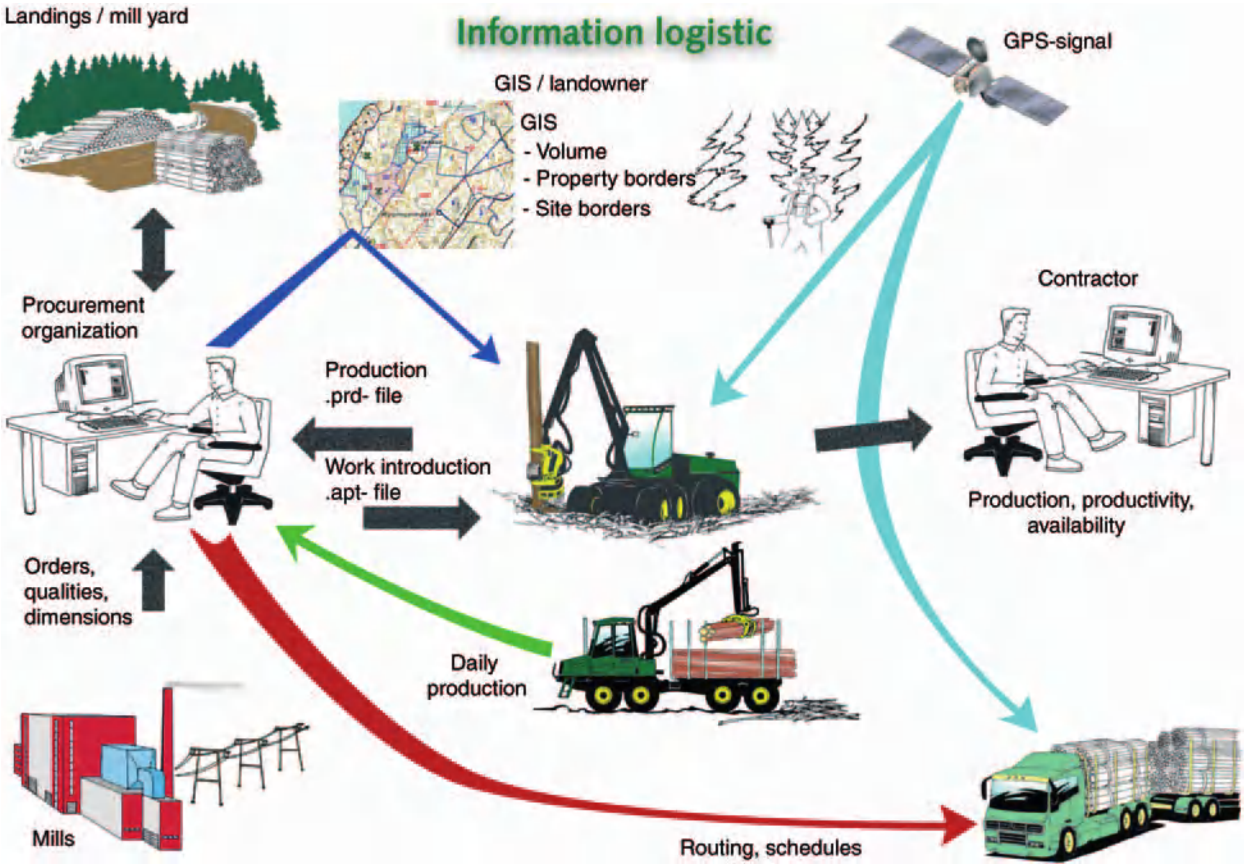

Figure 1 Spatial and production information flow/exchange in the logistics of wood delivery. Adapted with permission from Timberjack OY, Finland.

Mechanized wood harvesting systems consist of multiple operations (**Figure 1**), with a range of complex interactions. The overall efficiency of the operations may be optimized by integrating the individual operations for enhanced efficiency in wood production.

The salient requirements of the wood delivery logistics include:

- constant update of harvest plans
- real-time monitoring of production, machine productivity and availability assessments
- location of harvested material and delivery vehicles, delivery routing, and delivery schedules
- logical optimization techniques for individual processes, e.g., route optimization to minimize transportation cost.

For the illustrated linkages, it may be argued that there is need for a shared database for the different procurement organizations with common wood material sources, to allow for the exchange of raw material on the basis of dynamic production schedules.

Harvesting and Extraction

Harvesting systems are of primary importance in wood delivery for the following reasons:

1. Harvesting methods determine the mode of subsequent wood delivery systems used.
2. There is increasing emphasis on the use of combined harvesting and extraction systems to minimize soil disturbance and damage, e.g., the use of combined harvesting and extraction machines (see below).
3. Methods that are aimed at improving the cost-effectiveness of the wood supply chain, e.g., the delivery of forest residue (energy bundles) and wood chips are currently being redesigned to utilize the standard transportation vehicles used for wood delivery.

Harvesting Systems

Figures 2 through **6** show the five general classes of wood harvesting systems. The processes range from semimechanized to fully mechanized systems, and may be used in part, in whole, or in different suitable

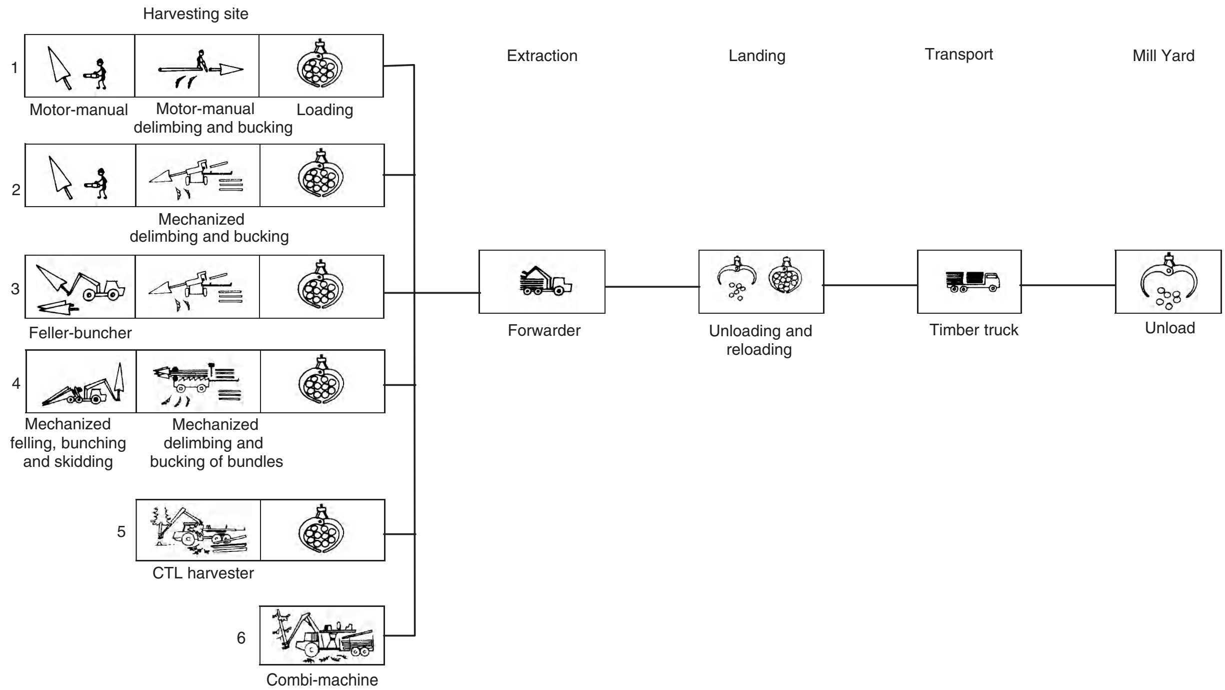

Figure 2 Cut-to-length (CTL) or assortment method of wood harvesting. Adapted with permission from Staaf KAG and Wiksten NA (1984) *Tree Harvesting Techniques*. Kluwer Academic Publishers, Dordrecht, The Netherlands: Martinus Nijhoff.

combinations (and sequence after tree felling) depending on the prevailing economic and socio-economic circumstances.

In the cut-to-length (CTL) or assortment system (**Figure 2**), the delimbing and bucking processes are carried out at the stump, and logs are forwarded over short distances to landings. This method is suitable where mills are far from the harvesting site. The system may be semimechanized, i.e., may use manual felling with chainsaws (also termed motor-manual), and manual delimbing, and bunching, or wholly mechanized with a CTL harvester for felling, delimbing, and bucking in a single operation. The full-pole system (**Figure 3**) may also be semimechanized (chainsaw felling, delimbing, and topping followed by skidding of stems) or fully mechanized (feller-buncher, skidder for in-forest transport, and processing with a stroke-delimber). In this system, the entire delimbed trunks or bucked logs are transported to mills.

In the whole-tree system (also called tree method), the un-delimbed trees are extracted for processing at landings (**Figure 4**). The concept is based on mass handling of tree stems, which compensates for the small tree sizes and enables cost-effective harvesting of coppice stands. Trees are bunched after felling to enhance the efficiency of subsequent handling.

Un-delimbed trees may also be separated into smaller stem sections and extracted for processing at the landings, followed by secondary transport as logs or tree parts, i.e., the tree-part system (**Figure 5**). In the chipping method (**Figure 6**), the harvested tree undergoes size-reduction into wood chips, in a process that may include debarking. The chipping may be done in the stand or after extraction of tree parts. The whole tree including the stumps may be chipped, but the presence of soil impurities makes quality control of wood chips difficult and expensive.

The full-pole and whole-tree methods are suitable for alpine, mountainous, and steep terrains, where they are typically combined with cable extraction systems. Whole-tree and tree-part methods are advantageous where the by-products of tree harvesting (limbs, tops, and sawdust) are valued for fuel. Due to the bulk nature of the material to be transported, they are deemed to be economic where harvesting sites are located in close proximity to the mills. Whereas CTL harvesting is popular in Europe, commercial whole-tree harvesting is common in North America.

Extraction Systems

Extraction refers to the phase of wood delivery in which whole trees, stems, or logs are moved to a major delivery point, either for further transport, or for secondary conversion, or both. Forwarders and skidders (**Figures 3** through **6**) are utilized in ground-based CTL and whole-tree harvesting systems, respectively. In comparison to skidders, forwarders allow for movement of larger loads, hence the density of the forest access road network may be

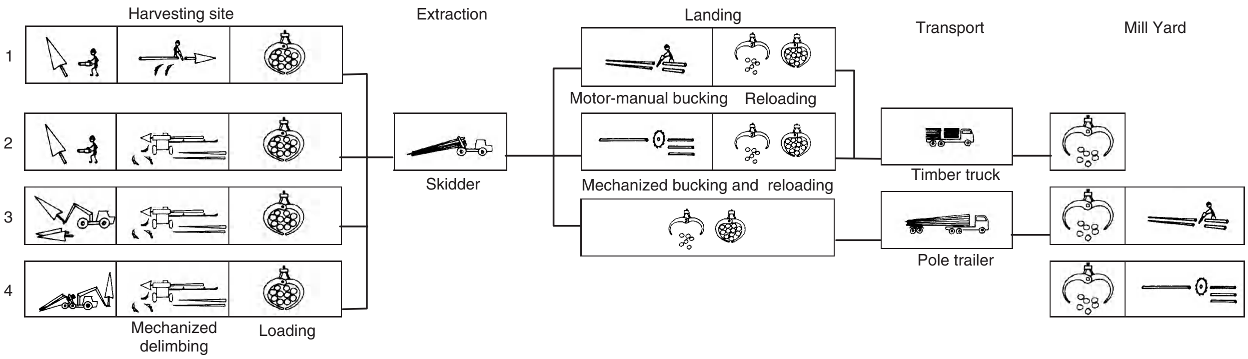

Figure 3 Full-pole method of wood harvesting. Adapted with permission from Staaf KAG and Wiksten NA (1984) *Tree Harvesting Techniques*. Kluwer Academic Publishers, Dordrecht, The Netherlands: Martinus Nijhoff.

reduced to minimize operation costs. They also cause less damage to the timber and residual tree in the harvesting of thinnings, since the logs are not dragged on the ground. Cable extraction is used in alpine conditions and on sensitive sites where there are limitations on machine flotation and mobility (*see* **Harvesting**: Forest Operations under Mountainous Conditions).

Environmental considerations in wood extraction are specifically aimed at minimizing disturbance and soil damage at the harvesting site. These include:

- soil disturbance, compaction and rutting due to machine traffic, which may impede the growth of residual trees in thinning operations, and also increase the potential for soil erosion and windthrow
- physical damage to residual trees and other vegetation on site, which may lead to loss of timber value and volume in subsequent harvests
- direct and indirect damage to streams and water pollution, e.g., introduction of spilled fuel and lubricants into streams and water sources in close proximity to the harvesting sites.

Soil disturbance and damage may be minimized by using brash, i.e., the portions of trees (stems or branches) with diameter below the minimum set for utilization (about 70 mm). Spreading of brash along the expected extraction routes during the harvesting process offers considerable support for subsequent machine traffic and can be very effective in minimizing rutting and soil damage (**Figure 7a, b**).

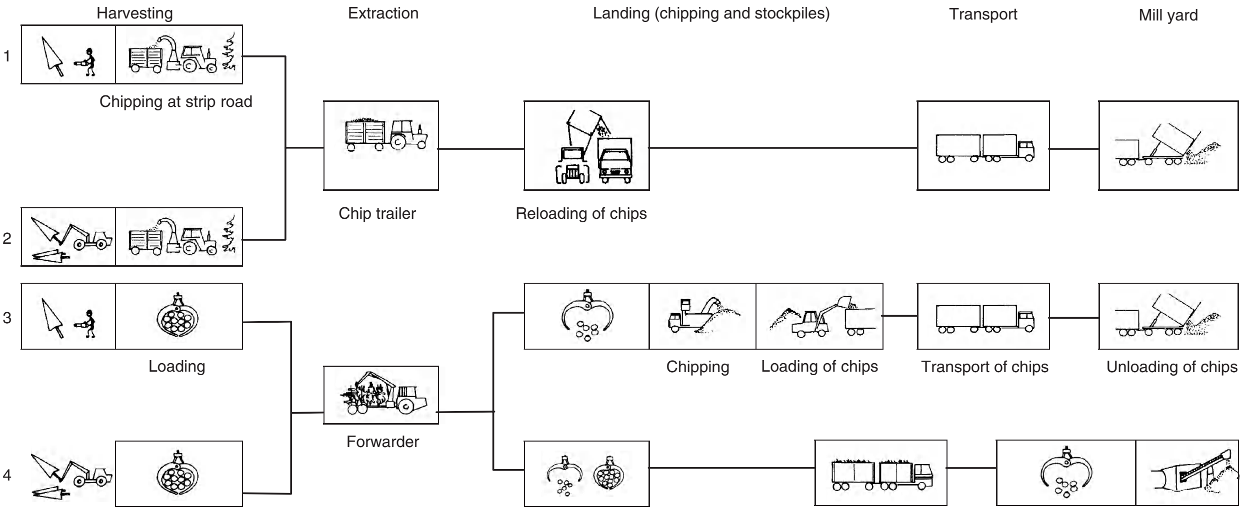

Figure 6 Processes in the chipping method of wood harvesting. Adapted with permission from Staaf KAG and Wiksten NA (1984) *Tree Harvesting Techniques*. Kluwer Academic Publishers, Dordrecht, The Netherlands: Martinus Nijhoff.

Low ground pressure machines are required for operation on soft ground such as on peat soils. Since wheeled forwarders as standard are unsuitable for the task, their nominal ground pressure may be reduced using band-tracks to enhance flotation (**Figure 7c**). When wheel slippage is limiting, wheel chains are used to enhance traction (**Figure 7d**). Alternative methods for minimizing damage on extremely sensitive harvesting sites have also been tested (**Figure 7e, f**). Site and timber quality limitations may necessitate a combined harvesting and extraction operation to limit the number of machine passes at a site (**Figure 8**). Aerial extraction using helicopters (heli-logging) or balloons (**Figure 9**) offers unique advantages for small clear-cuts (e.g., conservation sites), and may achieve specific visual impacts on difficult terrain such as wetlands and on steep slopes.

The importance of environmentally sensitive forest harvesting has a direct bearing on the efficiency of wood extraction operations. For example, in the CTL system, the forwarder is considered a higher environmental risk since the speed and size of its payload determines its productivity, whereas these also increase the risk of site damage. The need to control site disturbance and potential soil damage due to machine traffic and the enhancement of operation efficiency are the basis for terrain classification.

Terrain Classification

Terrain classification systems provide simple, uniform, and practical descriptions of site characteristics, and are primarily intended for:

- planning of wood harvesting, extraction, and silvicultural operations
- operations control, e.g., control of site damage
- evaluation and comparisons of mechanization options
- machine development and marketing plan
- harvesting contract negotiations.

The systems used in European countries (e.g., Ireland, the UK, and Scandinavia), the USA, and Canada are based on researched site descriptors, covering the three main factors that affect off-road machine mobility and performance. These are soil-bearing capacity, surface roughness, and ground slope or grade. On the basis of these factors, guidelines for suitable harvesting and extraction systems may be prescribed.

Ancillary Considerations in Harvesting and Extraction

It is recognized that even with the best planning and maintenance, main extraction routes in a harvesting site eventually degenerate through wear and tear. Some damage is also inevitable when the extraction is over long distances, and is more serious where brash supply is exhausted, or where there is a limited choice of routes. A limited flexibility in the choice of machines may also exacerbate site damage. However, since only a small proportion of the ground (about 10%) is covered by extraction machine trails, such damage may be remedied after the operation where it may be deemed necessary.

Periodic monitoring of harvesting operations should identify excessive site disturbance and damage, and allow for implementation of effective countermeasures. The following guidelines apply to harvester and forwarder routing:

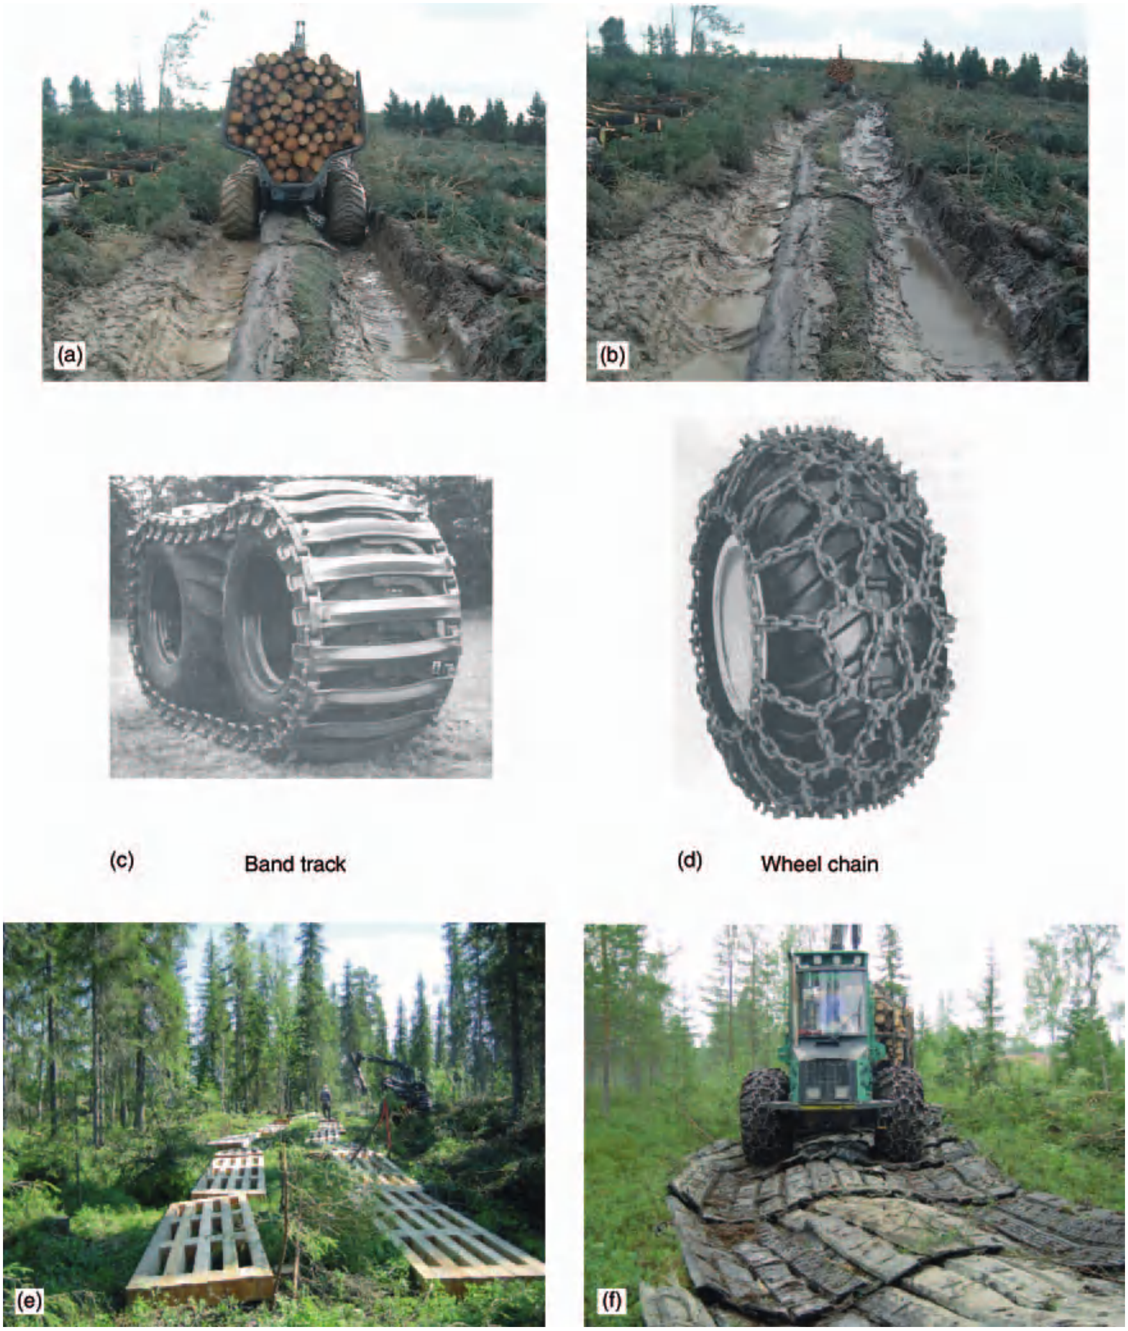

Figure 7 Illustration of (a) site damage by excessive rutting in cases of long extraction routes, and (b) laying of brash mat to minimize damage, and (c) machine band tracks and (d) wheel chains for enhancement of flotation and traction, respectively. Other possible mechanical strengthening of ground with (e) wooden platforms and (f) discarded tire mats may be applied, but the economic feasibility is a function of distance to be strengthened and volume of wood to be transported. Reproduced with permission from Forest Engineering Unit, University College Dublin; Clark Forestry Equipment UK; and Department of Forest Resource Management, University of Helsinki, respectively.

1. The use of partial forwarder payloads may be considered, but it invariably necessitates double-handling operations, and therefore increases the overall cost of extraction.
2. Adequate track reinforcement (with brash or other retrievable material), stream crossings, and embankment rolling should be provided in time and before the start of harvesting operations.
3. Sensitive sites that require the use of brash mats should be completed when the brash is still fresh and effective in the control of traffic-induced site damage. Delayed working should be avoided as it

allows the brash to dry and be degraded easily before the extraction is complete.
4. Route the extraction through corridors with adequate soil bearing capacity or with a good brash mat layer, while completely avoiding the sensitive spots or avoiding driving through them during the loaded trips.
5. Avoid uphill driving when loaded, and where possible, machine travel should be along the contours (rather than up–down) in areas that are prone to erosion.

Transportation

Profit is not realized in the production of timber and by-products until they are delivered to the mills, hence an efficient transportation system is of primary importance in forest harvesting. Transportation programs are drawn up on the basis of the source of wood, i.e., the mill's own forest, private forests, or imports. Ideally, the different options including road, rail, and waterways should be considered with respect to wood and by-product cost, and the production requirements and timetables at the mills or other delivery points. However, road transport can access remote harvesting sites, and also link the harvest sites to the rail systems and waterways, if such secondary transportation is required. **Figure 10** shows the characteristics of some of the vehicles used in road transportation of timber and wood chip.

Roads and Road Transport Regulations

Well-planned and well-managed roads are prerequisites for efficient wood delivery. Road classification determines the most appropriate haulage routes, hence, the economics of transportation. Road layout (viz. location, gradient, alignment, turning points, and haulage distance) can restrict the use of certain timber haulage rucks. Road quality (viz. surface condition such rutting, potholes, and roughness) also has a direct influence on the efficiency of wood delivery. For example, a weak, rutted, and potholed road or a rough road with poor alignment and steep grades increase the transportation cycle times. Road roughness is important since it excites dynamic behavior of trucks such that the associated loading is magnified to increase road damaging potential and to compromise driving safety. Other factors that influence road damage potential of haulage trucks include axle spacing and the load sharing characteristics, and the type of suspension systems. Therefore, wood delivery by road is carried out within strict limitations of axle loads and gross vehicle weights (**Table 1**). Ergonomic concerns with respect to increased vehicle vibrations (which affect operator comfort) may also impact on the efficiency of wood delivery.

Figure 10 Categories of machines and trucks used in wood delivery. Reproduced with permission from Forestry Contractors Association, UK, and Timberjack OY, Finland.

Environmental and Ancillary Considerations in Transportation

Damage to transportation routes constructed over naturally weak road substrata (e.g., organic soils) or those that are weakened by seasonal variations (e.g., the influence of spring thaw) present considerable limitations to wood delivery. Such damage imposes expensive repair and maintenance procedures, and therefore makes transportation a costly factor in the overall timber production process. Maintenance and repair costs for timber haulage trucks are also higher than the average for the transport industry in general, because of the rugged nature of the operating conditions and the heavy and bulky loads of wood.

It is well documented that reducing truck axle load decreases its road damaging potential exponentially. However, the economics of timber transportation necessitates a maximization of truck payload, so that wood delivery consignments need to be at about the maximum permitted truck axle and payloads (**Table 1**). The current operational practices aimed at enhancing the serviceability and minimizing the overall maintenance cost of wood delivery route networks include (1) the improvement of design standards for new roads and upgrading of weaker links in the delivery route networks; (2) use of road-friendly truck axle configurations and suspension systems (e.g., air suspension), and (3) the use of trucks with central tire inflation (CTI) systems which adjust tire pressures to suit actual environmental conditions.

Table 1 National axle load regulations for the OECD countries

Country	Maximum permitted loading on a single axle (kg)		Maximum permitted loading on tandem axle (kg)
	Driving	Carrying	
Australia	4 600–9 000		9 000–16 500
Austria	10 000	10 000	16 000
Belgium	13 000	10 000	20 000
Canada	4 500–10 000		16 000–20 000
Denmark	10 000	10 000	16 000
Finland	10 000	10 000	16 000
France	13 000	13 000	21 000
Germany	10 000	10 000	16 000
Ireland	10 500	10 170	11 500–20 340
Italy	12 000	12 000	19 000
Japan	10 000	—	20 000
Luxembourg	13 000	10 000	20 000
The Netherlands	10 000	10 000	18 000
Norway	10 000	10 000	16 000
Spain	13 000	13 000	21 000
Sweden	10 000	10 000	16 000
Switzerland	10 000–12 000		18 000
UK	9 000–10 000		16 000, 16 000–20 000, 34 000
USA	9 000	9 000	15 400

Machine Telemetrics and On-Board Electronics

Machine telemetrics refer to on-board electronic systems that are used for machine and harvesting process control, including measurement and optimization of stem cutting, communication equipment (voice and data), and navigation and route optimization functions. Other on-board electronic equipment include visual display screens, audio and visual warning and fault diagnostic systems, and weighing scales for determination of payloads.

Modern harvesters have on-board computer-based measurement and production data recording and monitoring systems. These can provide stem diameter, log length, and assortment categories, and the operator has options for production value optimization in response to market demand for specific wood assortments. Electronic files can be transmitted between different machines, for monitoring and control of production processes (**Figure 1**). Other peripheral devices that are necessary for data transfer (e.g., GSM connection, satellite navigation, and geographical information systems (GIS) maps), and route optimization systems based on global positioning systems (GPS) and GIS are also available.

Stem Optimization

Features of a typical harvester head are shown in **Figure 11**. The main components include the electromechanically actuated sawblade control, feed rollers and delimbing knives with adjustable grip pressures, and automatic vertical positioning of the head to minimize splitting which incurs quality loss. The systems also allow for easy monitoring of volume and assortments of the harvested wood. With the integrated measuring and control system, wood is processed to customer specifications at the stump, thereby enhancing the supply chain efficiency. Stem optimization also allow for tree processing on the basis of market price and product priority matrices. In fully integrated mechanized harvesting systems, real-time transfer of production data is possible between the harvester and the procurement station to meet dynamic customer specifications (**Figure 1**).

On-Board Weighing Scales

The transportation of timber (like all biological materials) under strict limitations of axle load and gross vehicle weights outlined in **Table 1** is exacting. Therefore there is a trend towards the use of on-board weighing devices on transportation trucks and on loading and unloading machines. Such devices are used to ensure that the payload and axle load comply with active road haulage load limits, and for economic reasons, also allow for the maximization of truck load capacity. On-board weighing systems include crane link weighing systems (which weigh and display individual grab weight; cumulative weight of a loading/unloading operation may also be displayed) and payload platform and axle overload indicators (weighing devices that can handle bulk loads such as logs and wood chips).

Routing of Extraction and Transport Operations

The aim of extraction routing is to minimize or avoid site disturbance and damage or degradation of a harvesting site. Spatial information in the form of base maps or when collated in a GIS may be used to demarcate harvesting sites on the basis of the most important factor, e.g., soil bearing capacity. This enables operators to identify areas that require special attention, e.g., precipices and crags, waterways, and swamps. However, site impact due to extraction routing is highly dependent on operator skills. Good understanding of inherent environmental constraints is therefore central to the control of site damage; operations on sensitive sites should be allocated to experienced operators.

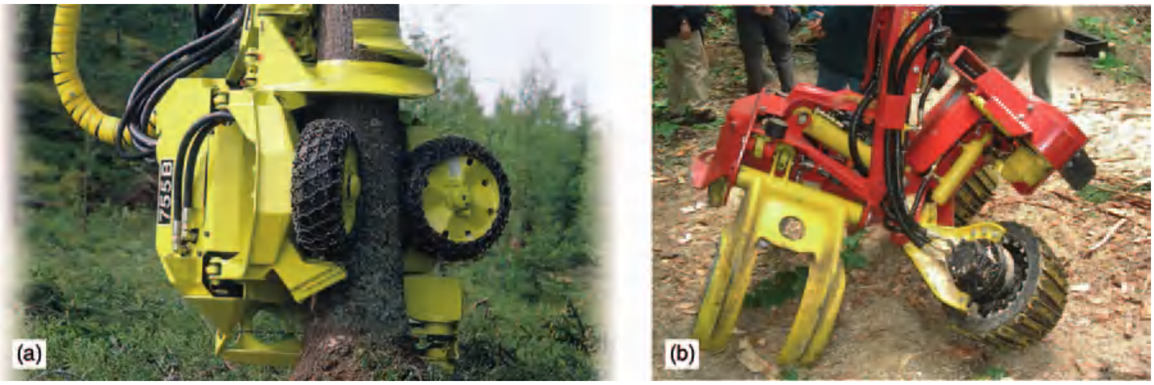

Figure 11 Single grip harvester head with (a) stem optimization capability and (b) a variance consisting of articulated delimbing knives and feed rollers for autonomous processing and loading capability. Reproduced with permission from Timberjack OY, Finland and Forest Engineering Unit, University College Dublin.

The main factors that are usually considered when selecting the location and cost-effective transportation routes include (1) route-dependent factors, such as the cost of road construction and maintenance, and the associated haulage costs, and (2) route-independent factors, including topography, soils, geography, and land use. When dealing with existing road networks for wood delivery, the former factor is most critical. Routing strategies associated with current networks must also address problems such as narrow road segments and bridges with load-carrying and vertical clearance restrictions. Other issues such as public safety and potential environmental pollution (emissions, noise, and transportation of hazardous materials) should be considered.

Site Harzards and Safety Issues in Wood Delivery

Hazards attached to wood delivery operations include:

- overhead power cables e.g., involved in the use of loading cranes mounted on high truck platforms
- poor site conditions and visibility
- operations in close proximity to tree felling areas or cable extraction corridors
- poor road and landing areas.

Such hazards require special considerations with regard to safety. For example, machine or vehicle operators should have appropriate protective outfits for tasks in loading/unloading, stacking, and securing of loads on trucks. Since they often work unsupervised in secluded and constantly changing environments, there is need to enhance their training in health and safety protocols on a regular basis.

Machine operators should also be aware of dangers of oil, fuel, and any chemical spillage. The risk of significant oil or chemical spillages is higher at the landings than elsewhere. Apart from acting as temporary timber storage areas for secondary transportation, landings also act as the end-points for the transportation cycles of both extraction machines and haulage trucks. They are also used for the delivery and storage of fuels, machine oils, chemicals, and spare parts, and may therefore be vulnerable to spills of oils and chemicals. All machines and trucks used should have kits for containing minor spills. The operators should also be trained in the protocols for dealing with major pollution incidences.

Monitoring of Performance of Wood Delivery Systems

Monitoring of components or whole wood delivery systems is essential for achieving optimum performance outcomes. The monitoring processes should include work analyses related to productivity in off-road and on-road transportation, and site impact assessments, with a view to identifying factors that may be improved through machine and process development or the enhancement of operator competence.

In-Process Assessments

These are systematic checks that are required during an operation. Since the site characteristics may be highly variable and obstacles may be obscured, machine operators are expected to make decisions on an ongoing basis. Prerouting assessment is important for the location of inherent obstacles in order to enhance efficiency in wood delivery. The importance of such assessment will be higher for unskilled operators. In-process assessments may also involve more advanced manual or machine telemetric system based time–motion studies to develop productivity functions. Time–motion study allows for objective and systematic examination of all factors which govern operational efficiency of a specified activity in order to effect improvement. With respect to forest machines, this may lead to improvements in harvesting procedures and planning for the necessary access locations during establishment of forest stands.

Post-Process Assessments

These are systematic checks that are required after an operation is completed. They are mainly geared to reverting a site to its original condition and to preventing secondary environmental degradation. For example, poor maintenance of access roads, extraction tracks, and landing areas may cause accelerated soil erosion and depreciation of water quality in the streams and water sources in the vicinity of a harvesting area, long after the operations are completed. Inadequate or poorly maintained roads incur high transportation costs. Therefore routine maintenance, rehabilitation, and upgrading of forest road networks should be implemented.

Forest Operations under Mountainous Conditions

H R Heinimann, Swiss Federal Institute of Technology, Zurich, Switzerland

Introduction

About 28% of the world's forests are located in mountainous areas, where forest management aims at simultaneously providing goods and welfare services while maintaining ecosystem functions at prudent, sustainable levels. Forest operations aims at delivering plans and operations that are technically feasible, economically viable, environmentally sound, and institutionally acceptable. To achieve this, there is a need to know best practices and to continuously improve them. Design, implementation, and control of forest operations for the specific conditions of mountainous areas are challenging due to difficult terrain conditions and high risks of adverse effects on environmental functions and values. Off-road transportation technology is the critical part of steep slope harvesting operations, and cable-based systems are often the backbone of harvesting systems. The main challenges for future developments probably are: the continuous improvement of practices and technologies for nontrafficable terrain, operationalization of environmental performance by quantifying the 'industrial metabolism' of operations, and development of both human resources and local capacity aspects of technology choices.

Significance and Characteristics of Mountain Forests

Mountain regions occupy about one-fourth of the earth's land surface (**Figure 1**). They are home to approximately one-tenth of the global population and provide goods and services to about half of humanity. Accordingly, they received particular attention in Agenda 21, endorsed at the United Nations Conference on Environment and Development (UNCED) in Rio in 1992. Chapter 13 of that document focuses on mountain regions, and states:

> Mountain environments are essential to the survival of the global ecosystem. Many of them are experiencing degradation in terms of accelerated soil erosion, landslides, and rapid loss of habitat and genetic diversity. Hence, proper management of mountain resources and socio-economic development of the people deserves immediate action.

The global mountain forest area covers about 9.1 million km^2, sharing about 8% of the global land area, and about 28% of the world's forests (**Figure 1**). One-half of the mountain forest area is located in temperate and boreal zones (west of North America, Europe, Far East), while the other half is located in subtropical and tropical regions (Central America, Eastern Andes of South America, continental and insular Southeast Asia, especially Borneo and Papua New Guinea). Mountain forests are fragile ecosystems, which are important for (1) the maintenance of life support services, (2) the supply of renewable resources (biomass, water), and (3) the provision of welfare services, such as mitigation of natural hazards, recreation, or intellectual stimulation.

While the supply of renewable resources, including fuelwood, timber, and other products, has been an important and familiar part of the economy, it has been less appreciated that natural ecosystems perform fundamental life support services (e.g., habitat, biodiversity, nutrient cycling, biogeochemical cycling, food-web functions). This array of services is generated by a complex interplay of natural cycles powered by solar energy and operating across a wide range of space and timescales.

The challenge is to develop land use policies and practices for mountain forests that will provide goods and welfare services simultaneously with maintaining ecosystem functions at prudent, sustainable levels. There is a need to incorporate major ecological considerations into silvicultural practices, e.g., imitating natural processes, reducing forest fragmentation, avoiding harvest in vulnerable areas, or restoring natural structural complexity to cutover sites.

Forest Operations in Context

Forest operations consist of all technical and administrative processes required to develop technical structures and facilities, to harvest timber, to prepare sites for regeneration, and to maintain and improve quality of forest ecosystems on a wide range of space and timescales. It aims at providing plans and operations that are:

- environmentally sound considering impacts on the natural and social environment and efficient use of natural resources including nonrenewable materials, renewable materials, water, energy, and space
- technically feasible considering the physical laws, engineering disciplines, and environmental aspects of the forest
- economically viable considering the cost and benefits of short- and long-range consequences
- institutionally acceptable considering the laws and regulations governing forest operations, landowner objectives, and social values.

The United Nations Environment Program UNEP has been promoting the concept of environmentally sound technologies (ESTs) to significantly improve environmental performance relative to other technologies. These technologies use resources in a sustainable manner, are less polluting, protect the environment, recycle more of their wastes and products, and handle all residual wastes in a more

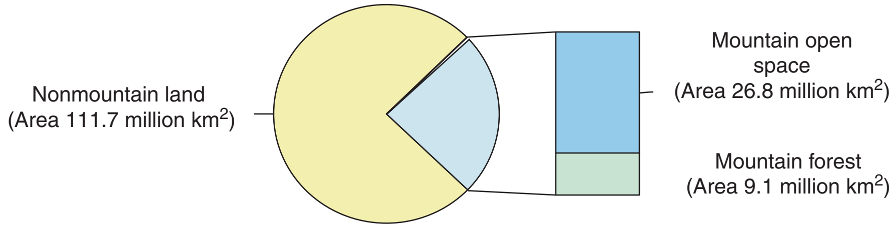

Figure 1 Proportions of the world's mountain forests.

environmentally acceptable way than the technologies for which they are substitutes. Additionally, they have to be compatible with nationally determined socioeconomic, cultural, and environmental priorities and development goals.

Forest operations technology aims at providing best practices that are the result of a continuous process of suiting harvesting practices to silvicultural regimes, and of improving economic and environmental performance. Best practices (BP) consist of strategies, activities, or approaches that have proven to be both effective and efficient.

Forest Operations Technology for Mountainous Terrain

Development and Deployment of Forest Operations Technologies

Accessibility is the most critical factor influencing feasibility of operations in mountainous terrain. Transportation consists of two phases, off-road and on-road, which are heavily dependent on each other. Four main concepts are available for facilitating off-road transportation: (1) ground vehicles moving on natural terrain, (2) ground vehicles moving on skid roads, (3) carriages moving on cable structures, and (4) aircrafts moving in the atmosphere (**Figure 2**). In nonmountainous terrain, off-road transportation is based on ground vehicles. System complexity increases with the effort to ensure off-road locomotion. Ground vehicles may move on a path over natural terrain or, if the terrain conditions become too complex, over geotechnical structures (skid roads). If terrain conditions become too difficult, cable structures enable the transport of partially or fully suspended loads over large distances overcoming various terrain obstacles. Aircraft-based technologies use the atmosphere as the medium for transport. Although at a high operational cost, helicopters have found a niche in transport for a number of site-specific situations when road costs are high, speed of operation is important, or fragile ground conditions exist.

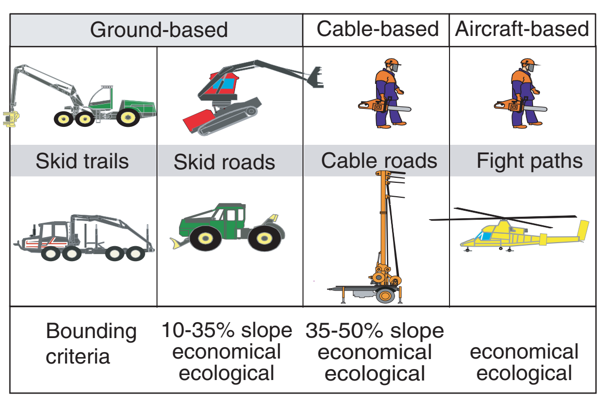

Figure 2 Basic harvesting system concepts. Off-road transportation technology is decisive for the layout of road networks and harvest units.

During the 1980s the engineering approach to developing road networks changed. It evolved from a technical task of cost minimization to a task that integrates technical processes with public involvement, environmental impact assessment, and public choice. At present, we are moving from an analysis–synthesis–evaluation design principle towards an engineering phase of algorithms and artificial intelligence. Availability of sophisticated computers, smart software, and digital terrain models are the backbone of future engineering work. The most advanced systems for the layout of both road networks and harvesting patterns are able to generate plans semi-automatically. Difference in the lifespans of on-road and off-road technologies is another problem becoming increasingly important. While the lifespan of roads is about 30–50 years, it has only been about 10–20 years for off-road technology. Therefore, a need to re-engineer forest road networks is emerging because off-road equipment has been altering its capabilities.

In trafficable terrain, ground vehicles are the basis for mechanized felling, processing, and transportation of trees. Mechanization of transportation progressed mainly in the 1960s and 1970s resulting in special machines like skidders, forwarders, or clambunk-skidders. Mechanization of felling and processing operations first took place in gentle terrain and slowly evolved on slopes. Beginning in the mid-1980s, manufacturers adapted tracked carriers for the special conditions of slopes. Being capable of processing trees mechanically in the stand increased the application of cut-to-length harvesting systems, first in thinning operations.

In nontrafficable terrain, cable yarders are the determinant technology of harvesting systems. Cable operations have been increasingly used in thinning operations, extracting small-size timber. This trend leads to emergence of smaller harvesters, and leaving systems developed for clear-cutting, such as high lead, grapple yarding, etc. The most advanced yarders make use of information technology to control speed, to move loads to pick-up locations, and to monitor the state of the system automatically.

Despite the options of sophisticated technology, biomechanical power (humans, animals) for felling, processing, and transportation is still important in many regions of the world, especially in developing countries. The dissemination of knowledge and the development of human resources in the forestry sectors is therefore an important issue to be emphasized in the future.

Cable Systems: The Backbone of Steep Slope Harvesting Systems

Cable yarding technology has a long tradition in Central Europe, in the Pacific Northwest of North America, and in Japan. In other regions of the world, it has been introduced only tentatively.

The basic structural model consists of a cable suspended between two points (**Figure 3**). A configuration is designated standing if the cable is fixed at support points A and B. A live line configuration has the cable fixed only at one support point B, with a mechanism to control the tensile force in the line at support point A. A running line configuration has a mechanism to control tensile forces at both support points (A, B). To make such a system operable, the two control mechanisms are integrated at the head end (A) while a pulley at the tail end diverts the tensile force. A difference between tensile forces is required to produce lift, and to move a load.

The simplest cable system configuration consists of an uphill yarding system (**Figure 4**). The load-supporting structure consists of (1) the skyline, (2) the head spar, (3) the tail spar, and (4) the anchors, which have to be designed and setup specifically for each cable corridor. The yarding process requires (5) a carriage moving on the skyline, (6) a mainline to pull the carriage, and (7) a mechanism to slackpull the mainline, to lift the load, to attach it to the carriage, and to release it at the landing. Gravity moves the carriage downhill to the location where a load is picked up. A mechanism clamps the carriage to the skyline, and the mainline is slackpulled manually to the position where chokers attach logs to it. The winch pulls in the mainline until the load attaches to the carriage and releases the clamp. The load then moves partially or fully suspended to the landing.

A downhill yarding configuration (**Figure 5**) requires additional lines and mechanisms. The yarding process requires – as for uphill yarding – (5) a carriage moving on the skyline, (6) a mainline to pull the carriage, and (7) a mechanism to slackpull the mainline, to lift the load, to attach it to the carriage, and to release it at the landing. A haulback line (8) moves the carriage uphill to the location where a load is picked up. A mechanism clamps the carriage to the skyline, and the mainline is slackpulled mechanically to the position where chokers attach logs to it. There are several slackpulling mechanisms available: driving a sheave by the yarder's slackpulling line, by an electromechanical engine, by a fuel engine, or by a hydraulic pump. The winch pulls the mainline in until the load attaches to the carriage and releases the clamp. The load then moves partially or fully suspended to the landing, simultaneously controlled by the mainline and the haulback line.

Operational efficiency depends far more upon rational organization of work processes than upon equipment capabilities, or workers' skills. It is therefore important to understand the essence of the workflow organization of cable-based harvesting systems. A harvesting system is designated 'tree length' if the conversion of trees to logs is done after the extraction operation at the landing or at mill site. This means that only felling is done at the stump site, either motor-manually or using steep slope feller-bunchers. Directional felling and bunching affect productivity positively. Several trees are chokered to a single load, which is attached to the mainline and extracted by a

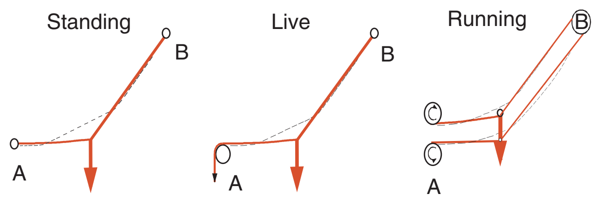

Figure 3 Types of load-supporting cable structures.

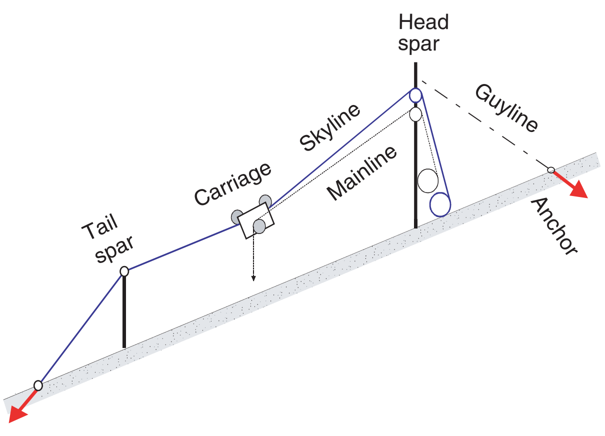

Figure 4 Components of a skyline yarding systems for uphill yarding.

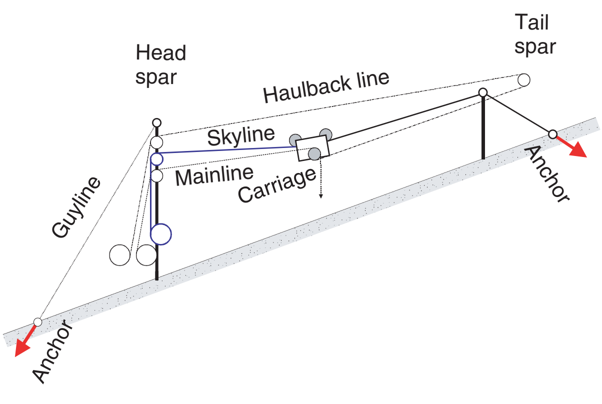

Figure 5 Components of a skyline yarding system for downhill yarding.

cable yarder to the landing. At the landing, the following operations have to be done: releasing the load, limbing, bucking, and piling. These operations may be mechanized by using an excavator with a stroke-delimber, which is common in North America. In Central Europe, a boom with an attached processor head is integrated into the yarder. A standard crew consists of one or two choker setters, one yarder operator, one processor operator, and one chaser. In countries with high labor cost, such as Central Europe, rationalization efforts have led to automated systems which can be operated by a two-man crew: one choker setter and one yarder operator. The yarder moves the load automatically from the stump to the landing and the empty carriage from the landing to the stump site. The yarder operator therefore gains additional time which can be used to process trees to logs while the carriage is moving automatically. Such a system requires radio-control of the yarder. Future developments aim to introduce bucking-to-value and bucking-to-order procedures as they are implemented in the Nordic wheeled harvester systems.

A harvesting system is designated cut-to-length (CTL) if the conversion of trees to logs is done at the stump site before the extraction operation. Felling, limbing, and bucking are all done at the stump site. Motor-manual systems use workers equipped with chainsaws. Mechanized systems are based on steep slope harvesters with the capacity to level the swing table. Several logs are chokered to a single load which is attached to the mainline and extracted partially or fully suspended by a cable yarder to the landing. A grapple attached to a boom handles the logs and piles them. In North America, an excavator-based loader usually does this operation, whereas in Central Europe the boom is integrated into the yarder. A standard crew is of the same size as for tree-length harvesting, and the minimal crew size consists of two, one choker setter and one yarder operator. As in tree-length harvesting, a crew size of only two requires radio-control of the yarder and the carriage. CTL systems may be used in both thinning and clear-felling operations. However, CTL cable yarding is best to minimize damage to residual trees in thinning operations.

Improving Operational Efficiency

Production economics investigates the interactions of factors of production with the output of production. It is only possible to develop empirical models with a limited range of validity due to the complexity of harvesting systems. Forest operations research has been analyzing and developing productivity models, which are the basis for estimating production rates (e.g., production rate in m^3 per productive system hour), and for optimizing systems' performance. The professional literature reports many of those studies. However, comparability is limited due to different standards of study layout, of timber volume measurement, and of time units. Another problem is that the number of different harvesting systems has reached a variety that demands too much effort when using traditional study methods. Future research will therefore have to concentrate on families of technologies (harvesters, forwarders, yarders, etc.), and on real-time gathering of operational data using sensors and data loggers. Optimization has been another field of forest operations research. Problems are often so complex that the use of traditional techniques of operations research, such as linear programming, needs excessive computing time or is even impossible. Advances in heuristic techniques open new possibilities to optimization, offering a broad area of future research.

Minimizing Environmental and Social Impacts

Since the 1970s, public awareness of environmental concerns has steadily increased. The UNCED conference adopted the concept of sustainable development as a programmatic goal for future development. However, there has been much debate on how to transfer this concept to the level of operations and harvesting systems. Risk analysis is one approach of studying the impacts of specific processes on safeguard objects. In forest operations the relevant safeguard objects are: (1) watersheds, (2) sites, (3) human beings, and (4) natural resources. Human activities affect these safeguard objects in different ways and on different scales of space and time.

Watersheds

Land use activities such as road network construction and harvesting regimes may have adverse effects on watershed processes. Research on erosion and sedimentation processes is complex and needs large-scale spatial data sets of a few critical variables to develop better understanding. Hypotheses postulate that channel networks integrate the cumulative effects of geotechnical and topographical variability, climatic triggering events (rainstorms, fires), and management regimes (roading, harvesting). Road erosion and identification of landslide trigger sites are problems that can be immediately remedied by considering rules of drainage, and roadway design. Imperviousness is an indicator for cumulative impacts at the watershed scale, which can be easily measured at all scales of development, as the percentage of area that is not 'green.' Current research converges toward a common conclusion:

that it is extremely difficult to maintain integrity of catchment processes when development exceeds 10–15% impervious cover. There seems to be a strong relationship between imperviousness and runoff, water quality, stream warming, stream biodiversity, and other dimensions of aquatic quality.

Site Disturbance

Harvesting activities such as off-road traffic and felling cause several site disturbances. Research has been concentrating on long-lasting effects, such as soil erosion and soil compaction. One aim is to understand the behavior of the vehicle–soil interaction and to provide threshold values to limit possible damages to an acceptable level. Mechanical behavior of soil depends on its water content. One strategy to limit soil disturbances is to avoid traffic whenever the water content approaches the limit of liquidity, or even exceeds it. Another approach is to minimize the actions at the wheel–soil interface by using low-ground-pressure tires. A third strategy is to limit traffic on fixed transportation lines (skid trails). Although progress has been made to reduce site disturbances, there are still many unsolved questions.

Health and Safety

Forest work may have impacts on health and safety of the workforce. Forestry is one of the sectors with the highest accident rates often resulting in heavy injuries or even death. Research investigates stress–strain processes of different systems, as a basis for system improvement and development. The International Labour Office (ILO) offers information on occupational health and safety, ergonomics, etc. A recent code of practice aims to protect workers from hazards in forestry work and to prevent or reduce the incidence of occupational illness or injury. It is intended to help countries and enterprises that have no forestry-specific regulations, but there are also useful ideas for those with well-developed prevention strategies. The available body of knowledge is considerable. The problem is how to disseminate it and how to apply the basic rules in firms and enterprises.

Life Cycle Assessment

Manufacturing processes are using energy and materials and releasing wastes to the environment. Life cycle assessment (LCA) has become an important tool to assess those energy and material uses and releases to the environment. It forms part of the novel orientation in environmental management, moving away from 'end of pipe' to 'begin of pipe' approaches. In forestry, use of LCA methodology has just started recently; therefore only preliminary results are available. The LCA framework is an important step to shift environmental issues from 'good feeling' to hard facts, and to establish a set of operational performance indicators (OPIs), as proposed by international standards on environmental performance (ISO 14031).

Prospects for the Future

We are looking back on a phase of development that has been dominated by environmental and institutional issues. Many people therefore misjudged the significance of technology and engineering sciences, and their role for sustainable development. There is a considerable body of knowledge on forest operations technology, even for sensitive mountainous areas. Improving the understanding of natural processes and their interactions with land use activities is important. However, dissemination of available knowledge and the development of human resources are probably more important, first in mountainous areas where the risk of degradation is high. The forest operations community will continue to improve the technical systems of forestry. The main challenges for future research and development will probably be:

- the shift to a process focus, considering all technical and administrative processes along a whole value chain of production (business re-engineering focus)
- active collaboration in the process of improving and developing the institutional framework (adaptation of policy instruments such as auditing, scientific based environmental standards, etc.)
- planning procedures based on algorithmic knowledge and spatial databases
- operationalization of environmental issues, following the emerging discipline of industrial ecology (quantification of the 'industrial metabolism') using and improving tools such as LCA or substance flow analysis (SFA)
- expansion of the concept of operational efficiency considering the 'eco-efficiency' approach proposed by the World Business Council for Sustainable Development
- development of human resources on all levels of forestry, taking into account future organizational concepts (virtual organizations, network-based structures) and new job profiles (novel training methods, new wage models, teamwork, promotion by performance)
- use of a mechatronic's paradigm of development, providing some 'intelligent behavior' to future machines and systems (sensing devices, control systems, etc.).

Sustainable development of mountain areas depends on recycling of resources rather than their extraction and eventual discard following use, and on turning from 'end-of-pipe' thinking to forward-looking approaches to product and process design. There is a big potential for this shift in thinking to develop sustainable management practices for mountain forest ecosystems.

Diagnosis, Monitoring and Evaluation

M Ferretti, LINNÆA ambiente, Florence, Italy

Introduction

Over the last 30 years forest health became a popular issue together with the concern about acid rain, air pollution, and climate change. Terms like forest decline, and the German 'Waldsterben' (forest death) and 'Neuartigen Waldschäden' (new type of forest damage) became frequent in scientific literature as well as in popular media. This concern resulted in an unprecedent effort to study and monitor forest health. Since then the situation has evolved and now forest health diagnosis and monitoring is relevant to a much broader area of interest, including recent (e.g., climate fluctuation and change, biodiversity, sustainable resource management) and 'traditional' issues (e.g., pests, diseases, forest fire). Broadly, forest health diagnosis, monitoring, and evaluation aims to identify forest health problems, track forest health status through time and identify its relationship with environmental (biotic and abiotic) factors. It embraces a variety of activities and involves several topics and scientific disciplines. Forest health diagnosis, monitoring and evaluation is addressed here in terms of (1) definitions, factors affecting forest health and most known forest health declines in the world, (2) methods of diagnosis, monitoring, and evaluation, and (3) relevance and applications.

Forest Health

Importance of Definitions and Concepts

The definition of forest health is important as it provides guidance for the operational steps of the monitoring, e.g., the choice of the most suitable indicators (see below). A problem is that forest health still lacks a consensual definition. In most cases, definitions are based on the expectations of particular interest groups: a person interested in commercial timber (e.g., the owner of a pine plantation) would have a 'utilitarian' perspective (wood production), while a natural reserve manager would consider a more 'ecological' approach, taking into account, the wildlife, the preservation of species and habitat diversity, and the ecological processes. According to the approach, definitions may refer to different entities (individual trees, the stand, the forests, or the entire forest ecosystem) and consider different indicators (e.g., from injury to individual trees to the incidence and severity of pests, diseases, and mortality rates, presence and abundance of exotic species, growth rate, specific and structural diversity, fluxes of energy and chemicals from the atmosphere, and change in soil properties). This has clear operational consequences for the design of a monitoring program. Recent definitions of forest health as well as the criteria and indicators for sustainable forest management (SFM) consider key words such as 'long-term sustainability,' 'resilience,' 'maintenance' of 'ecosystems structure and functions,' 'multiple benefits and products.' Overall, this suggests that the health of individual trees is somewhat different from the health of the forest: although the detection of individual unhealthy trees is important as they may be signaling the occurrence of problems that may become serious in the future, it is important to consider that death of trees is as important as birth and growth to the vitality of forests. Thus, a healthy forest ecosystem may include unhealthy or dead trees. This means that forest health is no longer thought to be a property relevant to individual trees and stands but to forest ecosystems. In the remainder of this article the emphasis will be on forest and forest ecosystem health rather than on tree health, although reference to tree health will be made under specific chapters.

Factors affecting Forest Health

The health of forests can be subjected to many stressors (**Figure 1**) that may affect individual trees as well as the entire ecosystem.

Recognizing the stressor(s) of concern and its expected mechanism of action and pathways is important as it may help considerably the choice of the indicators to be adopted for monitoring. Natural and anthropogenic factors may act as stressors, singly and/or in combination. In addition, anthropogenic factors may substantially alter the occurrence and severity of natural ones. The role of the various stressors may change, and – according to the situation – the same factor may have a different role at a different time in the sequel of steps of a progressive or reversible decline. For example, air pollution is known to cause direct damage and even death of forest trees at very high concentrations. At low concentration, however, air pollutants may just weaken the resistance of forest trees to insect attacks; in this case a subsequent attack of an insect may cause the death of the trees that were already weakened by the exposure to pollutants. Emphasis on the interaction between different factors and on their ordering according to the peculiar site condition is also a convenient framework to identify the scenario of concern and to proceed toward a diagnosis.

Forest Declines

Instances of poor forest health have been documented worldwide. **Tables 1** and **2** report the best-known ones. Reports are almost always based on the evidence of the decline of forest trees and cover a wide array of ecological situations and forest species. Declines can occur as natural processes and as a result of anthropogenic activity.

Natural forest declines Natural forest declines (**Table 1**) include those related to the action, singly or in combination, of 'traditional' factors (e.g., pests, diseases, climate perturbations, nutrient disturbances, vegetation successional dynamics, and competition). Natural forest declines may involve individual trees of a given species at a certain site, an individual species throughout its range or within an ecosystem, and multiple species. In many cases, the cause of the decline is not obvious as there are complex interactions that need careful examination according to clear diagnostic criteria (see below).

Human-induced forest declines Different human activities may affect the health of forest ecosystems: fire and mismanagement are probably the most obvious ones. However, much work on forest decline concentrated on atmospheric pollution. Traditionally, a distinction is made between the decline of forest trees around pollution sources and those declines for which the effects of nonacute, background pollution level are advocated.

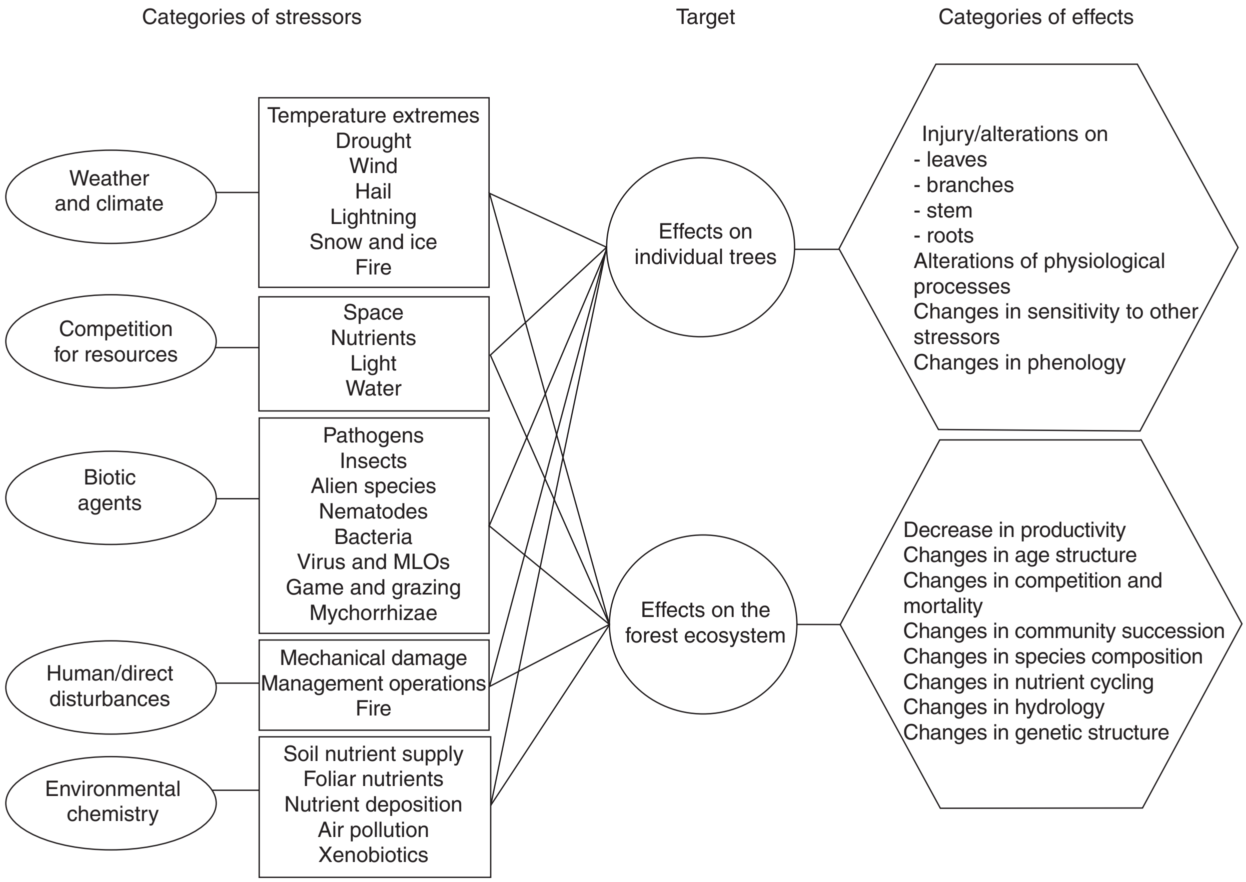

Figure 1 Stressors that may affect forest trees and ecosystems causing various effects. MLOs, mycoplasma-like organisms. Compiled on the basis of Committee on Biological Markers of Air Pollution Damage in Trees (1989) *Biological Markers of Air Pollution Stress and Damage in Forests*. Washington, DC: National Academy Press.

Declines around pollution sources Declines around pollution sources usually involve a distinct spatial pattern, with the most damaged areas being located close to the pollution source. Here, acute foliar injuries are almost always present; they are caused by concentration of pollutants that are directly toxic to plants. As the distance from the source increases, chronic injury and/or indirect effects may occur. The best-known cases of declines around pollution sources for which conclusive studies have been reported are shown in **Table 2**. Tree mortality and/or damage have also been reported around sources of pollution in Europe (Arc Valley, Maurienne, France; Øvre Årdal, Norway; Leanachan Forest, Fort William, Scotland, UK) and evidence for other cases in the Kola Peninsula of China, Korea, and the former USSR is emerging.

Forest declines and regional air pollution Well-documented cases of regional forest decline that can be attributable to air pollution are limited (**Table 2**). This reflects the inherent complexity of research into cause and effect; with few exceptions, at the regional scale the concentration and deposition of air pollutants is usually not enough to cause direct injury to the trees; rather, secondary effects (e.g., soil mediated) can occur, but they usually are less obvious and involve a suite of other factors. Examples of regional effects of air pollutants include the effects of ozone (O_3) on the decline of *Abies religiosa* (Desierto de Los Leones, Mexico) and on the pines (mostly *Pinus jeffreyi* and *P. ponderosa*) in the western USA. In Europe, the damage to Norway spruce (*Picea abies*) in the area between the northern Czech Republic, south Poland, and southeast Germany due to sulfur dioxide (SO_2) is the most widely known example. In several other cases, air pollution was suspected to be involved but evidences were not conclusive.

Methods in Forest Health Diagnosis, Monitoring, and Evaluation

Diagnosis

Identifying whether the forest of concern is healthy or not and, if unhealthy, what could be the cause of

the observed unhealthy condition can be a difficult task. Acute injury on trees is easy to diagnose; on the other hand, nonacute, subtle effects on trees and/or ecosystems can be difficult either to identify in the field or to ascribe to a particular cause. In many cases, different factors may interact (see **Figure 1**); depending on the case, an accurate diagnosis needs careful examination of the various potential causal agents and the use of diagnostic criteria and tests.

Diagnostic criteria Several criteria have been developed that can provide a convenient framework for cause-and-effect research and for diagnostic purposes (**Table 3**). These criteria are based upon traditional human and plant pathology and have been developed further to take into account the complexity of certain situations. For example, the criterion of strong correlation implies that both cause and effects can be identified and measured and this is not always

Table 3 Diagnostic criteria for forest health diagnosis

Koch (1876)	*Committee on Biological Markers of Air Pollution Damage in Trees (1989)*	*Schlaepfer (1992)*
The infecting agent must be present in all patients showing symptoms of disease	Strong correlation	Detection and definition of the problem
The infecting agent must be isolated from the patient	Plausibility of mechanism	Description of magnitude, dynamics, and variability of the phenomenon
The infecting agent must produce the disease under controlled laboratory condition	Responsiveness or experimental replication	Detection of associations in space and time between the symptoms and the hypothetical causes
	Temporality	Experimental reproduction of the observed symptoms
	Weight of evidence	Explanation of mechanism
		Validation of the models

possible: the physiologically active dose of an air pollutant (the fraction of the pollutant present in the atmosphere that enters the plant through the stomata) cannot be measured as a routine procedure e.g., during large-scale monitoring. In addition, one must consider that correlation does not necessarily mean causation, and this is the reason for which the other criteria in **Table 3** need to be considered.

Diagnostic procedure for individual trees While a forest is more than the sum of the trees present, the diagnosis at individual tree level remains important for different situations, including commercial plantations and recreational forests. Individual tree diagnosis is supported by a number of textbooks that provide useful identification keys, practical examples, pictorial atlases as well as the approach for a sound diagnostic procedure. Tree-related diagnosis is also related to pathology and entomology (*see* **Entomology**: Bark Beetles; Foliage Feeders in Temperate and Boreal Forests; Sapsuckers. **Pathology**: Diseases affecting Exotic Plantation Species; Diseases of Forest Trees). A suitable diagnostic procedure involves the collection of preliminary information (species identification, site condition, recent tree history) and close examination of the case in hand. A careful examination of the aerial parts of the trees is essential to identify and describe the symptoms and injuries together with the location in relation to existing knowledge about the species being considered. If the case in hand matches the known description, confirmatory evidence is sought and – if found – the diagnosis is achieved, its reliability being dependent on the weight of evidence. If the case in hand does not match existing knowledge, or if no confirmatory evidence is found, additional investigations have to be considered which may involve destructive sampling. In some cases the problem may remain unexplained either because the damage is too old or the evidence is insufficient for a diagnosis.

Diagnostic tests Besides the above criteria and procedure, careful diagnosis may involve the use of diagnostic tests. Biochemical, physiological, and morphological tests are available (see the section on 'Indicators'). With few exceptions, diagnostic tools involve complex sampling procedures and laboratory analysis and can be expensive. This may limit their applicability at the large scale.

Monitoring

Definition Monitoring is a general term to identify a type of study that can be applied to several environmental resources. Monitoring can be defined as 'the systematic observations of parameters related to a specific problem, designed to provide information on the characteristics of the problem and their changes with time.' Emphasis should be placed on the connection between the monitoring and the management of the resource being considered, e.g., the monitoring is carried out to track the progress toward a management objective. The management action can be understood at local level (e.g., thinnings) or at the large scale (e.g., political negotiations to decrease pollutant deposition). Note that the emphasis on management objectives forces the monitoring designer (1) to obtain an unambiguous definition of forest health from stakeholders and (2) to establish clear conceptual and/or mechanistic models to link forest health as defined and the expected management action. These are important as effective monitoring can only be based on explicit assessment and measurement endpoints.

Two important characteristics of monitoring are its time dimension and its nature of routine, systematic and organized activity. This implies monitoring should be based on a careful design, which has to cover a series of issues (**Table 4**).

Monitoring approaches Monitoring can be carried out to obtain information about the status and trend in the spatial and temporal development of forest health over a defined spatial and temporal domain, and for cause-and-effect investigations. Forest health monitoring can be of value also in the framework of before-and-after studies but in this case it needs to be placed in the context of an experimental design.

Status and trend (extensive studies) In general, the assessment and monitoring for status and trend of forest health is carried out on regional populations of forests, with regions being small (e.g., local, subnational scale) or large (e.g., national, international scale). At the stand level, assessment of status and trend can be necessary for economically important forests and it was carried out for example in commercial pine plantations in the southeastern USA, and *Acer saccharum* forests (syrup production) in southeast Canada and the northeastern USA. In such cases, careful diagnostic approaches and specific indicators are essential. At the large scale, status and trend investigations usually concentrate on a few, easy to measure, low-cost, and sometime simplistic indicators that are measured at many sites by trained observers. However, as many observers are needed for this type of survey, their skill in forest pathology and entomology may be not always high, and – together with the indicators used and the limited time available for site visits – this can have consequences for the quality of the results. In many cases, a careful diagnosis cannot be carried out, and causes of poor forest health may remain unexplained unless the observed phenomenon is very obvious. This clearly indicates that – in most cases – large-scale monitoring programs have a role as detection monitoring, to identify problems to be investigated in more detail at a later stage. In this respect, integration between a survey approach (e.g., terrestrial and aerial surveys) and extensive and intensive studies can provide a number of benefits for detecting, diagnosing, and monitoring health problems. Status and trend surveys must allow inferences on a statistical basis. False-positive (Type I) and false-negative (Type II) errors as well as sufficient precision of the estimates of population parameters must be considered, and a statistically based sampling design is essential to ensure the success of status and trend monitoring.

Cause-and-effect (intensive studies) Cause-and-effect investigations aim to establish a relationship between stressors(s) and response(s). In the field stressors are difficult to isolate from other factors that need to be accounted for. For this reason, cause-and-effect investigations require data about a number of variables, usually referred to as stressor (independent variables, or predictors, in a statistical model), response (dependent variables), and intermediate (covariates) variables. Cause-and-effect investigations can be very expensive and usually are carried out on a limited number of selected sites. In general, sites for intensive studies are selected purposively, according to the hypothesis being tested and/or the scenario of concern (e.g., plots along gradients of pollution, age, or succession). Under some circumstances, plots can be installed as case studies: this can occur to study the effects of extreme/catastrophic events that may offer the chance for studies otherwise impossible. Although sites for cause-and-effect studies are selected on a preferential basis (thus prohibiting statistical inference), observations and measurements within sites should always be based on a sampling design.

Indicators of forest health An indicator is a characteristic that can be measured or assessed to estimate status and trends of the target environmental resource. A number of indicators can be used in forest health monitoring and the choice of the most suited ones depends on the problem being examined, the available resources, the available expertise, and the

Table 4 Design issues for a forest health monitoring program

Design issue	*Areas of concern*
Definition of the scientific problem	Users' needs and clear questions for the designers
Sampling design	Formal definition of nature, iteration, selection, and number of (sub)samples; inferences
Quality assurance	Standard methods with known performances; data reproducibility and consistency
Field and laboratory work (when needed)	Safe procedures and logistics
Data management/analysis/reporting	Proper data management, accessibility, data analysis and reporting

ecological, spatial, and temporal coverage of the investigation. Indicators can be considered according to their nature (e.g., stress, response), ecosystem compartment (e.g., atmosphere, vegetation, soil), platform used (terrestrial, aerial, satellite), and method of detection (from visual assessment in the field to biochemical analysis in the laboratory). An overview of indicators most frequently adopted in forest health monitoring programs is given in **Table 5**.

It is notable that **Table 5** does not cover the zoological component of the ecosystem which is important but which is very seldomly covered in forest health monitoring. This reflects both the 'old,' tree-oriented, concept of forest health and the difference between the spatial scales used in typical forest studies (mostly based on a plot size of less than 1 ha) and those needed for e.g., bird investigations (typically more than 30 ha). Recent emphasis on

Table 5 Most common indicator categories and measurement methods

forest ecosystem health and the role of biodiversity to promote sustainable forest management has led to a reconsideration of this approach, and now soil biota, rodents, birds, butterflies, and small and large mammals are increasingly considered.

Terrestrial investigations

1. Visual indicators of tree condition consider the appearance of plant organs, in general foliage, reproductive structures, branches (often as a single unit, the crown), and stem. The roots are usually difficult to examine as routine indicators, but are of interest in in-depth cause-and-effect research. The examination of the various organs usually considers the frequency and intensity of symptoms as well as their cause, when possible. In the case of reproductive structures, the timing and abundance of flowering and fruiting are important. **Table 6** reports a list of indicators used in forest health surveys in Europe and North America. Since visual indicators are based on visual estimates they are prone to observer bias, and this needs to be taken into account with adequate Quality Assurance programs (see below).
2. Quantitative measurements of leaf/needle biomass and needle retention can include systematic collection of litter by litter traps, direct measurement of leaf area index (LAI), the identification of needle traces from branches and stems, and the analysis of digital images of crown condition. All these methods are useful as they provide objective data respectively on primary productivity, past needle retention, and crown condition. However,

their application is usually limited at intensively monitored sites because of technical and operational difficulties and costs.

3. A number of nonvisual indicators are available to assess tree health (**Table 7**). Most of them require time and appropriate equipment and can hardly be incorporated in large-scale surveys. Rather, many of them are attractive for intensive studies and cause-and-effect research.
4. Indicators for ecosystem-level health assessment. Ecosystem-level health assessment goes beyond the health of individual components: individual trees may die from insect attack but the ecosystem can still be healthy. The reverse is also true: for example, nitrogen deposition may substantially affect the nutrient balance of the system. This may affect species composition and diversity, population and community dynamics, herbivores' behavior, soil biota, soil water, and runoff quality without necessarily killing trees. In general terms, health assessment at the ecosystem level needs to consider resilience, vigor, and organization of the ecosystem as well as the presence of stressors that may exceed the tolerance limit of the system (see below). Resilience, vigor, and organization can be interpreted in operational terms as diversity, integrity of the physical, biotic, and trophic networks, productivity, equilibrium between demand and supply of essential resources, resistance to catastrophic change, and ability to recover. Also, the occurrence of endangered species has to be considered. To measure these characteristics, a number of proxies have been adopted, most of them being already listed in **Table 5**. Indicators such as birds and various other groups of taxa (e.g., rodents, small and large mammals) would be a useful complement. References and methods for ecosystem-level studies and monitoring are available, covering carbon and energy dynamics (above-and belowground primary production estimation from global to local levels), nutrient and water dynamics, and manipulative experiments.

Remote sensing Remote sensing is mostly based on analysis of imagery that can be collected from aircraft or from satellites; it includes aerial photographs, airborne or spaceborne multispectral scanner recordings, and radar recordings. Applications can be relevant at a variety of spatial scales, from local ($>1:25\,000$) to global ($<1:2\,50\,000$). It is important to acknowledge that different scales require different platforms and sensors: for example, satellites NOAA-AVHHR are the most used at the global scale, while sensors like the Landsat Thematic Mapper (TM), SPOT HRV/Xs, and IRS-1C/LISS are used at the regional scale. However, technical progress is rapid in this respect.

Remote sensing by aerial photographs can provide valuable information concerning yellowing, crown density, and mortality. In this respect, color-infrared (CIR) imagery is believed to provide more useful information than black-and-white imagery, although

it seems less valuable when damage differentiation is not clear. A more sophisticated and expensive technique is based on multispectral imagery; it is based on the spectral characteristics of the green vegetation (pigment absorption in 0.4–0.7 μm range) whose changes can be related to changes in chlorophyll-*b* content. In the past, the resolution of satellite imagery was insufficient to detect the condition of individual trees, and applications were mostly useful to provide information about insect and fungal problems over large forest areas. However, recent technical progress and the use in combination of geographic information systems (GIS) and Landsat TM data make it possible to identify site susceptibility to insect attacks as well as to detect attacks on individual trees. An example is the identification of mountain pine beetle (*Dendroctonus ponderosae*) attacks on lodgepole pine (*Pinus contorta* var. *murrayana*) in various districts of British Columbia, Canada. These data are used to inform forest management and this is a valuable advance. Remote sensing and its application to forest monitoring are undergoing rapid evolution. Applications are now available in many fields related to forest health, including forest biodiversity, structural parameters, productivity, and carbon and chemical content of the foliage. For example, studies of ecosystem gross and net primary production (GPP and NPP, respectively) at the global scale received great benefits from recently improved remote sensing from the Earth Observing System. Implications for estimates of forest growth, seasonal dynamics of CO_2 balance for global carbon cycles studies and thus for important political and economic questions are obvious. From the monitoring point of view, advantages of using imagery include the opportunity to keep a permanent record of the forest under investigation and the possibility of adapting the sampling design and the sample size for imagery-based studies according to the investigation being undertaken. Disadvantages include the impossibility of making a careful diagnosis, and the difficulty of recognizing detailed symptoms and obvious damaging agents; in addition, assessment is made using a coarser method. Subjectivity is not completely solved, although it does not seem to be a major problem since images taken at different years can be rescored by the same interpreter.

Quality assurance An important part of any monitoring programme is quality assurance (QA). QA is a key issue for investigations aiming to generate representative results at the large scale (national, international) and in the long term, as it aims to improve the consistency, reliability, and cost-effectiveness of the program through time. QA is a systematic, formally organized series of activities that defines the way in which tasks are to be performed to ensure an expressed level of quality. The QA program ensures (1) proper design of the monitoring and its documentation, (2) the preparation, use, and documentation of standard operating procedures (SOPs), (3) the training of field crews, ring tests between laboratories, calibration and control phases, and (4) the formal, statistical evaluation of data quality.

Data management Data management (i.e., storage, evaluation, accessibility) is an increasingly important issue and can even determine the success or the failure of the monitoring program; it should be carefully planned at the early stage of the monitoring design. A data management plan should be prepared with details about (1) needs and goals, (2) available computer resources (hardware, software, protection, maintenance), (3) data resources (nonspatial data and GIS resources, data load, data standards, database design and file formats, metadata), (4) human resources, (5) data management strategies (data acquisition, QA/quality control data maintenance, legacy data, data security, data archives and storage, data applications, data dissemination), and (6) implementation.

Evaluation

Evaluation approaches and limitations Evaluation of data generated by forest health monitoring is usually driven by the monitoring approach adopted, the technique used, and the indicator adopted. Usually, data are evaluated in order to identify spatial and/or temporal trends and/or to identify cause-and-effect relationships. Data analysis is subjected to the nature and properties of the data (determined by the sampling design adopted, the metric of the indicator used, and by the frequency distribution of the observations), the comparability of the data (both in space and time) and by the reference adopted, i.e., the definition of what is to be considered 'healthy' or 'normal.' While the data issues can be managed from a technical point of view, the question about 'health' thresholds is controversial. For example, the classification adopted by the UN/ECE program in Europe identifies 25% crown defoliation as a threshold for damage. The 25% threshold was set to indicate a sort of 'no – return' limit, i.e., a tree whose defoliation exceeded that limit would have no chance to recover. This is now demonstrated to be untrue and cases of rapid recovery have been reported.

Uncertainty in health thresholds occurs because stressors may affect forests with different intensity and frequency. For example, herbivores are usually present on the foliage of trees. Yet their action affects the health of the trees only when they exceed some tolerance limit. Therefore, a first information need is to know this limit. In addition, tolerance limits may be exceeded cyclically and this can be seen as an integral part of the ecosystem dynamics. Thus, a second information need is to know the historical frequency of the insect infestation. It implies that an indicator of forest health has a range of natural and historical variation: if such a range is known, then it would be possible to establish thresholds that can be used as diagnostic tools. Recognizing the inherent variation of the potential stressor has a clear importance for evaluating the health of a given forest.

Evaluation methods Evaluation methods include various statistical and geostatistical approaches and are subjected to the same data limitations reported for the evaluation approach. Several references exist that may help in making decisions about most appropriate statistical analysis. When status and trend monitoring is concerned, data processing should provide summaries of descriptive statistics (e.g., totals, descriptors of central tendency, descriptors of frequency distribution), estimates of population parameters (e.g., estimates of population means, totals, and proportions), comparison between two subsequent sampling occasions (with statistical tests), and comparison between sites/group of sites (with statistical tests). It is important to remember that both parametric and nonparametric statistics need sampling to be based on random elements. Similarly, decisions about the most suitable statistical test should be based on the metric of the indicator used and the frequency distribution of the observations. Association and relationship between indicators can be explored by means of various univariate and multivariate statistical analyses. In the case of large-scale, long-term monitoring the use of models to incorporate the effects of covariates (e.g., the age of the trees or the effect of difference in methods) and for mapping purposes is essential.

In the case of cause-and-effect monitoring, relationships between indicators of for example, tree condition and indicator of stress (e.g., drought indices, pollutant deposition) are usually investigated by means of various multivariate techniques (e.g., discriminant analysis, ordination techniques, factor analysis, multiple regression). Recent work has focused on multiple regression techniques that may allow the quantification of the proportion of the variance of a response (dependent) variable (e.g., tree crown defoliation) explained by various predictors (independent variables).

Relevance and Applications of Forest Health Monitoring

Relevance

Forest health monitoring programs have potential in many respects. While they were started in relation to air pollution and within that framework as a contribution to international conventions and legal mandates, now the area for application is much broader. A first advance was to place more emphasis on traditional damaging agents. More recently, forest health monitoring has been included in program related to issues such as biodiversity, carbon sequestration, long-term ecological research, and international processes dealing with SFM and long-term resource management. For the above reasons, forest health diagnosis, monitoring, and evaluation is an area of concern for politicians, decision-makers, resource managers, and scientists as well as for the public. In this perspective, progress towards integration between monitoring networks with different topics (e.g., freshwater and forests) and scale of interests (local, regional, global) can provide a considerable added value.

Forest Health Monitoring Programs

Forest health monitoring is carried out at a variety of geographical scales, from local to international. Initial development occurred in Europe and North America, where comprehensive monitoring programs were developed (**Table 8**).

Monitoring Results: Examples

The data collected by monitoring programs provided insight into different topics. Examples may include the documentation of (1) changes in tree condition, (2) the incidence of pests on forest health, and (3) the role of various natural and anthropogenic factors that may affect forest health.

Changes in tree condition The collection of data about tree condition in Europe revealed that complex patterns could occur both in space and time. The development of the condition of trees varies with the species and the region being considered. **Figure 2** shows an example related to Scots pine (*Pinus sylvestris*) in Europe. As with many environmental variables, the frequency of trees with more than 25% defoliation changes through time; it fluctuates in the Mediterranean region (rapid increase and decrease), while the trend is different for the North Atlantic

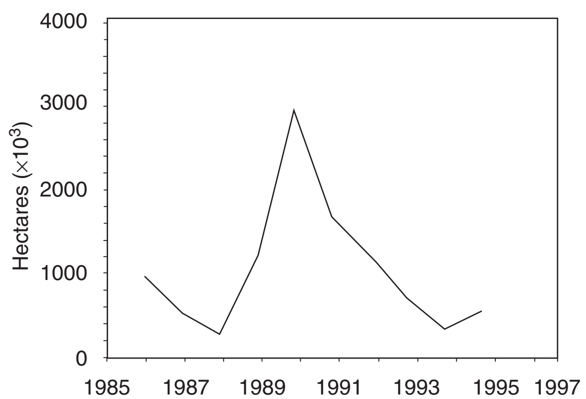

Figure 3 Area with aerially detected defoliation by gypsy moth (*Lymantria dispar*) in the USA over the period 1986–1995. Based on data by Forest Insect and Disease Condition in the US Report 1986–1995.

region, where an increase of defoliated trees was obvious only in the years 2000–2001. The interpretation of this as a directional trend needs caution, as the previous example clearly shows that it may be reversed in a few years.

Assuming that data are comparable through time and space, the data in **Figure 2** confirmed that no general decline in the health of forest was occurring: rather, the dynamics seem to be specific for individual species at certain sites or group of sites.

Incidence of pests The changes in the severity of an insect's action is exemplified by the aerial survey in the USA (**Figure 3**) which shows remarkable

variation in gypsy moth (*Lymantria dispar*) defoliation over the period 1986–1995.

Role of various natural and anthropogenic factors Data collected at the intensive monitoring sites in Europe indicate that, at many plots, the present deposition of acidifying compounds may exceed the critical load for the impact on soil; excess occurs at 45%, 65%, and 80% of sites for pine (mostly Scots pine, $n = 57$), spruce (mostly *Picea abies*, $n = 96$), and beech (mostly *Fagus sylvatica*, $n = 42$). However, the statistical studies carried out so far have confirmed that natural factors have the major role in determining forest condition at the sites concerned. Statistically significant effects of nitrogen and sulfur deposition were also detected although their role is less clear in size and direction (**Table 9**).

Biochemical and Physiological Aspects

R Ceulemans, University of Antwerp, Wilrijk, Belgium

Introduction

Forest ecosystems fulfill various functions with economic, social, and ecological significance. They also form habitat for various species of plants and animals. However, forest ecosystems are exposed to serious threats from attacks by parasites and diseases, from air pollution, fires, and climatic changes. As forests are sensitive ecosystems, they are susceptible to these disturbances, whether caused by biotic or abiotic influences. These biotic and abiotic influences could be of natural origin (such as fires, insect or pathogen attacks, and species invasion) or anthropogenically caused (such as air and soil pollution, global climatic changes, and fragmentation). In this article some physiological and biochemical aspects of tree responses and forest health will be reviewed. The contribution is focused on air pollution (in particular ozone) and climate change (in particular elevated atmospheric CO_2 concentrations) and how these relate to forest health. These two issues provide a good basis for understanding the links between biochemistry and physiology and forest health. So, the contribution is restricted to these two stress factors as they are used as examples of how trees respond to external stresses.

With regard to air pollution, various atmospheric pollutants might affect tree growth and forest health such as nitrogen dioxide (NO_2), nitrogen oxides (NO_x), ozone (O_3), sulfur dioxide (SO_2), hydrofluoride (HF_6), and hydrocarbons (such as CH_4). Air pollution can change the physical and chemical environment of forest trees. Pollutant stresses, as well as competitional, climatic and biological stresses, have important implications for forest growth and ecosystem succession because they provide forces that favor some genotypes, affect others adversely, and eliminate sensitive species that lack genetic diversity. Pollutant stresses in a forest ecosystem are superimposed upon and interact with the naturally occurring stresses that trees are already experiencing. These additional stresses can accelerate the processes of change already underway within ecosystems.

Forests and the human uses of forests and forest products have an impact on greenhouse gas concentrations in the atmosphere. There is a feedback from the climate system where forests are affected by the changes in climate, and the chemical composition of the atmosphere. Forest ecosystems and wood-based products also have the ability to sequester atmospheric CO_2 and thus offer an opportunity to mitigate climate change. However, this balance must be correctly understood, quantified, and modeled if we wish to assess the potential of forests to regulate sudden climatic changes, to improve the reliability predictions, and to reduce the uncertainty of the consequences of climatic change on forest health and forest ecosystems. As photosynthesis is the key process that all autotrophic organisms (trees, green plants, and algae) use to exchange mass and energy with the environment, this process will first be briefly reviewed.

Photosynthesis and the Importance of Nitrogen

Photosynthesis is the principal process to perform two essential transformation processes – on the one hand the conversion of high-quantity solar energy into high-quality chemically fixed energy, and on the other hand the conversion of simple inorganic molecules (CO_2, H_2O) into more complex organic molecules (sugars and carbohydrates). The harvestable product of a tree, generally the stem, depends not only on photosynthetic carbon uptake by the foliage, but also on respiration of the various organs and carbon investments into renewable organs (leaves, fine roots) and generally nonharvested organs (branches and large roots). Consequently, there is no obvious relationship between photosynthesis and wood production. A fast-growing tree generally needs high photosynthesis, but the reverse is not necessarily true. When growth is related to total net photosynthesis integrated over the entire growing season and the total light intercepting leaf area, positive relations are generally obtained. However, photosynthesis remains the principal physiological process that also closely reflects the response of a tree to abiotic or biotic disturbances.

Abiotic factors such as light, temperature, CO_2 concentration, vapor pressure deficit, and nutrient status, but also air pollution, climatic changes, and drought, have a major effect on net photosynthesis, and thus on tree growth and productivity. All environmental conditions that tend to reduce the photosynthetic rate (including low light, low temperature, low nutrient availability, and high air pollution levels) reduce the photosynthetic carbon gain. Plant water status and ozone level, for example, influence the carbon relations of a tree at the gas exchange and growth levels. Low nutrient uptake reduces the amount of nutrients available for incorporation into new living biomass. In particular, a shortage of phosphorus and nitrogen severely affects the photosynthetic capacity. In addition, the partitioning of carbohydrates will favor construction of a larger root biomass for nutrient uptake. All tree species appear to have a large degree of adaptability to the climatic conditions of their habitat at the photosynthesis level.

Nitrogen is required by trees (and all other plants) in large amounts. To a large extent, it governs the use of phosphorus, potassium, sulfur, and other nutrients. Approximately 75% of the nitrogen in a plant leaf is required for the photosynthetic machinery. In natural ecosystems, such as most forests, nitrogen is usually a growth-limiting factor. In mature forests, however, nitrogen demand can be low. Changes in the nitrogen supply of an ecosystem can have a considerable impact on its nutrient balance. Nitrogen saturation can mean that some other resource such as carbon, phosphorus or water, for example, rather than nitrogen, becomes the growth-limiting factor. There are pronounced differences in nitrogen content and in photosynthetic capacity per unit of nitrogen among tree leaves grown under different conditions of light (both quantity and quality), of soil nutrient content, and of atmospheric composition (CO_2 level, ozone concentration). Specific leaf area (i.e., the ratio of leaf area to leaf dry mass), nitrogen content, and photosynthetic quantum efficiency differ significantly among leaves grown under these various conditions.

Tree Responses to Air Pollution

General Effects of Air Pollution on Forest Health

The degree to which vital tree functions are affected by pollutants and the extent to which visible damage can be detected depend on many factors, both biotic and abiotic. The most important of these factors are the species, age, growth form, developmental phase, and general vigor of the plant, climatic and edaphic conditions, but also the chemical nature, concentration, time, and duration of action of the different pollutants. Air pollutants can act on trees in both chronic and acute ways. In several cases the effects of pollution are proportional to the product of the concentration of the air pollutants and the duration of exposure, but the relationship is only linear over a certain range. The lower limit of this range is set by the concentration threshold, below which there are no observable changes, even after prolonged exposure to pollution. At the upper limit of the range, i.e., when a certain high concentration is exceeded, even very brief exposures cause damage. The effect of pollutants also depends on the time of day when their concentrations are highest. Peak concentrations of atmospheric pollutions occurring before noon, when the stomata are usually fully open, are more harmful than if they occur during the night. On the other hand, if the trees have only been exposed to toxic fumigations (e.g., photooxidants) for a few hours during the day, the night can be a time for recovery.

The symptoms of damage are varied and usually nonspecific. The same pollutant may generate quite different effects in different species and, on the other hand, the same symptom may be produced by several different pollutants. The nature and intensity of damage caused by individual pollutants are modified by all other simultaneously active environmental and stress factors. Trees subjected to pollution suffer greater damage from drought and frost than healthy trees. Criteria for early warning of incipient pollution damage are: disturbances in photosynthesis and modified response of stomata, accumulation of pollutants in the tree, reduction of buffering capacity of tissues, reduced or enhanced activity of enzymes, appearance of stress hormones (especially ethylene), and increase or decrease of respiration activity. However, in order to evaluate a stress situation, conclusions cannot be drawn from certain symptoms alone, but response patterns based on more than one criterion should rather be considered.

Acute damages appear as erosions of epicuticular waxes on the surface of leaves or needles, e.g., as a consequence of acid effects; other acute damages due to toxic effects are chlorophyll leaching, discoloration of leaves, necrosis of tissue, dieback of shoots, or dying of the whole plant. Generally, damage of this kind only occurs in the immediate vicinity of the pollution source. Spatially restricted forest damage caused by inputs of high concentrations of sulfur dioxide (SO_2) and halogenides in the vicinity of smelting works and industrial plants is well known. On a larger scale, a decline in growth vigor and severe damage were observed in spruce forests of central Europe at the beginning of the 1970s. Supposedly, the far-reaching air pollution of sulfuric gases and the associated soil acidification due to depositions in those days were the main cause of the damage. Chronic damage leads to reduced productivity and defective fertility (e.g., pollen sterility). In trees, growth, especially cambial growth, decreases. Based on changes in the structure of the wood and on the analysis of annual tree rings, the progressive pollution injury can be tracked and dated. As a particular example the physiological and biochemical responses of trees to one specific air pollutant (ozone) will be reviewed and summarized.

The Impact of Ozone

Ozone (O_3) is formed by photodissociation of molar oxygen and by electrical discharges. Like other air pollutants, ozone can act on trees in both chronic and acute ways. In the latter case, episodes of short duration (e.g., half an hour) and rather high O_3 concentration (100 to above $200\,nl\,l^{-1}$) may cause sudden and irreversible, physiological and macroscopic injury. The proposed initial event is membrane destruction. Depending on the location and climate, such O_3 episodes may be rare events. However, at many sites in the northern hemisphere, the mean seasonal O_3 exposure over a long period is significantly enhanced above the preindustrial level. This type of ozone impact is termed chronic. Tree responses to chronic exposure can distinctly differ from those to acute impact, even though the accumulating O_3 doses may be similar. Contrasting with acute effects, responses to chronic impact may reflect acclimatization, i.e., metabolic regulation, to ozone stress, including enhanced defense and repair capacities, but also endogenous burst induction. Also, such effects may eventually become irreversible. Under most field scenarios, chronic rather than acute ozone regimes appear to be ecologically meaningful for the long-term development of trees. Therefore, experiments that have employed acute O_3 regimes may have little relevance for interpreting plant performance, in particular of long-lived plants, like trees, under the prevailing chronic ozone scenarios of given field sites.

There is evidence that ozone after passage through the stomata rapidly decomposes into secondary oxidative derivatives which themselves can be injurious to the metabolism and structure of leaves so that the concentration of ozone approaches zero in the intercellular space of the leaf mesophyll (**Figure 1**). The decay of ozone into reactive derivatives, unless already occurring during the diffusive influx process, largely occurs in the mesophyll apoplast which contains antioxidants like ascorbate that form the first line in oxidant defense. To the extent that O_3 or its derivatives reach the plasmalemma, they may link to receptors that can initiate oxidative burst reactions and programmed cell death, leading to local necroses as a means against spreading injury. Such defenses are mediated at the gene level through molecular signal chains, including the oxidative ozone derivatives, ethylene formation, as well as salicylic or jasmonic acid. As ozone hardly reaches the chloroplasts, molecular signaling is also suggested to induce the decline of chloroplasts (loss of pigments and Rubisco activity). The mechanistic nature of the receptors and signal chains has only partly been unraveled to date; however, it appears that the primary defense against O_3 is rather similar at the cellular level to responses elicited by biotic agents.

Physiological and Biochemical Defense Mechanisms

After an exposure to air pollutants such as ozone, reactive oxygen species (ROS) are primarily formed within the apoplastic fluid of tree leaves. This first reaction is similar for other external stressors (including enhanced ultraviolet B radiation and salinity stress). Most probably the antioxidative capacity within the apoplast of exposed leaves is of significant importance in determining the resistance of trees to air pollution. Therefore forest researchers, and in particular tree modelers, are eager to introduce this parameter in models describing the real ozone flux, for example. However, the apoplastic antioxidative capacity should be considered with caution as it is not entirely clear what the best parameter is to estimate this antioxidative capacity. Many apoplastic antioxidants in relation to ozone and other air pollutants have been reported in the literature and ascorbate has been mentioned the most in this regard. Indeed, experiments have indicated high reaction constants between ascorbate and, e.g., ozone, ROS and other radicals, but its relative antioxidative capacity *in vivo* is still largely unknown. Moreover, the decay of ozone through a direct reaction with cell wall ascorbate is not sufficient to explain the different degrees of ozone sensitivity of different tree species.

The capacity to scavenge ROS has been assigned to a wide variety of molecules other than ascorbate. Examples of low-molecular antioxidants are phenolics (such as ferulic acid, caffeic acid, catechol, syringic acid, and *p*-coumaric acid), polyamines, diketogulonate, and glutathione. The involvement of phenolic compounds in the sensitivity of poplar (*Populus*) to ozone has clearly been demonstrated: after a single pulse exposure of a resistant poplar clone there was a marked increase of phenolic compounds. Phenolics are present in the apoplastic fluid and play an important role in lignin biosynthesis. Lignin is a complex macromolecule that originates from the oxidative polymerization of cinnamyl alcohols as the principal monomeric units. The question remains: how efficient are phenolic acids, compared to ascorbate, in scavenging ROS? Generally, this question remains

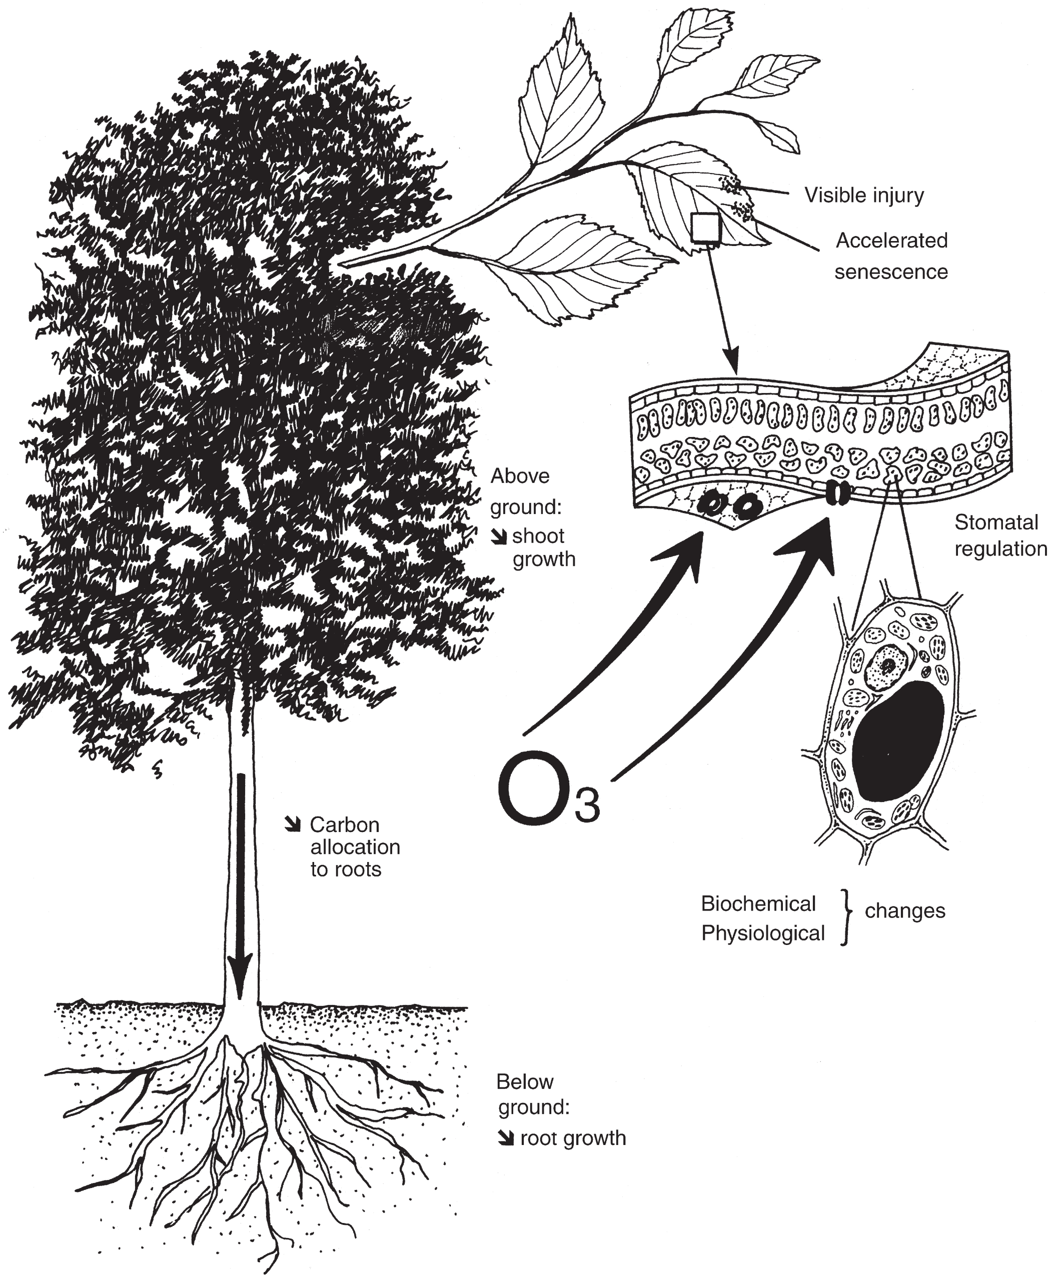

Figure 1 Schematic diagram of the impact of tropospheric ozone (O_3) on different physiological and biochemical processes at various hierarchical levels of organization. Ozone that enters the leaf through the stomatal pores alters different physiological and biochemical processes inside the leaf and the cells, but also affects a range of other functions and structures. *Environmental Pollution and Plant Responses* by Bortier K, Ceulemans R, and De Temmerman L. Copyright 1999 by CRC Press Inc. Reproduced with permission of CRC Press Inc.

unanswered, but a few naturally occurring components seem to have larger instantaneous antioxidative power than ascorbate (e.g., diketogulonate, ferulic acid, *p*-coumaric acid, gallic acid, resveratol, and quercetin). Because electronic transfer can take place between ascorbate and other antioxidants (e.g., phenolic acids), possible synergistic effects should be further considered in the future.

Climate Change Effects on Forest Trees

Role of Forests in the Global Carbon Cycle

In terms of carbon storage and cycling, forests represent the most important vegetation type on the earth. Although forests cover around 30% of the land area of the globe, they accomplish a disproportionately large part of the terrestrial bioproductivity

(65%), i.e., forests fix worldwide more or less 25 Gt of carbon per year. By their perennial character and longevity, forest ecosystems contain 80–90% of the above-ground plant carbon and 60–70% of the soil carbon on the globe. As such, they contain over 60% of the carbon stored in the terrestrial biosphere. So, forest ecosystems make up a stock of nearly 500 Gt of carbon in their biomass and a stock of nearly 700 Gt of carbon in the necromass, essentially under the form of organic matter in the soil. This impressive mass illustrates the buffering role that ecosystems can play in view of the additional carbon flux generated by the use of fossil fuels, by deforestation, and by changing land use. Apart from their significant role in the development of rural areas, forests have a major value for nature conservation, play an important role in preserving the environment, and represent a critical controlling factor of the hydrological cycle. However, forests are also key elements of the carbon cycle and represent significant carbon sinks.

The net carbon exchange of terrestrial ecosystems is the result of a delicate balance between uptake (photosynthesis) and losses (respiration and decomposition), and shows a strong diurnal, seasonal, and interannual variability. Under stable conditions, during daytime the net ecosystem flux is dominated by photosynthesis, while during the night, and for deciduous ecosystems in leafless periods, the system loses carbon by respiration. The total amount of carbohydrates produced in a forest canopy by photosynthetic carbon fixation is the gross primary productivity (GPP). Part of the produced carbohydrates is lost through autotrophic leaf respiration, while the rest is allocated from the leaves to other (tree) organs where it can be used for the construction of biomass or for metabolism and then respired as CO_2. The total amount of carbon incorporated in the biomass is the net primary productivity (NPP). The present atmospheric concentration of CO_2 limits the ability of forest trees to fix carbon. As tree photosynthesis is highly sensitive to atmospheric CO_2 and as NPP is strongly related to net photosynthesis, a stimulating effect of elevated CO_2 on NPP might be expected, provided that nutrient conditions are not limiting.

Tree Responses to Elevated Atmospheric CO_2

Because of the dependence of photosynthetic carbon fixation on the atmospheric CO_2 concentration, any increase in CO_2 tends to enhance the rate of assimilation and therefore plant growth. The reason why net photosynthesis may be enhanced is related to a number of factors connected to the characteristics of the primary carboxylating enzyme (i.e., Rubisco). Woody plants, when exposed to elevated CO_2 for varying periods of time, show not only stimulated photosynthesis, but also increased growth rate and biomass accumulation. Experiments on field-grown trees suggest a continued and consistent stimulation of photosynthesis of almost 40–60% for a doubling of the atmospheric CO_2 concentration and there is little evidence of a long-term loss of sensitivity to CO_2 that has been suggested by earlier experiments with tree seedlings in pots. Such an increase in photosynthesis translates into a 38% and 63% average increase in the biomass of coniferous and deciduous species, respectively. The relative effect of CO_2 on above-ground dry mass of field-grown trees is, however, highly variable and larger than that on seedlings or young saplings. Despite the importance of respiration to a tree's carbon budget, no strong scientific consensus has yet emerged concerning the potential direct or acclimation response of woody plant respiration to CO_2 enrichment. Effects of CO_2 concentration on static measures of response are often confounded with the acceleration of ontogeny observed in elevated CO_2.

A more robust and informative measure of tree growth in field experiments is the annual increment in wood mass per unit leaf area, which increases on average by 27% in elevated CO_2. There is no support for the conclusion from many studies of seedlings that root-to-shoot ratio is increased by elevated CO_2; the production of fine roots may be enhanced, but it is not clear that this response would persist in a forest. In general, nitrogen shortages are easily induced by accelerated growth in elevated CO_2, which could cause lower concentrations of nitrogen in leaves. Lower foliar nitrogen concentrations in CO_2-enriched trees result in larger attacks by herbivorous insects, an important contributor to fluxes of carbon and nitrogen in forest ecosystems. Experimental observations of lower nitrogen in leaves of trees grown in elevated CO_2 led to the suggestion that the behavior of herbivores feeding on those leaves is indeed affected. Although CO_2 effects on herbivory could have important ramifications for forest health, forest productivity, and nutrient cycling, there is not yet any framework for integrating the experimental observations with the population dynamics of the insect, as would be necessary for an assessment of the impact on ecosystem productivity.

Various climate models predict an increase in CO_2 emissions in the atmosphere and, simultaneously, an increase in the earth's temperature. Much of what we know about the contemporary global carbon budget has been learned from careful observations of the atmospheric CO_2 mixing ratio and the $^{13}C/^{12}C$ isotope ratio, interpreted with global circulation models. From these studies we have learned: (1) that about one-third of the annual input of CO_2 to the atmosphere from fossil fuel combustion and deforestation is taken up by the terrestrial biosphere; and (2) that a significant portion of the net uptake of CO_2 occurs at mid-latitudes of the northern hemisphere and that, in particular, north temperate terrestrial ecoystems (mainly forests) are implicated as a large sink. The method of stable isotope ratios combined with global circulation models provides the necessary global and continental scale perspectives for carbon balance calculations, but their use in addressing small temporal and spatial changes in the carbon balance is rather limited.

Over the last 200 years the flora of the earth has experienced a 28% rise in CO_2 concentration, having been progressively adapted to a CO_2-poor atmosphere for 20–30 million years. If current anthropogenic CO_2 emissions are not reduced and the rate of deforestation not slowed down, plants growing in the year 2040 will be exposed to around 500 ppmv CO_2, in contrast to the current levels of around 358 ppmv. The extent to which terrestrial ecosystems act as carbon sinks to buffer the increase in atmospheric CO_2 concentration (through enhanced NPP) is uncertain. However, the importance of forests and their interactions with climate are considerable, since trees account for nearly 65% of the terrestrial atmospheric CO_2 fixation. Their long life and large dimensions make them a considerable sink on carbon store on the earth. Evidence that past increases have directly affected trees is limited. Tree ring analysis and surveys of leaf chemical composition of leaves of herbarium specimens of 1750 AD revealed some important changes; the study of plant communities growing close to natural CO_2 sources has recently provided interesting and relevant information.

Actions to Monitor and Protect Forest Health

Worldwide actions have been and are being undertaken both to monitor and protect forest health. For example, European Community (EC) action has been developed over the years in cooperation with International Co-operative Programme on Assessment and Monitoring of Air Pollution Effects on Forests (ICP) and in line with objectives formulated in ministerial conferences on the protection of forests in Europe and the United Nations Conference on Environment and Development (UNCED, Rio de Janeiro, 1992). In January 2003 a proposal for a European Parliament and Council regulation (2003/C 20 E/10) was presented for the establishment of a new EC scheme on the monitoring of forests and environmental interactions to protect EC forests. The protection of forest ecosystems is a major concern to the EC. The main objective of the EC action is to contribute towards the protection of forest ecosystems in the EC by monitoring the conditions of these ecosystems. The EU and its member states are committed to the protection of forests and to the sustainable management of forests in all relevant pan-European and international processes related to forests. Forest ecosystem conditions, changes of these conditions, the reaction of forest ecosystems to environmental stress, and the effects of policies can only be traced by means of monitoring. Changes in forest ecosystem condition as well as the reasons for these changes may be recognized at an early stage, thereby allowing the adoption of timely and appropriate measures. The monitoring of air pollution and global change effects on forests will be carried out on a systematic network of observation points, which covers the whole Community, and a network of intensive monitoring plots. The systematic network provides representative information on forest conditions and changes. Intensive monitoring in selected plots allows for indepth monitoring activities in order to observe ecosystem processes. The intensive monitoring plots and the monitoring on the systematic network of points thus complement each other.

Integrated Pest Management Principles

M R Speight, University of Oxford, Oxford, UK
H F Evans, Forestry Commission, Farnham, UK

Introduction

Integrated pest management (IPM) has a variety of definitions, but its philosophy is simple. For a particular crop–pest interaction, one or more appropriate pest management tactics are combined into a package which minimizes costs and environmental impacts, whilst maximizing yields and net profits. Its two bedrock foundations are prevention and monitoring, i.e., strive to avoid pest problems at the outset, but keep a watch on the crop in case something significant goes wrong. IPM is a concept which is now widespread through all types of crop production, and it is increasingly the goal of any grower who loses yield, both quantity and quality, to damaging organisms such as weeds and nematodes, pathogens, and insects. As a practical crop protection solution, IPM is far from universal – it is often difficult, indeed sometimes impossible, to produce a viable IPM package. Problems which arise to curtail the full implementation of IPM include pest dynamics, host-plant and climate interactions, the practicalities of crop production, and very often, the socioeconomic conditions prevalent in the region of interest.

Forestry covers a very broad range of crop production tactics, from small-scale village forestry or agroforestry to huge plantations, either artificial or, at least initially, naturally occurring. Countries practicing forest management range from small, subsistence, isolated economies with little or no infrastructure to deliver education, specialist advice or spare cash to implement modern pest management protocols, to highly developed first-world countries to whom all the benefits of science and technology are theoretically available. Trees are grown from the furthest north and south temperate regions of the world to the equator, and from below sea-level to thousands of meters above sea-level. The trees themselves may be indigenous, native species growing in natural conditions to which they have evolved, or alternatively, they may be complete exotics with not even members of the family growing as natives in the locale, planted on sites which bear little or no relation to the conditions to which these trees evolved thousands of miles away. Nevertheless, many forestry practices and their associated pests and diseases have basic similarities, principles, and interactions, wherever in the world they occur.

In this section, insect pests will be discussed, but it must be borne in mind that many of the principles and indeed examples presented have a great deal of relevance to other forest pest situations, fungal diseases in particular. In fact, the modern approach to forest pest management is frequently not to target particular pests or diseases at the outset, but instead to employ the concept of general plant health and thus consider the widest range of symptoms and their underlying causes for tree decline and debilitation.

Insect Pests and Their Impacts

It is extremely helpful to consider trees as but one part in a complex ecology which has evolved over millions of years. Other crucial members of this association are at one end of the spectrum the environment in which the tree is growing (soil, climate, altitude), and at the other end, insects and diseases which utilize the tree for food or living space (or usually both). These herbivores themselves often have their own enemies in the form of predators, parasites, and pathogens, and the forester is simply one of these competitors for the resources which the tree provides. Unfortunately, this competition is very one-sided, especially in economic terms, since foresters cannot tolerate much, if any, resource removal by others – pests and diseases have to be defeated.

Paramount in this war to defeat the competition is the concept of impact. The actual harm done to a tree by an insect is frequently very difficult to assess. Heavy leaf loss may not be extreme when averaged over the life of the tree, especially when the trees are grown for many decades, whereas boring in the

Table 1 Pest types – defoliators

Insect groups
Larvae of moths (Lepidoptera) and sawflies (Hymenoptera), nymphs or larvae, and adults of grasshoppers (Orthoptera) and beetles (Coleoptera)
Activity
Leaves can be eaten partially or entirely, or the epidermises between the veins removed (skeletonization or leaf mining)
Primary impact
Main impact involves the removal of photosynthetic area, with a very wide range of deleterious effects. These include shoot, stem, and root growth loss, reductions in height and volume increment, reduction or cessation of flowering or seed set. Growth losses may be temporary, such that the tree reflushes foliage after an isolated defoliation event and growth returns to normal, or after extended and repeated bouts of defoliation, the tree dies. Actual impact losses are often impossible to quantify economically
Secondary impact
Tree vigor is considerably reduced and natural defenses against herbivores diminished, resulting in attacks by secondary pests such as boring Lepidoptera or Coleoptera. Trees can be killed in a short time by ring barking or girdling
Main examples
Teak defoliator moth, *Hyblaea puera* (India, South Asia, Southeast Asia), nun moth, *Lymantria monacha* (Eastern Europe), pine sawfly, *Neodiprion sertifer* (Western Europe)
See **Figures 1** and **2**

shoots or wood may not be a cause for concern if the tree can still survive and produce a marketable product. In particular, if pest management tactics have a financial implication (and they usually do), then, in order to calculate a realistic cost/benefit analysis, it is crucial to have some quantitative notion

Figure 2 Pine sawfly.

Table 2 Pest types – sap-feeders

Insect groups
Nymphs and adults of bugs (Hemiptera, especially Homoptera; aphids, psyllids, scale insects, mealybugs)
Activity
Removal of phloem or, less commonly, xylem sap or plant cell contents using piercing mouthparts from leaves, shoots, stems, or roots. Note that sucking is a common misnomer for many sap-feeders–relatively high internal plant pressure negates the need to suck
Primary impact
Removal of primary production synthates and organic nitrogenous compounds from the tree and hence a significant reduction in yield resulting in the same losses as defoliation. There may also be direct loss of foliage arising from a wound reaction to injection of saliva by the feeding insect
Secondary impact
Local or widespread leaf mortality and loss, with same consequences as chewing defoliation. Shoot and stem feeding also causes bark necrosis and damage, allowing invasion of inner tissues by pathogens such as fungi
Main examples
Cypress aphid, *Cinara* spp. (South and East Africa), Leucaena psyllid, *Heteropsylla cubana* (pan-tropical), spruce aphid, *Elatobium abietinum* (Western Europe)
See **Figures 3** and **4**

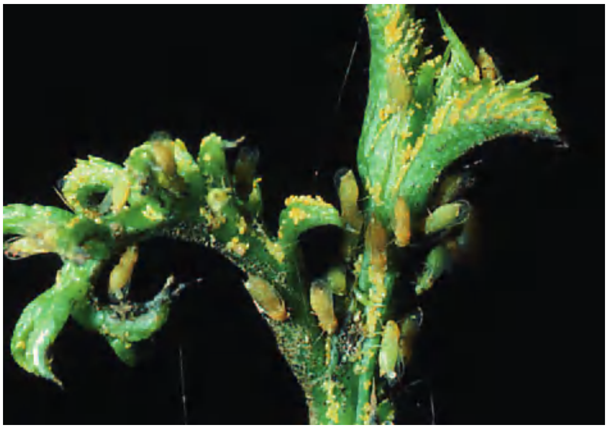

Figure 3 Leucaena psyllid.

of how much economic damage is being done to see if control, if possible at all, is cheaper. In forest situations in particular, this knowledge is frequently lacking or at least inadequate, and many countries now have active research programs involving long-

Table 3 Pest types – shoot-borers

Insect groups	Larvae of moths (Lepidoptera – Tortricidae, Pyralidae; shoot-borers, tip moths) and larvae and adults of beetles (Coleoptera – Scolytidae – shoot beetles)
Activity	Tunneling inside growing shoots, usually leaders followed by secondaries. Tunnels become larger and more elongated as the insect grows and develops
Primary impact	Death of attacked shoot, followed by cessation of growth in very young trees, or the new dominance of one or more secondary shoots in older saplings. Trees become distorted, bushy, and dead-headed
Secondary impact	Production of straight, non-forked logs prevented. Expected dominant height not achieved
Main examples	Mahogany shoot-borer, *Hypsipyla* spp. (pan-tropical), pine shoot moth, *Rhyacionia* spp. (Southeast Asia, North and Central America, Western Europe), pine shoot beetle, *Tomicus piniperda* (Western Europe)
See **Figures 5** and **6**	

term monitoring to provide impact data related to pest density. As might be expected, such data are only likely to be available for a minority of tree/insect associations, and then mainly in developed countries.

Insects which have evolved to utilize tree resources can be split into several distinct types. The major types are sap feeders, defoliators, bark feeders, shoot borers, bark borers, wood borers, and root feeders. The methods which they employ to exploit tree resources, and the tactics available to foresters to defeat them, vary according to their behavior and ecology. **Tables 1–7** present the main characteristics of these types of pests, together with examples of some major forest pests from each category.

Reasons for Outbreaks

The IPM of forest insects must be considered to be a preventive technique first and foremost. For ecological, economic, technological, and social reasons, it is frequently impossible to control a pest outbreak or eradicate a damaging species even locally once the damage has begun, and so it is vital to grow trees, whether at a local agroforestry level or in an industrial plantation, in ways that reduce the probability of serious pest incidence. The first stage in this preventive strategy involves developing a sound knowledge of why insect pest outbreaks occur. Armed with this knowledge, foresters and economists can, if they choose, grow trees using methods which avoid such occurrences. Of course, it may be that a tactic which is well known to increase the likelihood of pest (and disease) problems, such as intense monocultures, is essential to sound silvicultural practice, and hence

Figure 5 (a) Shoot moth damage. (b) Shoot moth larva.

cannot be avoided. **Table 8** considers tree health and its decline, as major predisposing factors to insect and disease outbreaks, whilst **Table 9** itemizes forest management tactics known to exacerbate pest problems for even healthy trees. Note that various items in both tables are interlinked and overlap; **Figure 15** provides a flowchart which attempts to link various aspects of tropical forestry which can result in pest problems.

Some of the factors presented in the tables will be considered in more detail here.

Tree Species Resistance and Site Matching

Of all the predisposing or avoidable problems mentioned in these tables, two related items stand out as fundamental to promoting and preserving tree health and reducing pest or disease attack. These are: (1) tree species and site-matching (essentially environmental); and (2) the use of resistant or nonsusceptible tree species or genotypes (essentially genetic). Put simply, even if a tree which is genetically resistant to an insect or a fungus is chosen, it may still be rendered prone to attacks by planting it in a place where the soils and/or climate are unsuitable. On the other hand, if a susceptible tree species or genotype has to be used for sound economic reasons, then planting it in a habitat where its health and vigor will be optimal may enable resulting pest problems to be tolerated. The type of pest also has an influence here. Sap-feeders and stem, shoot, or bark borers seem to be particularly influenced by tree stress or lack of vigor in the host, whereas defoliators are less predictable. Defoliators may be deterred, however, if a tree genotype is basically disliked or rejected by a potential pest, irrespective of where it is planted.

Figure 6 Pine shoot beetle damage.

Table 4 Pest types – bark feeders

Insect groups
Larvae of moths (Lepidoptera – Cossidae and Indarbelidae), termites (Isoptera), adult weevils (Coleoptera – Curculionidae)
Activity
Larvae or adults feed on bark material, excavating shallow tunnels which may reach to the inner layers. Broad, irregular patches of bark can be excavated. Young trees may have bark stripped completely
Primary impact
Local bark necrosis; girdling and death of young transplants in the case of weevils. Most visual activity of termites such as earthen tunnels up trees from the soil is not life-threatening; only dead bark or wounds are targeted
Main examples
Subterranean termites (e.g., *Odontotermes*) (Asia-Pacific), pine weevil, *Hylobius abietis* (Western Europe)
See **Figures 7** and **8**

Figure 7 Termite galleries.

Figure 8 (a) *Hylobius abietis* (b) *Hylobius* damage.

A final problem may concern long-term changes to the environment, wherein host-plant or mortality factors which normally reduce outbreaks to tolerable levels break down, rendering a crop much more difficult to grow economically. One example involves the green spruce aphid, *Elatobium abietinum*, in the UK, where the incidence of cold snaps in late winter is the only significant mechanism for checking

Table 5 Pest types – bark-borers

Insect groups	Larvae and adults of beetles (Coleoptera – Scolytidae, Platypodidae, Cerambycidae, Buprestidae; bark beetles, ambrosia beetles, longhorn beetles, flathead borers)
Activity	Adults lay eggs on bark surface or in maternal galleries excavated in the bark at the parenchyma/sapwood surface. Larvae ramify through inner bark in usually solitary tunnels which expand as the larvae grow. Pupation occurs at the end of the tunnel or within the wood and new adults emerge through characteristically shaped holes in bark. Nonvigorous trees are more likely to be attacked
Primary impact	Species-specific patterns of engraving of galleries on sapwood which, if extensive, causes ringbarking (girdling of tree and hence death). Dead trees then become breeding sites for more beetles of the same or different species
Secondary impact	Production of large numbers of new-generation adults that may overcome defenses in even healthy trees (mass outbreak). Note that attack by secondary pests can be indicative of general tree decline and ill-health, linked to climate or site mismatches, pathogens, soil conditions, overcrowding, and so on
Main examples	Acacia longhorn beetle, *Xystrocera festiva* (Southeast Asia), eucalyptus longhorn, *Phoracantha semipunctata* (pan-tropical, Mediterranean), European spruce bark beetle, *Ips typographus* (continental Europe), southern pine beetle, *Dendroctonus frontalis* (USA)
See **Figures 9–11**	

population upsurges. Warmer winters, for whatever climatic reason, are now allowing the pest to cause much more damage to the widely planted but genetically susceptible Sitka spruce.

One example which encompasses both environmental and genetic factors involves the eucalyptus longhorn beetle, *Phoracantha semipunctata* (Coleoptera : Cerambycidae). This species is a native of Australia, but has now spread to most parts of the tropical, semitropical, and warm temperate parts of the world where eucalyptus is grown, including Asia, Africa, southern Europe, and the USA. Adult female beetles seek out trees whose bark moisture contents are reduced – larvae cannot survive in hosts with high bark moisture. Some commercial species of eucalypt such as *Eucalyptus grandis* are known to be drought-intolerant, in that they grow poorly on dry soils and should therefore be inappropriate for planting on arid sites in low-rainfall conditions or at or near the tops of slopes, and so on. Such tree species seem to exhibit low bark moistures in general, and although they may be able to withstand attacks by *Phoracantha* in relatively high rainfall areas, in drier conditions the beetle larvae thrive under the bark, killing large numbers of trees. The logical approach to the prevention of this pest is (1) to plant *Eucalyptus* species which are naturally drought-tolerant; and (2) if drought-intolerant ones are required for silvicultural reasons, only put them on sites with moist soils in climates without a prolonged dry season.

Pest Reservoirs

Even when relatively resistant tree genotypes are to be utilized, and the sites in which they are to be planted are essentially suitable for them, it is possible to increase pest risks. In the case of pine shoot moth outbreaks in Southeast Asia, it was clear that the most serious damage to tropical pines caused by the tunneling larvae of *Dioryctria* and *Rhyacionia* species occurred when the young plantations were established in close proximity (literally mere tens of meters) to naturally occurring stands of indigenous *Pinus* species. The latter trees were relatively lightly attacked by the pest, but the insects quickly discovered the exotic trees, which were not only more suitable but also planted in large, even-aged stands on very poor soils. The resulting damage to leading shoots caused a reduction in expected dominant height at 10 years old of 25+ m down to a non-economic 5–6 m at the same age.

Trees of the same species within the same stands can also act as pest reservoirs, especially when

Table 6 Pest types – wood-borers

Insect groups
Larvae of moths (Lepidoptera – Hepialidae, Cossidae (goat and swift moths)), larvae of woodwasps (Hymenoptera – Siricidae); larvae of beetles (Coleoptera – Cerambycidae (longhorn beetles), Buprestidae (flathead borers)), termites (Isoptera)

Activity
Larvae tunnel from the outside, frequently leaving a telltale wound or exudation point on the bark surface. Tunnels extend either within the surface timber, or in the center of the heartwood

Primary impact
Serious degrade of timber. Note that, in most cases, the tree itself remains healthy, only the economic value is degraded. With termite attack, ingress is normally only through previous physical damage such as pruning wounds, or after primary fungal infection. Almost all woodwasp and beetle attack is secondary, following tree stress

Main examples
Beehole borer, *Xyleutes ceramica* (South Asia, Southeast Asia), woodwasp, *Sirex noctilio* (Europe, New Zealand, Australia), pine sawyers, *Monochamus* spp. (worldwide in temperate forests)

See **Figures 12** and **13**

Figure 12 Woodwasp.

Figure 13 Xyleutes larvae.

outbreaks are, initially at least, localized to small pockets of damage or death. These small pockets provide new colonists which spread into the surrounding forests, causing much more widespread and serious damage. One example of this involves the mountain pine beetle, *Dendroctonus ponderosae,* in the USA and Canada. Larvae feed and grow under the bark of lodgepole pine trees; when they are sufficiently abundant, their tunneling ring barks (girdles) the host tree which dies, providing, incidentally, ideal breeding sites for a large number of

Table 7 Pest types – root-feeders

Insect groups
Termites (Isoptera), larvae of beetles (Coleoptera – Scarabaeidae (white grubs or chafers), Curculionidae (vine weevils)), larvae of moths (Lepidoptera – Noctuidae (cutworms))
Activity
Roots of very young transplants most frequently eaten whole or have bark removed. Some tree genera such as *Eucalyptus* are more susceptible than others
Primary impact
Small trees wilt, die back, and die soon after planting, particular problems in forest nurseries
Secondary impact
Older trees may be attacked following root deformation or damage earlier in life (as in nursery handling)
Main examples
Subterranean termite, *Coptotermes curvignathus* (Asia-Pacific), white or curl grub, *Lepidiota* spp. (Australia), vine weevil, *Otiorhynchus sulcatus* (Europe)
See **Figure 14**

secondary pests. Low-level (endemic) populations of mountain pine beetle persist in one or two stressed trees per stand until numbers build up sufficiently to

Table 8 Reasons for insect pest outbreaks – tree health decline

Attack by a primary pest
Damage at nursery stage
Dry soil
Infection by a primary pathogen
Natural disasters (fire, drought, wind)
Old age
Overcrowding
Poor soil
Waterlogged soil
Wrong site/species matching

Table 9 Reasons for insect outbreaks – detrimental management tactics

Damage during growth (e.g., pruning or brashing)
Introduction of exotic pests by travel and trade
Mishandling in nursery
Monocultures
Planting near to pest reservoirs in older and/or natural stands
Poor match between tree and site/climate leading to tree stress
Provision of pest reservoirs in thinnings or logs
Underthinning
Use of susceptible species or genotype

overcome the resistance of healthier, large-diameter trees in the vicinity. Outbreaks then ensue as groups of infested trees form bigger patches until most of the stand is infested and all the trees are killed.

Handling Damage

There are various stages in the growth of a forest crop when hands-on intervention is called for. This can start in the nursery, continue into young plantations, and still be prevalent as far as harvest and beyond. For example, it is very easy to damage the roots of nursery stock by rapid and rough transplanting. Root curling is a common problem which, whilst not serious enough at the outset to prevent vigorous young trees establishing in a plantation, can lead to early root decline, secondary pest attack, and tree death, as in the case of *Acacia mangium* in Sabah. Pruning and brashing are frequently called for as the young forest grows, and untrained or careless actions can provide ideal sites for the ingress of insects such as termites, and other problems such as fungal pathogens. Later, stands need thinning to reduce competition between trees. Certainly, the maintenance of tree vigor by thinning is a significant factor in reducing susceptibility to pests, but it is important not to leave thinned timber lying within stands or even in adjacent log piles, for fear of new pests breeding and proliferating in the debris. Examples include the massive increase in bark beetles, especially the highly damaging spruce bark beetle, *Ips typographus,* in Europe after wind storms. In such cases the wind-felled trees act as breeding resources for pioneer beetles that build up to sufficient numbers to attack and kill the remaining healthy standing trees. Forest hygiene is, therefore, another form of preventive pest control. Finally, when the trees are eventually harvested, damage to remaining trees by logging or skidding damage must be avoided, and log piles must not remain for any length of time close to younger plantations. Felling only when a market is ready to receive the produce can avoid the risk of mass outbreaks of pests such as bark beetles and longhorns.

Practices which increase the risk of pest outbreaks can be avoided under the general heading of ecological (or silvicultural) control, which is summarized in **Figure 16**.

Interventionist Management Tactics

Prevention is thus much better than cure, but is unfortunately not entirely dependable. As mentioned above, defoliators in particular are less influenced by attempts to grow the healthiest trees, and various ‘risky’ strategies such as growing monocultures of exotic tree species on poor soils may be unavoidable logistically and economically. Appropriate management tactics differ for different types of insect pest, and actual ‘hands-on’ control of insects and indeed diseases is often not a viable option. However, recourse may be made to more interventionist tactics if available. These may either be in the form of longer-term, semipermanent control using natural enemies of pests in biological control, or the short sharp tactic of employing various types of pesticides, biological or chemical, in response to an acute outbreak.

Inspection and Quarantine

Almost all countries in the world take part in some form of trade in trees, timber, and/or wood products. The movement of such material from one region of the world to another, especially across international borders, is an ideal way of spreading forest pests. There are classic examples of forest pests being introduced deliberately into new countries, such as the gypsy moth, *Lymantria dispar*, into the USA from Europe in the 1880s to form a new silk industry, but **Table 10** shows some examples of pests introduced by accident. Hence, a vital part of IPM for forest insect pests these days is a routine but efficient system of inspection at docks and harbors to prevent such imports, to quarantine infested material, and to seek out and destroy imports already arrived and potentially dangerous.

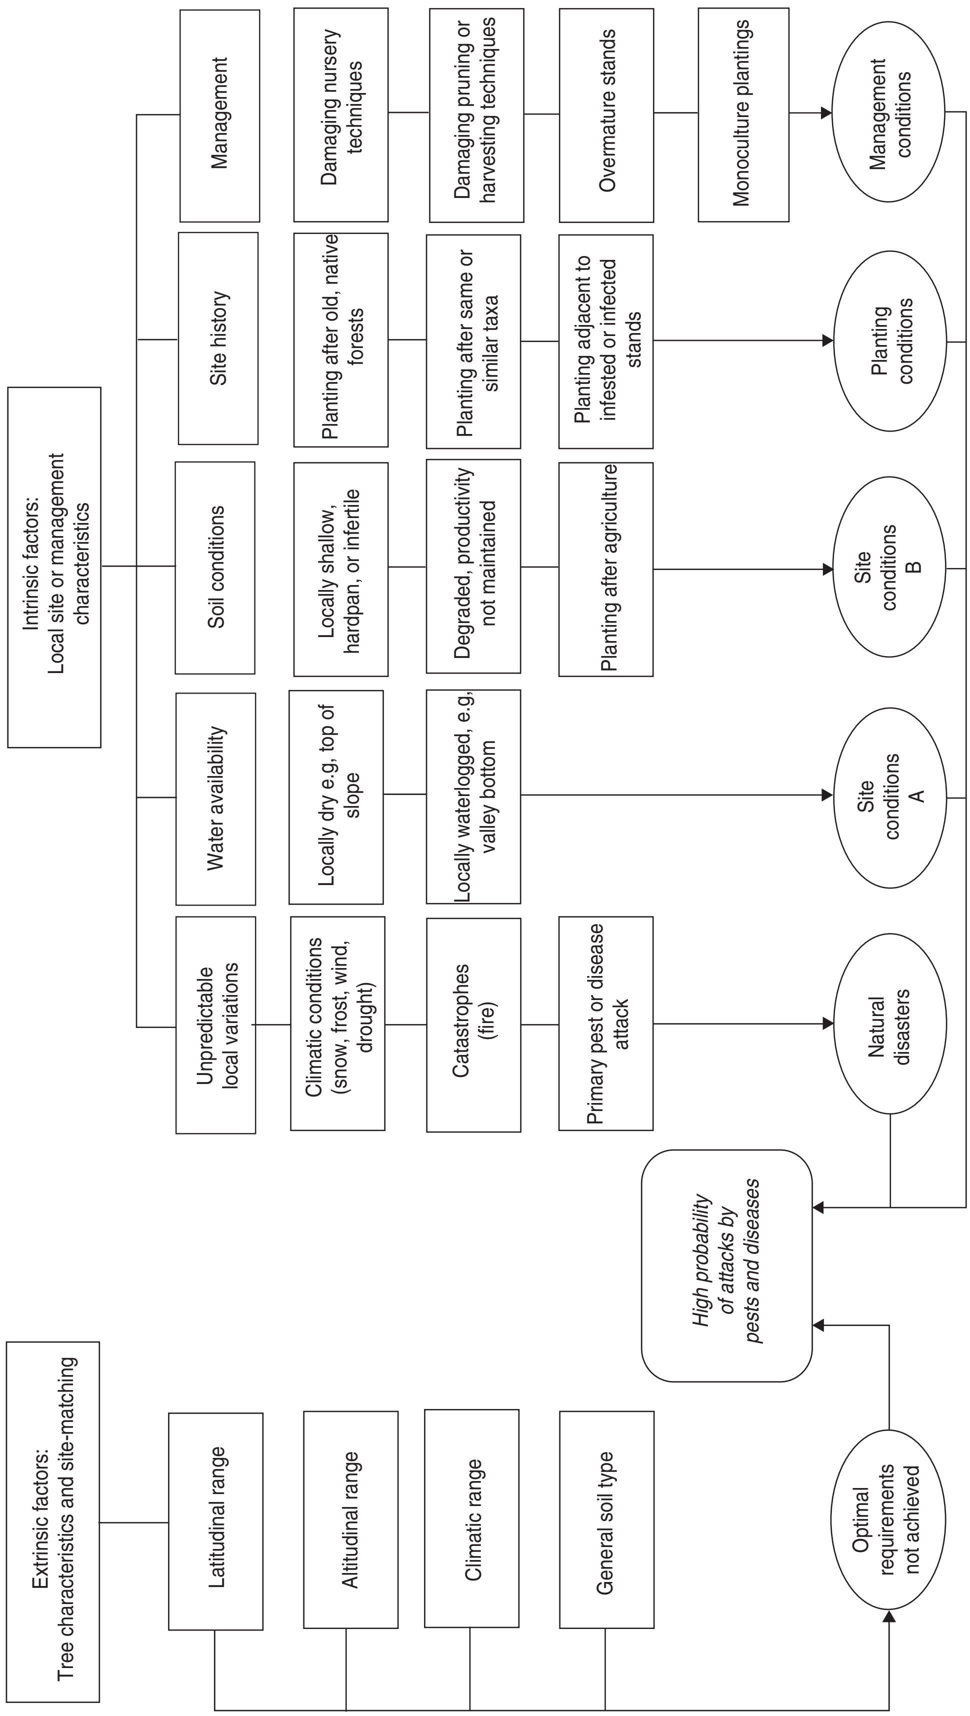

Figure 15 Factors which increase the risk of trees being attacked by pests and diseases.

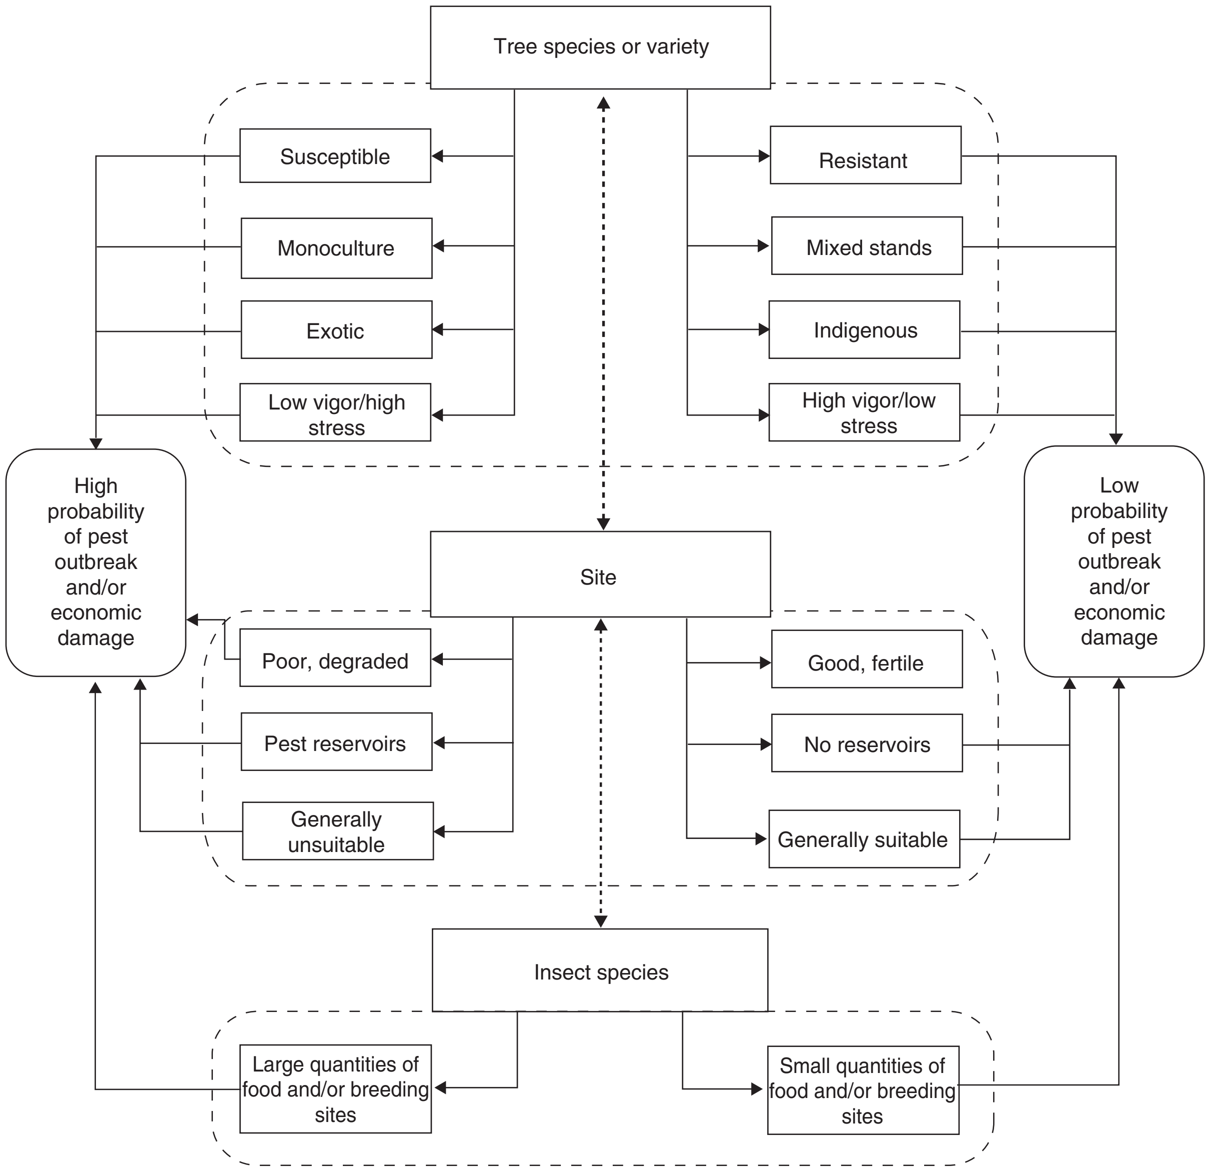

Figure 16 General flowchart depicting the 'rights and wrongs' of ecological control.

Table 10 Examples of forest pests introduced from one country to another

Pest	*From*	*To*	*Method*
Gypsy moth (*Lymantria dispar*)	Europe	USA	Egg masses on wheels and chassis of returning army trucks
Bark beetles (Scolytidae)	South Africa	St Helena	Bark beetles in the timber of food packing cases
Asian longhorn beetle (*Anoplophora glabripennis*)	Asia	USA	Larvae carried in solid wood palettes and crates
Spruce bark beetle (*Ips typographus*)	Continental Europe	UK	Adults in packing, bark, debris, 'wainy edge' on saw timber
Termites (Isoptera)	Asia	New Zealand	In processed timber products such as chopsticks
Pine woolly aphid (*Pineus pini*)	Australia	South Africa	On imported pine seedlings
Eucalyptus snout weevil (*Gonipterus scutellatus*)	Australia	USA	Aircraft stowaways
European pine woodwasp (*Sirex noctilio*)	Europe	Australia	Larvae inside miscellaneous wood and timber material

Biological Control

In theory, the use of natural enemies of forest insect pests to regulate their numbers below a level where damage is economically important is a very useful strategy. Predators such as birds, small mammals, and especially other insects seem to consume large numbers of lepidopteran larvae or aphids, whilst more host species-specific parasites (parasitoids) in the insect orders Hymenoptera and Diptera can reduce the densities of pests considerably. The problem, however is that in many cases this reduction in percentage mortality is insufficient either to prevent significant damage or to reduce existing outbreaks sufficiently. Put very simply, the reasons behind the outbreak where clearly the pest is being very successful for one reason or another tend to outweigh the ability of the enemies to make serious inroads into the pest population until most of the pest's food, such as foliage, has disappeared. By then, of course, it is too late for pest management to prevent significant losses. In the case of forestry, unlike many situations in agriculture and horticulture, there are relatively few pest management success stories for biological control using predators or parasitoids of insect pests. Major limitations include the sheer size of forest stands, the fact that many pests are concealed in bark wood or soil, and that many forest pest outbreaks occur because the odds are stacked in favor of the pests, as indicated earlier. However, **Table 11** shows some examples where at least partial success has been achieved.

Biological control in forest pest management has a better track record when considering the potential of insect pathogens. Bacteria, nematodes, viruses, and fungi have all been shown to have real success in pest management in other types of crop production, and for certain groups of forest pests, the defoliators in particular and possibly some of the shoot-borers and stem-feeders, pathogens show promise. **Table 12** summarizes the various types of pathogen, and shows how they are or may be employed. The most widespread pathogen at the moment is *Bacillus thuringiensis*, which is used in much the same way as a conventional insecticide. Major forest areas in North America, for example, are routinely sprayed from aircraft with *B. thuringiensis*, targeting pests such as gypsy moth, *Lymantria dispar,* and, in particular, spruce budworm, *Choristoneura fumiferana*. For the future, nematodes are showing a great deal of promise for the control of pests such as root

Table 11 Insect enemies as biological control agents in forestry

Enemy type	*Pest insect*	*Country*	*Biological control*
Predator	Great spruce bark beetle (*Dendroctonus micans*)	UK	Specific predatory beetle, *Rhizophagus grandis*, introduced from continental Europe; success in 5–10 years
Predators and parasitoids	Golden mealybug (*Nipaecoccus aurilanatus*)	Australia	Severe damage to hoop, bunya, and kauri pines reduced by a combination of 10 or so indigenous natural enemies
Parasitoid	Web-spinning larch sawfly (*Cephalcia lariciphila*)	UK	Fortuitous appearance of *Olesicampe monticola* in UK; success in 3–5 years
Parasitoid	Cypress aphid (*Cinara* spp.)	East Africa	*Pauesia juniperorum* released and dispersed over large areas of Kenya and Malawi; significant reductions in pest damage predicted

Table 12 Insect pathogens as pest control agents

Pathogen	*Pests*	*Limitations*
Fungi, e.g., *Metarhizium*, *Beauveria Entomophthora*	Pine shoot-borers, termites, white grubs (scarab larvae), defoliating Lepidoptera	Moist conditions required; concealed pests may not encounter spores
Bacteria, e.g., *Bacillus thuringiensis*	Defoliating Lepidoptera, some Coleoptera	Bacterial toxins must be ingested (eaten); some commercial formulations are relatively expensive; nonpersistent; no proliferation in environment; application problems
Nematodes, e.g., *Steinernema*, *Heterorhabditis*, *Deladenus*	Root- and stem-feeding weevils; woodwasps	Relatively slow to contact pest larvae under bark; bulk production and application problems
Viruses, e.g., nucleopolyhedroviruses (NPVs)	Defoliating Lepidoptera and sawflies (Hymenoptera)	Viruses must be ingested (eaten); host-specificity means cross-infectivity unlikely; application problems; time lag before killing pests

and collar weevils, and great potential has been shown in the use of viruses. The nucleopolyhedrovirus (NPV) of the teak defoliator moth, *Hyblaea puera,* in southern India is the best example so far of pathogens in the control of tropical forest pests. NPVs are usually extremely species-specific, have enormous multiplication rates, and can persist in a stable forest environment for long periods of time. The remaining problems to their commercial adoption center around their production prior to application, the efficient timing and application of the pathogens, and the ability to respond rapidly to new and geographically isolated pest outbreaks.

Chemical Control

There are basically two types of chemicals with potential in the management of insect pests in forestry; insecticides and pheromones.

It is simplest to state that the use of insecticides in all but a very small minority of cases of forest pest problems is impossible, for economic, technological, and environmental reasons. The only occasions when they may be useful are in the nursery, or just at planting out when they may be used as dips or soil granules on occasion to protect young transplants from root- or stem-feeding insects such as termites, grasshoppers, or weevils. In a nursery, the major dilemma of a manager is when not to spray. It is very tempting to take action at the first sign of an insect or fungus in a forest nursery, especially if the person involved is responsible to a higher authority for the production of large numbers of healthy transplants. Caution has to be advised. Most observations of defoliation in a nursery are ephemeral and localized. In the vast majority of cases, a strategy of doing nothing will undoubtedly save money and reduce pollution of everything from silk farms to fish farms. However, more confidence can be gained by effective monitoring against known economic injury levels defined by a threshold population size for a given sampling effort.

The chemical treatment of growing plantations is extremely problematic, and only in the most severe cases should spraying be contemplated, even when the most advanced technological standards are available. These days, the whole concept of interventionist IPM is based on monitoring and prediction, so that if aerial applications of pesticides are called for, they are over a very small area with specific targets and timing. The technology for application is vital, ideally using atomizers producing optimal droplet sizes in a spray cloud (controlled droplet application: CDA) and hence minimizing the volume of chemical used (ultralow-volume: ULV). Most important is the type of insecticidal compound employed. Many developed countries have ever more stringent legislation preventing the use of older insecticides which have been employed effectively for generations, and those which remain tend, for political more than ecological reasons, to be the most specific and environmentally ‘friendly.’ Hence in Europe, for example, one of the most widely used insecticides for the control of defoliating Lepidoptera is diflubenzuron (Dimilin), not a poison at all, but instead a chemical which kills insects by interfering with chitin formation and thus effectively prevents larval pests molting to the next lifestage. This increases the relative specificity because it is only those organisms with chitin (invertebrates, mainly insects) that could possibly be susceptible.

Pheromones are used extensively for monitoring insect pest populations, but they have also had limited success in a technique known as mating disruption or confusion. In this technique, synthetic analogs of species-specific sex-attractant pheromones are uniformly released over large areas of forest from various types of dispenser. Male moths attempting to locate the point-source attractiveness of females lose the ability to find mates, resulting in far fewer eggs laid and hence significantly reduced pest populations. Field trials show that even shoot-dwellers, such as the pine shoot-borer *Eucosma sononama*, can be effectively controlled, and the potential for the technique for other more serious borers such as pine shoot moths (*Rhyacionia* spp.) and mahogany shoot-borers (*Hypsipyla* spp.) needs to be investigated.

Table 13 Monitoring systems for forest insect pests

Pest	*Country*	*Monitoring technique*
Pine looper moth (*Bupalus piniaria*)	UK	Count pupae in soil under canopies in winter to determine high-risk sites; eggs counted only in these sites in early summer
Five-spined bark beetle (*Ips grandicollis*)	Australia	Pheromone traps baited with synthetic pheromones to determine spread and arrival in new areas
Southern pine beetle (*Dendroctonus frontalis*)	USA	Aerial surveys to detect browning leaves in canopies, mid to late summer
Douglas fir tussock moth (*Orgyia pseudotsugae*)	USA	Pheromone delta traps catch male adults, known relationship between number of males in traps and later larval densities
Nun moth (*Lymantria monacha*)	Eastern Europe	Pheromone traps to determine the period of peak flight, monitor incidence of swarming moths during the period (walk-and-watch method)

Monitoring and Prediction

Using the appropriate chemical or biological tactic in the right place at the right time without wasting labor and money, whilst still achieving successful control, is an IPM juggling act. Perhaps the most fundamental feature of IPM compared with conventional pest management tactics is the reliance on some form of monitoring procedure to tell the forester whether or not he or she can expect to have a pest problem in the future. Hence the luxury of IPM is the decision to take no action, safe in the knowledge that nothing economically serious is going to happen. It is crucial to note that no monitoring system can be regarded as reliable without impact assessments, risk or hazard ratings, and a knowledge of threshold densities (numbers of the lifestage counted above which significant pest damage can be expected). Various techniques, some more laborious than others, are used in forestry as monitoring systems, and **Table 13** shows some examples.

Conclusions

An IPM 'toolbox' may be imagined which contains all the elements of pest management discussed above. These include preventive systems such as site choice and species matching, as well as interventionist tactics such as chemical and biological control. Underpinning these tactics is a sound and reliable monitoring system with which management decisions can be made. Clearly, not all specific forest pest situations will require each of these tactics, and so the 'toolbox' concept can be applied whereby the various components appropriate to a particular problem (and its solution) can be used, leaving the rest for a different scenario.

Integrated Pest Management Practices

H F Evans, Forestry Commission, Farnham, UK
M R Speight, University of Oxford, Oxford, UK

Published by Elsevier Ltd., 2004

Introduction

The principles of integrated pest management (IPM) (*see* **Health and Protection**: Integrated Pest Management Principles) require a comprehensive knowledge of the reasons for pest outbreaks and, further, an understanding of which processes can be manipulated to reduce the severity of any outbreaks. While the concepts of IPM are intuitively sound, the practical implementation of those concepts to reach a successful conclusion is not always so easily achieved. In fact, case studies to illustrate IPM successes in forestry are relatively few if a strict definition of 'integrated' is adopted, such that there is a requirement for a multifaceted approach across a range of disciplines. In reality, although there are multiple variables to contend with, management will tend to rely on one or two key elements to achieve pest reduction.

This article deals with case studies that have been selected to illustrate the principles of IPM in practice and also to illustrate how those principles are applicable in both temperate and tropical forest systems. In providing these case studies, it is clear that not all groups of insect pests can be included and, therefore, some emphasis is based initially on discussion of management tactics in a wider sense, followed by the specific case studies.

Options in Integrated Pest Management

Traditional pest management tends to rely on one or, occasionally, a low number of options for reducing the damage caused by a particular organism. Choices are driven by the economic threshold that can be tolerated and by how quickly the pest population must be reduced below the economic threshold. In some cases, there is little choice but to use direct intervention methods based on chemical pesticides and this is an option within an IPM strategy. However, the key advantage of IPM is assessment of a range of options and the choice of a combination of these to achieve pest reduction. IPM therefore requires a disciplined approach to decision making, taking account of the individual and combined effects of a range of options. Ideally, the choices will also be dynamic in that the strategies employed will change and evolve with the changing densities of the target pest. **Figure 1** illustrates a range of the steps required to develop IPM in forestry and distinguishes two complementary approaches to management, namely prevention and cure.

Although the actions involved in achieving these ends may be similar, the ultimate aim will be to develop prevention so that long-term, sustainable population management can be achieved. In reality, there is usually a balance between prevention and

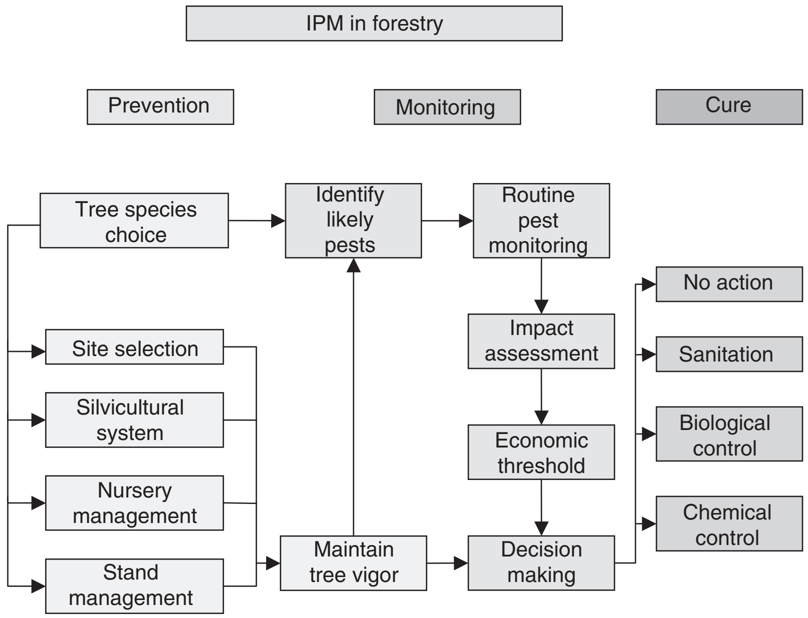

Figure 1 Schematic representation of the key components of integrated pest management in forestry.

cure, both of which depend on the quality of the monitoring and decision making components of the IPM system. Emphasis on maintaining tree vigor as a baseline component of an IPM system goes a long way towards achieving both prevention and, if there is an existing problem, cure.

General Management Tactics in Relation to the Feeding Strategies of Pest Insects

Insects are often classified according to the sites that are damaged during the life cycle. The majority of cases relate to the immature, larval, or nymphal stages of the particular pests. In part, this is determined by the processes employed by the adult pests to select suitable egg-laying sites that will lead to the highest likelihood of successful survival by their progeny. Consequently, the tactics employed to manage pests will be tailored to the types of feeding strategy by a given pest species. This is illustrated in **Figure 2**, which shows the four main categories of insect feeding strategy and some of the tactics employed to either prevent (a primary IPM strategy) or cure the problem.

Bark Feeders and Wood Borers

This group of pests is dominated by beetles (Coleoptera) but there are also significant representatives in the wood wasps (Hymenoptera) and moths (Lepidoptera). In the majority of cases the life cycle includes a period of feeding in the cambial layer of the inner bark which may occupy some or all of the larval feeding phase of the pest. Wood borers include an additional period during which the pest feeds in the sapwood or, occasionally, in the heartwood. Some, such as the wood wasps (in the hymenopteran family Siricidae) oviposit directly in the sapwood using a long ovipositor capable of boring into the wood.

The nature of these pests means that they spend the majority of their cycle in well-protected situations under the bark or in the wood itself. This makes it impractical or impossible to employ insecticides, although the use of systemic insecticides (those taken up by the roots of the plant) is being employed to attempt eradication of the Asian longhorn beetle (*Anoplophora glabripennis*) in the USA. An IPM approach, therefore, concentrates on understanding the nature of the interaction with the host tree and making use of the natural defenses of trees to prevent successful attacks. Thus **Figure 2** concentrates on prevention by matching trees to the site both in terms of tree species and of the mixtures and ages of trees that are present on site. There is considerable variation in the susceptibility of tree species and of the seed origins of particular species in relation to the ability of bark and wood borers to successfully attack trees. Defenses are usually manifested in aspects such as the nature and quantity of resins/sap produced (poisonous and sticky), bark thickness, presence of inedible stone cells (lignified tissue) and poor nutritional value. Healthy, vigorous trees have increased levels of defensive traits and it is possible, over the long term, to select or breed tree species with improved resistance to insect attack. Usually, however, we only realize how effective these defenses are when trees are damaged or stressed in some way and

MANAGEMENT TACTICS – BARK FEEDERS AND BORERS

PREVENTION
- Match tree species to site
- Avoid soil aridity or waterlogging
- Avoid overmaturity
- Avoid root damage in nursery
- Avoid log piles, etc. near stands
- Avoid pruning/brashing/extraction damage

CURE
- Injection with systemic insecticide for high-value trees
- Remove infested material from site before re-emergence of pest
- Change tree species mix/age structure to favor less susceptible species/age

MANAGEMENT TACTICS – DEFOLIATORS

PREVENTION
- Avoid preferred tree mixtures
- Avoid highly susceptible provenances

CURE
- *Nurseries* – local spray of insecticide only when serious leaf loss is observed
- *Plantations* – plant less susceptible species/provenances
- change tree species mix/age structure to favor less susceptible species/age
- Apply microbial insecticides
- Use mating disruption to reduce breeding success

MANAGEMENT TACTICS – SAP FEEDERS

PREVENTION
- Avoid nonvigorous trees (see BORERS)
- NB – prophylactic spraying in nurseries should **not** be carried out
- Avoid highly susceptible provenances

CURE
- *Nurseries* – local spray of insecticide only when serious leaf loss is observed
- *Plantations* – plant less susceptible species/provenances

MANAGEMENT TACTICS – ROOT FEEDERS

PREVENTION
- *Nurseries* – Avoid root damage
- *Plantations* – Reduce availability of breeding resources for weevils
- – Encourage alternative non-crop food sources
- – Incorporation of insecticide granules in planting hole if termite losses are high

CURE
- *Nurseries* – Soil drench of insecticide for white grubs, cutworms if losses serious
- *Plantations* – plant less susceptible species/provenances

Figure 2 Management tactics for the four main categories of pest feeding strategy.

then become highly vulnerable to attack. For example, wind not only destroys trees directly but also weakens standing trees to make them more vulnerable to attack by bark and wood boring beetles. Fluctuations of the eight-toothed spruce bark beetle *Ips typographus* in European spruce forests tend to be linked to episodes of tree stress that allow the beetle to build up in weakened trees before commencing attacks on the remaining living trees. Wind damage in France in the early part of the twenty-first century not only resulted in massive destruction from the wind itself but also ongoing destruction from the enormous populations of *I. typographus* that built up on the weakened and freshly killed trees. This has knock-on effects that are not confined to the area where the problems occurred initially. *Ips typographus* can be moved in wood with bark still present to other areas of the world where it is not native, thus posing a threat to those countries; this tends to increase during an episode such as that just experienced in France.

Prevention is, therefore, a practical proposition in relation to ensuring that trees are as healthy and vigorous as possible. Cure is also feasible, although this tends to require rapid action to prevent the pest populations from building up to epidemic proportions. A simple 6-week rule is used in many countries, including the UK; felled or damaged wood must be removed from site within 6 weeks of origin. This strategy acknowledges that the trees will be attacked rapidly but, by removing them quickly before the beetles are able to complete a full generation, the numbers of emerging adults on site is reduced significantly. Of course, the material taken off site must be processed quickly to prevent the movement of the pest to a new location.

In the longer term, restructuring of a forest may offer the ultimate management tool to keep bark and wood boring beetles within acceptable damage thresholds (this will be discussed in more detail in relation to the mountain pine beetle, *Dendroctonus ponderosae*, later in this chapter). However, the general principles are based on knowledge of the factors that encourage epidemic beetle populations. In the cases of bark beetles, this is often linked to the stocking densities and ages of the trees in a forest. For some beetles, high stocking densities, contiguous presence of trees, and an even age structure will be favored; this is the case for *I. typographus*, which sustains high populations in large contiguous forest blocks. Other beetles tend to attack older, overmature trees that offer thicker bark and tend to be less vigorous than younger trees. This is the case for mountain pine beetle and other *Dendroctonus* species.

The above examples are concerned with beetles that attack and kill living trees. However, economic damage can also be suffered as a result of secondary effects of bark and wood boring beetles. This is manifested in staining of wood as a result of fungi introduced by the beetles during attack and also the opening of the wood surface to colonization by saprophytic fungi and other organisms in the environment. This is generally a cosmetic degrade in that, provided the wood is harvested within a few months of attack, there is no loss of structural value but the wood tends to be downgraded because of its visual degradation. Wood borers also cause loss of value as a result of downgrading of wood quality resulting from presence of grub holes in the wood, often accompanied by fungal staining. In most cases, unless the attack is particularly severe, there is no significant loss in timber strength. The 6-week rule is effective against these organisms, although the introduction of staining fungi at the time of beetle attack and oviposition makes it difficult to prevent this form of degrade. General forest hygiene can help, but this has to be balanced against the desire, in relation to enhancing biodiversity, to retain deadwood in forests.

Defoliators

As the name suggests, defoliators damage trees as a result of feeding on the leaves. Their effects on the tree can range from cosmetic through to complete defoliation and death. Severity varies with the type of tree being attacked and on the time of year, relative to the growth cycle of the tree, when the attack occurs. For example, in temperate conifer forests the degree of damage and tree mortality is dependent on whether the pest attacks soon after bud burst and on whether it restricts its feeding to the older foliage or includes the current year's growth as well. In Britain the introduced lodgepole pine, *Pinus contorta*, is attacked by a range of defoliators that are normally associated with the native Scots pine, *P. sylvestris*. The European pine sawfly, *Neodiprion sertifer*, attacks older foliage on young trees and can completely strip that resource from the tree, leading to significant loss of tree growth. However, because it does not attack the current growth, trees normally survive even repeated episodes of defoliation. By contrast, attacks by pine beauty moth, *Panolis flammea*, include both the current foliage and, later, the older foliage and can lead to extensive tree mortality. Both the sawfly and the moth are sensitive to the seed origin of the lodgepole pine and this can be exploited, at least in part, to reduce the severity of attacks. More northerly provenances, particularly Alaskan origins, tend to have much higher levels of tolerance. Restructuring of the forest is also effective, particularly against pine beauty moth. In this case, switching to Scots pine results in lower levels of attack, partially linked to tree quality but mainly due to the greater presence of natural enemies associated with Scots pine. Thus an integrated approach would be to increase the proportion of Scots pine in a forest block and to include open spaces and an uneven age structure to attract and retain natural enemies, particularly small mammals that feed on the overwintering pupae in soil. Direct intervention is also feasible for most forest defoliators, with the preference being for application of microbial pesticides of which *Bacillus thuringiensis* (*Bt*) is the dominant agent. This has been used extensively in both Europe and North America and in an unusual case, for complete eradication of an imported moth (white marked tussock moth, *Orgyia thyellina*) in an urban situation in Auckland, New Zealand. *Bt* is the agent of choice for gypsy moth (*Lymantria dispar*) in Europe and North America, for spruce budworm (*Choristoneura fumiferana*) in North America, and for nun moth (*Lymantria monacha*) in Europe. It is normally applied from the air and, increasingly, is applied using sophisticated spray technology that enables effective targeting and minimal loss to non-target areas. It is relatively specific in its action and is regarded as environmentally sound. Even more specific microbial agents are found among the baculoviruses that tend to be monospecific or restricted to a few species within given genera. They have proved effective against both temperate (e.g., pine beauty moth, pine sawfly, gypsy moth) and tropical (e.g., teak defoliator moth, *Hyblaea puera* – see case study) pests. In all cases, precise timing to deliver the agent to the most susceptible larval stages is essential to ensure the highest mortality and most rapid kill. The drawbacks of using baculoviruses relate, ironically, mainly to their high specificity so that each pest requires a specific facility to produce the virus, usually *in vivo*. However, the environmental benefits are very high and, in some cases (e.g., pine sawfly) the virus can maintain natural epizootics once introduced and, therefore, reduce or eliminate the necessity for multiple applications.

Sap Feeders

Sap feeders are predominantly in the order Hemiptera, which includes adelgids, aphids, cicadas, leafhoppers, plant bugs, plant hoppers, psyllids, scale insects, and whiteflies. Both the adult and immature (nymphs) stages feed on sap by inserting their specialized sucking mouthparts (stylets) into the phloem or sometimes xylem (in the case of cicadas) of virtually any part of the tree but predominantly buds, leaves, or in some cases, bark. Damage can be severe and can occasionally lead to tree death. In most cases the trees survive but there may be secondary effects in making the trees vulnerable to attack by other pests and in the production of honeydew, a sweet waste product that is then colonized by fungi such as sooty molds. This can be both unsightly and further restrict tree growth by reducing photosynthesis due to coverage or remaining foliage.

IPM of sap feeders is similar to bark feeders and borers in that trees that are nonvigorous are more vulnerable to attack and, therefore, should be avoided. Similarly, there are large variations in the genetic susceptibility of trees to attack and careful selection of tree species, seed origins, and mixtures should help to reduce the severity of infestation. It is not practical to consider use of insecticides in plantation forests both because of the environmental impacts but also because of the rapid recolonization that tends to take place that would tend to require reapplication at relatively frequent intervals. However, sap feeders are also problems in nurseries and, in these situations, it is possible to consider emergency applications of insecticides to supplement any other measures such as encouragement of natural enemies and use of vigorous, more resistant species and seed origins.

Root Feeders

By their very nature as feeders in a hidden environment, this category of pest tends to be less studied, particularly from the point of view of delivering IPM through detailed knowledge of the factors leading to pest outbreaks. Within this group there has been most emphasis on pests at the nursery stage of production, where both the impacts and identities of the pests are easier to record and develop strategies for management. In temperate areas, root damage tends to be linked to beetle or lepidopteran larvae in the main. Weevils, especially in the genus *Otiorhynchus* (the vine weevil, *O. sulcatus*, being the best-known European example) and chafers, including the genera *Melolontha* and *Phyllopertha*, tend to be the most damaging. Cutworms in the lepidopteran family Noctuidae are also serious pests in that the larvae are soil dwelling and can browse both on the root collar and on the plant itself. Other pests include bibionid flies in the genus *Bibio* and nematodes, especially *Dolichorhynchus* spp. Tropical pests in this category include termites and white grubs (Coleoptera: Scarabaeidae).

Impacts in plantations can be serious but, not surprisingly, the cause can be overlooked because of the cryptic nature of the niche occupied by the pests. Young plants can be affected by the majority of pests associated with forest nurseries, with the addition of some root dwelling aphids, gall wasps, and bark beetles. In such situations, the key to success is reducing breeding resources for the pests as well as intervention using chemical or microbial pesticides in extreme cases. However, there has been relatively little work on this group of pests and it is likely that their impacts are often not recorded or underestimated.

Case Studies

Within the large array of forest pests in both temperate and tropical forests, there has been relatively little development of IPM from first principles (*see* **Health and Protection**: Integrated Pest Management Principles). However, it is possible to illustrate how approaches that fulfil the aims of IPM have evolved for selected temperate and tropical pests. We have, therefore, selected examples from temperate and tropical forestry to cover only two of the main feeding strategies discussed earlier, i.e., bark feeders/wood borers and defoliators.

Great Spruce Bark Beetle, *Dendroctonus micans* (Coleoptera: Scolytidae)

This is a serious pest of spruce throughout its range in Eurasia (**Figure 3**). However, as indicated in **Table 1**, the beetle can be managed successfully using IPM principles, with particular emphasis on early detection and introduction of the specific predatory beetle, *Rhizophagus grandis* (Coleoptera: Rhizophagidae) (**Figure 4**).

Great spruce bark beetle is somewhat unusual in its attack strategy compared with some of the more damaging, aggressive bark beetles that are also in the

Figure 3 Adult great spruce bark beetle, *Dendroctonus micans*. Photograph courtesy of Forestry Commission Research Agency.

Table 1 IPM of great spruce bark beetle, *Dendroctonus micans*

Great spruce bark beetle, Dendroctonus micans	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
A dangerous pest of spruce trees in northern temperate forests from Asia to western Europe. It attacks living spruce trees causing damage to the main stem and large branches and can kill trees during outbreaks.	Depending on location and average temperatures, the beetle has a life cycle that lasts from 12 to 24 months. Generations are not synchronized and eggs, larvae, pupae, or adults can be found at any time of the year. Females excavate an egg gallery in the living bark, each laying up to 350 eggs. Larvae feed communally, responding to a larval aggregation pheromone, which is a mechanism to enable them to withstand the sticky and toxic resins produced by the tree as a defense against attack.	Regarded as a serious pest of spruce in newly colonized forests and in forests where trees are particularly vulnerable to attack. It is a solitary bark beetle that completes its life cycle in living trees without the need for mass attack to overcome tree defenses. There is no adult aggregation pheromone or associated symbiotic fungi to overcome tree defenses.	Overmature, stressed, or damaged trees are more vulnerable to attack, but even apparently fully healthy trees can be colonized successfully. Trees planted on unsuitable soil types are particularly vulnerable to attack, e.g., Sitka spruce planted on relatively sandy soil in Denmark were attacked and killed by great spruce bark beetle.	1. Surveys to detect infestations, especially during early colonization in previously uninfested forests. This is particularly important in forests geographically isolated from known infestations and which may not have been colonized by the specific predator *Rhizophagus grandis*. 2. Selective felling to reduce or remove incipient populations in a newly infested forest or to reduce expanding populations in forests lacking *R. grandis*. Felling concentrates on removal of overmature or damaged/stressed trees, but avoiding further damage to remaining trees. 3. Restriction of timber movement to reduce the likelihood of infested timber being moved to uninfested forests. This applies particularly to those regions where *D. micans* is a new incursion (e.g., Great Britain, Massif Central in France) and where active management to contain outbreaks is being carried out. 4. Biological control using the specific predatory beetle *R. grandis*. This is a natural associate of *D. micans* throughout the majority of its Eurasian range. However, new incursions of the bark beetle will tend not to have the predator present and mass rearing and release strategies have been developed. The predator has been successfully introduced to the Georgian Republic, southeast France, Great Britain, and Turkey and is a key component of an IPM system.

genus *Dendroctonus* (see mountain pine beetle below). Females mate with males in the same brood chamber prior to emergence as mature adults. This, combined with the very high bias towards females in each generation (as high as 40 : 1 female : male), means that each female is immediately capable of attacking a host tree without recourse to attracting a male. In addition, the beetle is very well adapted to withstanding the copious resin flow that is characteristic of wounded spruce trees. It is not, therefore, necessary for the beetle to use mass attack strategies to establish a successful brood, nor does it require the added factor of an associated fungus to help overcome tree defenses. Thus, it is a relatively solitary bark beetle in which each female can establish a successful colony. This may, at least partially, explain why it has been able to expand its range westward into previously unattacked regions of Europe; it has established in the Georgian Republic, southeast France, Turkey, and Great Britain during the latter half of the twentieth century.

IPM strategies that have been adopted across Europe have included surveys to establish the extent of new infestations and then, dependent on the extent of the infestations, a number of options for management. In some cases, sanitation felling, including complete removal of forest blocks, has been carried out. This tactic reduces population pressure on remaining uninfested trees and, depending on the timing within the normal rotation of the crop, may

Figure 4 Larvae of the specific predator, *Rhizophagus grandis*, feeding on larvae of their prey, *Dendroctonus micans*. The predators feed gregariously and leave the empty husk of their prey behind before moving on to the next prey item. Photograph courtesy of Forestry Commission Research Agency.

only have a small impact on revenue achieved. However, in areas where both timber products and ground stabilization are management aims, early felling is not a viable option. In some cases, particularly in Great Britain, discovery of new infestations has been early enough to establish a containment regime such that movement of felled timber from known infested areas is regulated so that only wood that has been debarked is approved for transportation to uninfested parts of the country. The latter, under European Union rules, has been designated a Protected Zone and, at least in Great Britain, appears to have successfully restricted long-distance dispersal of the pest for the 21 years since the strategy was adopted. Natural spread, by beetle flight, still takes place, however, and this has been at a rate of 3–5 km per annum in the British outbreak. As part of the IPM strategy, a peripheral zone survey has been carried out annually and this has both quantified natural spread and also enabled new pioneer populations of the beetle to be managed by a combination of selective felling and further introductions of the predator *R. grandis*.

The cornerstone of an IPM approach to great spruce bark beetle is rearing and release of *R. grandis*. This predator is specific to *D. micans* and has been released with great success in all the new infested areas in Western Europe. In Great Britain, a program of releases was initiated in 1985 and has continued annually since then by concentrating on new infestations found on the periphery or in new areas remote from the main infested zone. For example, a completely new infestation was found in Kent, well to the east of the known infested area and this has also been successfully treated with *R. grandis*.

Overall, the combined strategy for great spruce bark beetle has been remarkably successful in all locations where predator-based IPM approach has been adopted. In relation to other bark beetles, this example is unique in that silvicultural management is not the main component of an IPM approach. This contrast is well illustrated by the mountain pine beetle example discussed below.

Mountain Pine Beetle, *Dendroctonus ponderosae* (Coleoptera: Scolytidae)

Mountain pine beetle is one of the complex of *Dendroctonus* species that affects conifer forests in North America. Within the current range of the pest in western North America, it is regarded as one of the most destructive, with particularly heavy attacks and tree mortality being observed on lodgepole pine, although other pines are affected to a lesser extent.

By contrast to the European relative *D. micans* discussed above, this species adopts an aggressive attack strategy that relies both on weight of numbers and on an associated fungus to overcome the resin defenses of living trees. Low-level populations of the beetle are maintained by opportunistic breeding in weakened and dying trees, brought about through a range of biotic and abiotic factors. For example, wind or fire damage can reduce tree defenses sufficiently for even small populations of the beetle to build up. These populations may be large enough to become aggressive and to mass-attack living trees in the vicinity, leading to further attacks in a positive feedback loop. This can result in enormous population increases and spread of the pest over large areas.

Extensive research into the factors that lead to population outbreaks has been carried out, culminating in a sophisticated decision support system based on sound IPM principles. This can be accessed on-line from the Pacific Forestry Centre in British Columbia, Canada which offers a range of mountain pine beetle planning tools, including an excellent risk rating computer program. The key elements are described in **Table 2**. It appears from the information gathered on the pest, that the problem is partially man-made in that there has been a tendency for retention of older age classes of trees, by a combination of avoidance during felling and through implementation of fire suppression programs. Stand age is one of the key elements of the stand susceptibility index (SSI), which is made up of the following components:

$$\mathrm{SSI} = A \times D \times P \times L$$

where A is stand age, D is stand density, P is percentage of susceptible pine, expressed as basal area, and L is location (latitude, longitude, elevation).

The factors are described briefly in **Table 2** but, as a general rule of thumb, trees greater than 80 years

Table 2 IPM of mountain pine beetle, *Dendroctonus ponderosae*

Mountain pine beetle, Dendroctonus ponderosae	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
The most destructive pest of mature lodgepole pine trees in western North America. Western white pine and ponderosa pine can also be attacked. Outbreaks develop rapidly and can result in very large areas of trees being killed within a relatively short time period. It mainly attacks living, older, large-diameter trees (overmature), with initial attacks in stressed, unhealthy trees.	Over most of its range, mountain pine beetle has a 1-year life cycle, although this may extend to 2 years at high altitudes and in the northern part of its range. Larvae overwinter and recommence feeding in the spring to pupate and emerge as adults in mid to late July. Adults range in size from 3.5 to 6.5 mm. Initial attacks are by females that bore into the bark and, once established, produce an aggregation pheromone that, initially, attracts females then males. Mating occurs under the bark, after which the females bore vertical egg galleries in which eggs are laid in niches on the sides; up to 75 eggs are laid per gallery, but females can produce up to 260 eggs. Eggs hatch quickly and larvae feed at right angles to the axis of the egg gallery. They feed until winter, usually reaching 2nd or 3rd instar.	A highly destructive bark beetle that initially attacks weakened trees, but then uses mass-attack strategies to overcome apparently healthy trees. The beetle carries a blue-stain fungus that also contributes to overcoming tree defenses and, combined with larval feeding in the cambium, can lead to tree death. Losses arising from attack by the beetle can be enormous; during the period 1997–2002 an area of 9 million ha was affected in British Columbia, leading to losses of 108 million m^3.	Risk rating systems have been developed for mountain pine beetle. These offer the prospect of managing outbreaks by reducing the risk factors. The key factors are: 1. Stand age. Beetles prefer older trees which are less resistant and, being bigger, are easier to locate. 2. Stand density. Beetles prefer moderate densities which offer suitable bark thickness and only moderate tree defenses. Microclimate is favorable to the beetles. 3. Percent susceptible pine (basal area). Beetles prefer large trees with thicker bark and well-developed phloem that provides protection and ample breeding resources. Higher stand densities reduce searching time for new host trees. 4. Location factor. Beetles are more successful when temperatures support a 1-year life cycle. This factor is driven by latitude, longitude, and elevation.	1. Stand susceptibility index. A product of the four risk factors. This is a component of the mountain pine beetle decision support system which uses susceptibility ratings for longer-term forest management. A computer model has been developed to aid this process and is freely available from Natural Resources Canada. 2. Risk index. Beetle pressure is a function of the size and proximity of beetle populations to the stand being assessed for management. This is based on the relative size (small, medium, or large) of the beetle infestation within 3 km of the stand at risk. This information is then used in a lookup table for distance to the nearest infestation to derive a beetle pressure index. Together with the stand susceptibility index, this is combined to give an overall risk index between 0 and 100. 3. Reduction of stand risk through IPM. Stand susceptibility can ~be altered through silvicultural management, with the aim being to break up large, homogeneous stands predominantly composed of large highly susceptible trees. This requires selective felling to thin 'from above' thus lowering average age, size, and stand densities towards an acceptable susceptibility index. Beetle pressure is not so easily managed but includes factors such as sanitation logging and debarking, fell and burn, or possibly insecticide use.

old and stand densities from 751 to 1500 stems ha^{-1} are intrinsically the most susceptible. Combined with the proportion of pines with diameters >15 cm, but especially >40 cm, and a factor to reflect temperatures calculated from an equation for longitude, latitude, and elevation, an overall SSI from 0 to 100 can be calculated, with 100 being the most susceptible. Further assessment of risk includes a beetle pressure index (B) derived from lookup tables for size of infestation (small, medium, or large) and distance from the nearest infestation, ranging from within the stand to >4 km away. A value of $B=1$ indicates a large infestation within the stand, whereas a value of $B=0.06$ represents a small infestation >4 km from the stand.

Prior assessment of risk is a key tool in longer-term management of the threat posed by mountain pine beetle. Prevention can be achieved by working towards a reduction in the SSI towards a nonsignificant value. This can be achieved by controlling the stocking density in young stands as part of planning for future protection. In older stands, SSI reduction can be achieved by specific thinning, particularly of larger diameter, older trees combined with felling to reduce the proportions of pine within stands. Naturally, care must be taken in restructuring stands to avoid 'high-grading,' which could leave only inferior trees that have lower silvicultural and environmental values and be more vulnerable to abiotic factors such as wind and snow damage. Careful management of stands to reduce stem densities below $750\,\mathrm{ha}^{-1}$ can still achieve an acceptable SSI and leave sufficient larger, old pines for biodiversity interest.

If it is not possible to prevent beetle build-up, then a number of direct measures can be employed to manage and reduce the beetle outbreaks. These include rapid removal of infested material to prevent re-emergence of the pest. Fell and burn, treatment with insecticides, mechanical debarking, and sanitation felling can all achieve these ends, although they can be difficult logistically. Use of semiochemicals to attract beetles to trap trees or to traps placed away from the potential host trees has also been employed, with some success.

Pine Beauty Moth, *Panolis flammea* (Lepidoptera: Noctuidae)

Pine beauty moth has a long history as a pest of Scots pine, *Pinus sylvestris*, in continental Europe where it has periodically resulted in severe defoliation and tree mortality. By contrast, the moth is not regarded as a pest on Scots pine in Great Britain, where it remains at low levels on this tree species throughout the country. The appearance of large, outbreak populations of *Panolis flammea* on the exotic north American lodgepole pine, *Pinus contorta*, in Scotland during the 1970s was, therefore, a surprise. However, it also illustrates, in a converse way, one of the key principles of an IPM approach to pest suppression because the planting of an exotic tree species on marginal sites presented the moth with a situation in which key factors preventing population build-up were absent (**Table 3**). Specifically, trees were planted on deep, poorly-drained peat soils that provided ideal conditions for overwinter survival of the pupal stage and were also relatively impoverished with regard to presence of natural enemies.

The moth outbreaks were worse on deep peat sites over moine schist underlying rocks and, within the seed origins of lodgepole pine, were more serious on southerly provenances. This combination of high suitability as a larval food source and the enhanced overwinter survival led to rapid population increases that outstripped the available food supply in some forests, leading to a population crash but only after the host trees had been killed. Research into monitoring methods and aiming also to establish the economic threshold for lethal attack, indicated that when densities of pupae, determined by pupal surveys carried out during the winter months, exceeded $15\,\mathrm{m}^{-2}$, tree mortality was likely. Further assessment of risk was carried out by egg surveys on trees in the same vicinity as the pupal surveys. When densities exceeded 600 eggs per tree, lethal damage was very likely and decisions on direct intervention had to be made. Surveys using the sex attractant pheromone of pine beauty moth provided useful corroborative data of population trends, but were not accurate enough or sufficiently in advance of egg hatch to allow control operations to be organized.

Early work on direct control of the moth concentrated on low-volume aerial application of the chemical insecticide fenitrothion. Although this was generally effective, considerable effort was put into finding more effective application technology, such that ultra-low-volume controlled droplet application is now the only method used for aerial application in Britain. This methodology employs spinning disc or spinning cage technology to deliver droplets within a relatively narrow range of sizes and which are captured by the target canopy zone with an efficiency exceeding 90%. Intervention has been carried out several times in Scotland, mainly using the insect growth regulator diflubenzuron delivered at volumes of $1\text{–}4\,\mathrm{l\,ha}^{-1}$. Tests with baculoviruses also proved effective, although the registration for the viral agent in Britain has lapsed.

In the longer term, management of pine beauty moth is likely to include choice of tree species and avoidance of particularly susceptible soil types. Mixtures of lodgepole pine with other conifer species will provide partial reductions in susceptibility, particularly when Scots pine, with a higher level of associated natural enemies present, is planted in mixture. Avoidance of highly susceptible provenances will also reduce the likelihood of lethal populations developing.

Teak Defoliator Moth, *Hyblaea puera* (Lepidoptera: Hyblaeidae)

Teak defoliator moth is the most important of a number of moths associated with teak and other trees and shrubs in the Orient and Australasia (**Table 4**). It is characterized by very rapid development, leading to multiple generations each year, depending on the average temperatures at a particular location. Although generations overlap at a regional scale,

Table 3 IPM of pine beauty moth, *Panolis flammea*

Pine beauty moth, Panolis flammea	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
A pest of older Scots pine in continental Europe and, although present at low levels on Scots pine throughout Great Britain, has become a pest of the introduced North American lodgepole pine (*Pinus contorta*) in Scotland. Extensive outbreaks can lead to tree mortality, especially on deep peat sites.	The moth has a singe generation per year which commences with adult emergence in the spring, usually in March or early April, followed by oviposition up to May. Egg hatch occurs by around mid-May, after which larval feeding commences in the current year's foliage. Later instars (3rd to 5th instar) feed on older foliage so that large moth densities can result in complete defoliation. Larvae drop to the forest floor to pupate in July and remain in the litter–soil interface until the following spring. Females produce a sex pheromone to attract the males.	Although pine beauty moth is a periodic and serious pest on Scots pine in Europe, with records of major outbreaks in Germany, Finland, Norway, and Sweden, it is innocuous on this tree species in Great Britain. Outbreaks leading to extensive tree mortality were noted on lodgepole pine in Scotland during the 1970s and have recurred periodically at 7–8-year intervals since that time.	In Britain the main risk factors are tree species and site type. 1. Tree species. As indicated above, outbreaks have been confined to lodgepole pine, which also shows considerable variation in susceptibility to infestation depending on seed origin. Thus, more southerly origins, such as Skeena River and South Coastal are more suitable hosts than northernly origins, such as Alaskan or North Coastal. This applies both to female choice for egg laying and to subsequent larval performance on the foliage. The low severity of attacks on Scots pine in Britain is linked to the greater action of natural enemies and the lower survival of pupae below Scots pine canopies. 2. Site type. Sites with deep, waterlogged peat soils support greater populations than other soil types, especially over the underlying rock type called moine schist. Although the trees themselves are not intrinsically more suitable, it appears that the underlying soil type is more suitable for pupal survival over winter.	1. Monitoring and economic thresholds. Monitoring of pupal numbers or adults in pheromone traps provides information on population cycles and also a threshold for possible direct control measures. Pupal densities of $>15\,\mathrm{m}^{-2}$ are likely to result in severe defoliation or tree death. If this threshold is exceeded, egg surveys are carried out to determine whether populations have exceeded the threshold for damage on a local basis; the threshold is >600 eggs per tree. 2. Reduction of stand risk. Planting of Scots pine as a replacement for lodgepole pine will reduce risk considerably. If sites are not suitable for direct planting with Scots pine, then a mixture of lodgepole pine with Sitka spruce may reduce risk, but this is not sufficient to eliminate the likelihood of lethal attack. Selection of northerly seed origins of lodgepole pine is also a positive measure to reduce risk. 3. Direct intervention. If the economic threshold is exceeded, then direct intervention may be the only option to prevent tree mortality. The targets for intervention are the 1st and 2nd instar larvae and, therefore, timing of spray application to coincide with 95% egg hatch is a core part of pesticide application. Currently the only insecticide that is employed is the insect growth regulator diflubenzuron. Promising results have also been obtained in application of a baculovirus. In both cases, the use of sophisticated ultra-low-volume controlled droplet application systems ensures that sprays reach the target area in the top one-third of the tree, with little contamination of nontarget areas.

each population has a discrete center in which all the stages from egg, through larvae and pupae to emergent adults are well synchronized. Repeat attacks on the same trees are uncommon because moth populations migrate *en masse* to new locations.

Management of teak defoliator moth is dependent on early detection of infestations if any direct intervention is being contemplated. Remote sensing has not been developed and, therefore, surveys tend to be based on visual assessments by trained survey teams searching for early stages of defoliation. There has been some success in using light traps, particularly solar powered versions that facilitate sensing in remote locations without local power supplies.

Table 4 IPM of teak defoliator moth, *Hyblaea puera*

Teak defoliator moth, Hyblaea puera	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
A serious pest of teak trees (*Tectona grandis*) in India, Myanmar, Sri Lanka, Java, Papua New Guinea, Northern Queensland, Solomon Islands, West Indies, and East and South Africa. Although the moth causes extensive defoliation, trees are not usually killed but serious losses of growth increment have been recorded, especially in younger plantation teak. Attacks take place during the growth period of teak in the monsoon season and follow the northward progression of monsoons.	The moth has a very short life cycle, which can be completed in as few as 19 days but could extend to 36 days, depending on temperature. This can result in up to 14 generations per year. Each generation commences with swarming of the adults and migration to suitable host trees where they lay their eggs, singly on the under surface, on young leaves (i.e., tender leaves). Eggs hatch quickly and the young larvae feed initially on the under surface and later within a leaf flap cut by the larva at the leaf edge. Larvae pass through five instars and then drop to the ground to pupate. Emergence of adults is followed by mass migration to another site suitable for a further generation. This migratory behavior is not fully understood and makes it difficult to predict where the next infestation is likely to occur.	Loss of growth is the main negative characteristic of this pest. Up to 44% loss of volume increment has been recorded in young plantations up to 9 years old, while an overall loss of 13% volume has been quoted for the crop to rotation age at 60 years. The migratory characteristics of the adults and the very rapid development from egg through larvae to pupae make it very difficult to predict when or where the next outbreak is likely to occur.	There is a complex of factors that affects the likelihood of outbreaks occurring at both the local and the regional scales. 1. Flushing of teak. Teak does not grow during the dry season, although it will do so if availability of water is sufficient, as has been demonstrated in intensive plantation systems with drip irrigation. In natural and plantation forests, flushing of teak is coincident with the onset of monsoon rains and, therefore, breeding resources are regionally determined by the northward extension of the monsoon each year. 2. Proximity of alternative host plants. The moths are known to spend the dry season on food plants in the natural forest, of which 29 species have been recorded. Adult moths also rest on the foliage of non-food understory plants. It is thought that populations move from the natural forest to teak plantations when teak flushes in the spring. 3. Wind and migration. Mass migration of moths is linked to local wind conditions so that some sites, with well-defined wind directions, tend to have localized intense outbreaks while others where wind is more diffuse have distributed infestations.	1. Monitoring and economic thresholds. The migratory nature of teak defoliator moth makes it difficult to monitor the arrival of new populations for management decisions on direct intervention. Ground spotting using teams of trained observers has been employed in India with some success. This relies on rapid determination of infestations and the feeding back of information to managers. However, this is not a routine process. Use of light traps has also been studied and provides some promise for future monitoring. 2. Reduction of stand risk. It is known that some varieties and species of teak have early flushing, which could render them less susceptible to attack, e.g., varieties, known as 'Teli' ('oily') flush at least 1 month earlier than normal teak and appear to escape infestation. 3. Direct intervention. Although the moth is susceptible to a variety of chemical insecticides, most effort in India has concentrated on assessing the potential of microbial agents. Great advances have been made in isolation, production, and application of a naturally occurring baculovirus. Success in application of this agent depends on early detection of newly established populations.

Development of a full IPM system is in its infancy but work at the Kerala Forest Research Institute has thrown light on both population dynamics, migratory behavior of the adults and, with scientists from the Forestry Commission Research Agency, use of naturally sourced baculovirus applied using ultra-low-volume controlled droplet application technology. In this sense, there are interesting parallels to the management of pine beauty moth in Scotland, despite the enormous differences in generation times of the two moth species. Application of baculovirus in antievaporant oil formulations, but without any additional protection against ultraviolet light, has proved to be effective against 3rd instar larvae on standing teak trees. The targeting of this larval stage provides a longer window of opportunity for application and also takes account of the movement of the larvae over the leaf surfaces, which increases the likelihood of encountering lethal dosages of virus. On the basis of the results obtained in field testing, a virus production facility has been constructed by the Kerala Forest Research Institute to develop further the use of baculovirus as a key component of IPM of this important pest. Further work is needed to solve the difficult problem of development of an effective monitoring and tracking system for migratory moth populations. Remote sensing and use of geographical information systems (GIS) interfaces and predictive models offer prospects for success in the future, the principles of which will be applicable to other moths with rapid generation times and dispersal between generations.

Mahogany Shoot Borer, *Hypsipyla* spp. (Lepidoptera: Pyralidae)

This complex of moths poses the single most important threat to the commercial production of mahogany timber anywhere in the world. Apart from on a handful of isolated Pacific Islands, such as Fiji, all members of the mahogany group (Swietenoidea) within the Meliaceae are attacked the world over. Tree genera include *Swietenia* and *Cedrela*, indigenous to Central America, *Khaya* from Africa, and *Toona* from Australasia, and all are attacked to a lesser or greater extent both naturally, and especially when grown in plantations. The taxonomy of the moth is obscure. For at least 100 years, book after book has reported the existence of merely two species, *Hypsipyla grandella* in the New World, and *H. robusta* in the Old World (all the way from West Africa to the Solomon Islands). Unlike the spread of certain tropical forest pests from a recognized point of origin (see *Phoracantha semipunctata*, below), *Hypsipyla* is likely to be indigenous throughout its global range, and hence there are undoubtedly numerous genetically distinct populations that are likely to represent a number of species in relatively local areas. This is clear from the varied activities which *Hypsipyla* species can be found exhibiting; though shoot boring is the only direct economic damage, larvae indistinguishable from each other can be found attacking the bark, shoots, fruit, and flowers at various stages of development on the same tree (**Figure 5**). Such a varied but as yet unquantified genetic diversity has vital implications for general insect ecology, host–tree interactions, and of course pest management.

Figure 5 Larva of *Hypsipyla* attacking a shoot on a mahogany tree.

Figure 6 A mahogany tree distorted into a forked shape after being attacked by *Hypsipyla* larvae.

The economic damage is centered around the larva's tunneling up and down the leading shoot of trees up to 4 years or so old. The leader then distorts and/or dies, with the result that the young tree becomes bent, forked, or otherwise misshapen (**Figure 6**). Marketable high-value mahogany must consist of a straight, single stem for at least the first 4 m of height, and since this height is usually reached within 4 years or even less in most species in most locations, the key to the IPM of *Hypsipyla* is to prevent larval attack from the nursery stage until this age or height is reached. After that, any further damage to the tree is not economically significant, though mature trees may act as reservoirs of pests which are then available to attack individual young trees or whole new plantations in the vicinity. Despite this seemingly easy goal, realizing this aim has proved to be hugely intractable over at least 50 years of trying. This type of insect is a classically low-density pest, in that it takes only one larva per tree to destroy any economic value; tolerance of even a low pest density is not possible in any but a small minority of situations where trees such as *Khaya*

Table 5 IPM of mahogany shoot borer, *Hypsipyla* spp.

Mahogany shoot borer, Hypsipyla *spp.*	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
A pest of many species of tropical mahoganies of such magnitude as to preclude the commercial and sustainable production of high-quality timber in almost all countries throughout Central and South America, Africa, southern and southeast Asia, and Australasia. Effective IPM programs would have huge economic significance for many tropical countries.	Eggs are usually laid singly on the upper leaves or shoots of young trees from the nursery stage onwards. The hatching larva soon tunnels into a leading shoot, constructing a tunnel which may eventually extend for 10 cm or more. Copious sap and resin exudes from an entrance hole somewhere along the length of the tunnel, which binds together boring dust and frass produced by the larva into an easily recognizable orange or brown mass. Pupation usually takes place inside the tunnel. The whole life cycle takes 1 to 2 months, depending on tree species and climatic conditions, and single trees may harbor several larvae at different stages of development.	The leading shoot usually dies and several buds are produced near or around the damaged tip. One or more of the resulting laterals become dominant. An unblemished stem of at least 4 m is required, which takes a minimum of 3 or 4 years to achieve with most host trees, but attacked trees routinely end up stunted, dwarfed, bent, or forked, any of which renders them economically valueless. Prevention of larval establishment in tunnels in the shoots is vital, since the probability of killing larvae once inside before appreciable shoot damage occurs is very low. The natural ecology of the genus in tropical forests is essentially unknown.	Risks vary from country to country and tree species to tree species. 1. Tree species. A large number of species within the Swietenoidea are attacked, and reliable genetic resistance has been hard to find. Host species exotic to a particular country may be less attacked by the indigenous borer populations than native species. Some tree species are better able to tolerate shoot attacks and grow straight subsequently than others. 2. Age. Trees of all ages may be attacked. Individuals between 6 months and 3 years old seem to be most heavily attacked, but this is linked to site and tree species. If a tree can be grown pest-free for the first 4 years of life, direct pest management is no longer required. 3. Site type. Trees growing on dry or conversely clay soils are more likely to be attacked. Soil aridity or waterlogging both increase attacks. Well-drained but moist soils in high rainfall areas show fewest attacks. Sites at the bottom of valleys appear to support fewer forked trees resulting from borer attack as compared with those on slopes or at the tops of hills. 4. Planting conditions. Trees planted in the open with no overhead shade suffer most attacks, and individuals in these locations may suffer most repeated attacks. However, trees in the open grow most rapidly, but they may be attacked when taller and older than those in shade. Trees in the shade of other vegetation, whether natural or	Much more detailed information is required about the pest's natural ecology and host–plant interactions. Various IPM components based on risk averse tactics may however be attempted. 1. Tree resistance and choice of species. Exotic species or those with the ability to grow straight after an attack may be preferable, especially those showing strong apical dominance. Fast growth especially for the first 3 years is very important. 2. Choice of planting site. Shady conditions should produce a higher percentage of unattacked trees, though they will grow more slowly. This growth rate may be improved if moisture is available. In some situations, this may be the only way to produce a few marketable individuals. Dry or waterlogged sites must be avoided. Line or enrichment planting may be preferable to plantations. 3. Biological control. Predators, parasitoids, and even pathogens are likely to be inadequate for the prevention of attack, or to remove the pest when it has established. 4. Chemical control: insecticides. Routine and regular contact poisons may prevent attack for the crucial first few years, but it is highly debatable whether or not such tactics are economically or environmentally viable. Systemic insecticides from soil-applied formulations are not sufficiently effective. 5. Chemical control: pheromones, etc. Producing the appropriate cocktail of synthetic sex-attractant pheromones has so far proved impossible. Suitable compounds derived either from a sex-attractant, or possibly from tree fruit and flower volatiles, for monitoring and/or mating disruption, have potential in theory.

Table 5 Continued

Mahogany shoot borer, Hypsipyla *spp.*	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
			seminatural forest or an early cash or tree crop, grow more slowly but show a higher percentage of nonattacked individuals, and if attacked at all, very seldom more than once. The chance of recovery to a straight stem after attack is higher with plants growing in shade. 5. Location. New plantings of individual trees or whole plantations, in the vicinity of older plantations, or natural forest which contains members of the Meliaceae, are more likely to be attacked. Extreme isolation will remove high risks for a while.	6. Sanitation and pruning. When a small proportion of trees in a stand are attacked, complete removal and destruction may be tolerable, at the early stages of establishment at least. When more than one lateral shoot becomes dominant after an attack on an otherwise vigorous tree, pruning of all but one shoot may eventually produce an acceptable tree (especially *Khaya*).

anthotheca in Mozambique appear to be able to regrow a straight stem after recovery from certain types of attack.

IPM of *Hypsipyla* species has yet to be achieved commercially (**Table 5**). If and when commercially viable tactics are devised, they are likely to be relatively specific to certain geographical locations or individual tree species. A single solution which works over all the tropics is unlikely to be practical, though some general tactics may be fundamental to all IPM programs.

Eucalyptus Longhorn Beetle, *Phoracantha semipunctata* (Coleoptera: Cerambycidae)

Phoracantha semipunctata is a native of Australia which began to spread throughout the world wherever eucalypts were grown from the early 1900s onwards. It is now firmly established almost everywhere, from South and Central America (including parts of the southern USA), through Africa and parts of Asia, and into various countries of the Mediterranean region. All species of *Eucalyptus* may be attacked, as well as other members of the same plant family (Myrtaceae), but some species, such as the widely planted *E. grandis*, seem to be particularly prone to attack (**Table 6**). The key to which host species are most preferred is undoubtedly linked to their ability to withstand arid conditions – *Phoracantha* is a classic 'secondary' pest where the host tree has to be stressed in some way before colonization can be successful. Essentially, the more drought-intolerant a species, the more likely it is to be attacked by *Phoracantha* as soon as soil conditions lose moisture. This is a particular problem for regions with dry seasons where water stress for trees is an annual event.

Adults mate on the bark of suitable host trees, and the eggs hatch into larvae which burrow under the bark and feed and grow between the inner bark and the sapwood surface (**Figure 7**), in much the same way as the bark beetles described earlier in this section. As the larvae grow, and especially when multiple attacks occur in one stem, ring-barking or girdling of the infested trees occurs, and the host dies. Final instar larvae tunnel into the wood and pupate in chambers prior to emerging through characteristically flattened or oval-shaped exit holes. The links between drought-stress and insect success are complex, but seem to be associated with the facts that young larvae have difficulty tunneling into trees with active sap flow. Once established under the bark, there is a further problem for them in that trees with high bark moisture in well-irrigated sites support little or no larval survival. Protection is, therefore, supremely simple – never plant drought-intolerant eucalyptus species in regions or sites where the soils may dry out.

Conclusions

IPM as an approach to sustainable forest pest management has many attractions. In particular, it is a knowledge-based system that involves development of a deep understanding of underlying processes. We have placed the emphasis on prevention of pest outbreaks so that planning for pest management

Table 6 IPM of eucalyptus longhorn beetle, *Phoracantha semipunctata*

Eucalyptus longhorn, Phoracantha semipunctata	*Life cycle*	*Pest status and characteristics*	*Risk factors*	*Integrated pest management*
A very significant mortality factor for many species of *Eucalyptus* planted virtually anywhere in the world, but only if the trees are significantly influenced by dry or arid soil conditions. Vigorous trees in normal moisture conditions should be resistant.	The whole life cycle takes between 2 and 12 months, depending on the climate. Between 10 and 100 eggs are laid in bark crevices (coarser-barked species of *Eucalyptus* enable beetle eggs to be better protected from predation and parasitism). Larvae hatch after 2 weeks or so and colonize the inner bark/sapwood interface where they can feed and grow for several months. Tunnels are typically flattened and filled with tightly packed frass. Pupation in the wood itself may last 10 days. Adult lifespans may reach 90 days or more, giving the pest ample opportunity to seek out the flowers of healthy trees for energy, and then new suitable, stressed, host trees over a large area of territory. The most significant mortality factor seems to be competition for food and space in overcrowded larval populations; the effects of natural enemies are not so important if host conditions are suitable for the pest.	The species is secondary; vigorous, nonstressed trees are not at risk. Infested trees are typified by thin crowns, yellowing leaves or considerable leaf fall. Patches of bark may be loose and easily stripped off to reveal larval tunnels and the insects themselves. Older attacks are identified by the exit holes of newly emerged adults. The numbers of trees killed in a stand or a plantation varies considerably. The beetle is only a minor pest in Australia (though recently it has become more serious in Queensland), but in other countries, where both beetle and tree are exotic, mortalities can reach over 40%.	1. Tree species. The most susceptible species of *Eucalyptus* include *E. globulus*, *grandis*, *nitens*, *saligna*, and *tereticornis;* more resistant ones include *E. camaldulensis*, *cladycalyx*, and *sideroxylon*. It is important to note that some of the most susceptible species are also the most desirable from a silvicultural perspective. 2. Age. Once trees reach a size at which the bark is thick enough to support the tunneling of beetle larvae, attacks can be expected. Eucalypts on rapid growth sites will reach such a stage within a very few years. 3. Site type and planting conditions. Dry soils, arid conditions, seasonal droughts, etc., coupled with eucalypt species that are inherently drought-intolerant, are in high-hazard categories. Even planting in localities where soil aridity is not usually a problem can be risky, so that individual trees on the tops of ridges in shallow sandy soils can be expected to be at high risk of attack. 4. Forest management. Log piles or larger thinnings and brashings allowed to remain in forest stands may easily provide the pest populations with the resources to initiate successful breeding and then to move on to attack even temporarily stressed adjacent trees. Similarly, trees allowed to remain in the plantations beyond their optimal harvesting age (overmature trees) also pose a threat by providing breeding material for *Phoracantha*.	1. Tree health care. The promotion of tree health and vigor by strict adherence to the risk 'rules' above will virtually guarantee that *Phoracantha* is not a problem. However, the provision of sickly, drought-stressed trees is an accident waiting to happen. Cure, once the trees have been attacked, is almost impossible. 2. Tree species choice. Avoid all susceptible species wherever possible. Highly desirable growth or timber characteristics are only useful if the trees survive to reach harvestable age and size. 3. Stand sanitation. Remove or process all potential sources of adult beetles, such as infested trees (young and overmature), log piles, thinnings, unbarked cut logs, etc. 4. Biological control. Both egg and larval parasitoids of *Phoracantha* are known, and vigorous research programs are being pursued, in California for example, to promote biological control. So far, natural enemy impact has not reached levels where mortality is reduced commercially in high-risk situations.

is included from the outset of any forest operations, from planting to harvesting. Although success in pest reduction can be achieved at any stage of the crop, the options available tend to diminish as the crop matures. For example, choice of less susceptible tree species or provenances is only an option that can be controlled fully during the establishment phase of a crop. Thereafter, adjustment to the balance of species, ages, sizes, and spacings of trees are viable options, provided that the processes employed to adjust the variables are understood. In this respect, the case study on mountain pine beetle provides a

Figure 7 Larvae of *Phorocantha semipunctata* and the damage they cause to eucalyptus bark.

good example of effective use of detailed biological and silvicultural information in offering options for both prevention and cure. Of course, it may not be possible to put the choices into practice in all cases, either for economic or for logistic reasons and, therefore, a high element of flexibility is needed to implement successful IPM.

The increasing trend to reduce the use of chemical pesticides provides further impetus to strengthen knowledge-based management systems, although no options should be ruled out until all variables have been considered and their consequences assessed. IPM is, therefore, not a quick-fix solution to pest management, but can provide sustainable long-term pest prevention or suppression with only limited recourse to repeated intervention, particularly with chemical pesticides. We can expect it to be an increasing part of forest pest management in the future.

Forest Fires (Prediction, Prevention, Preparedness and Suppression)

M Jurvélius, Forestry Department, FAO, Rome, Italy

Introduction

The problems and negative impacts associated with large-scale uncontrolled forest fires have increased worldwide over the past two decades. Globally an estimated 300–400 million hectares of forests and woodlands burn annually, emitting an estimated 9.2 billion tonnes of greenhouse gases; however, fire is a vital and natural part of some forest ecosystems, and a multitude of plants and tree species have become fire-dependent. In the early 1990s global changes had reached proportions that led to the global meeting in Rio de Janeiro (Earth Summit, 1992). Changes in the global fire dynamic and an increase in weather disturbances like El Niño have now created a growing awareness that fires are a major threat to many forests and their biodiversity therein, directly contributing to the climate change process.

In particular, tropical rainforests which were thought to be resistant to fires are now experiencing large-scale fires because of unsuitable silvicultural management practices. Globally 95% of all fires originate from various human activities; therefore these activities can be predicted and to some degree prevented well in advance. The difficulty lies in predicting and minimizing the impacts of the remaining 5% of all fires which are mostly caused by lightning.

There is therefore a need to develop proactive fire management strategies aiming at preventing fires from happening, i.e., allowing for the use of fire in useful or 'good' fires, but preventing destructive or bad fires (wildfires) from starting.

Fire preparedness includes a variety of activities with the aim of improving the capabilities to react in case of fire (reactive fire management strategies). Fire preparedness may have a totally different connotation depending on the country concerned.

Fire suppression or firefighting is the procedure or activity of mitigating the results of fire that already has started.

The fire itself consists of three separate components (oxygen, heat, and fuel) which are joined together. If any one of these components is removed, a fire will die.

The last step in extinguishing a fire is called mopping up, which ensures that the fire is dead and can no longer spread. After the fire is removed, the first silvicultural aspects can start, with the aim of rehabilitating the burned forest.

Background to Fire Management

The problems and negative impacts associated with large-scale uncontrolled forest fires have increased worldwide over the past two decades. By far the worst forest fires in recent times, in an economic sense, occurred between 2000 and 2003 in Australia and in the USA. However, the worst fires from an environmental, ecological, and climatological point of view took place between 1997 and 1998 when millions of hectares burned and smoke blanketed large regions of the Amazon basin, Central America, Mexico, and South-East Asia. Estimates suggested that these fires had an adverse impact on as much as 20 million hectares of forests worldwide, contributing to an estimated 13–40% of annual global carbon emission of fossil fuels, primarily through the burning of deep peat soils in South-East Asia. (Peat is a renewable natural resource which will start to replenish once the water table level of the burned area is returned to the level preceding the drainage.)

Global Warming

Contributors to the increase in global warming are found in deforestation, in shifting cultivation and land use changes which normally account for 20% of annual global carbon dioxide emissions.

Globally an estimated 300–400 million hectares of forests and woodlands burn annually, emitting an estimated 9.2 billion tonnes of greenhouse gases; however, fire is a vital and natural part of some forest ecosystems, and a multitude of plants and tree species have become fire-dependent over the last 15 000 years, due to human-induced fires.

Historical Use of Fire

Fire has been a part of the natural landscape for millions of years, forming these landscapes long before human beings arrived. The use of fire by hominids is thought to be 1.5 million years old. During the early period of human use of fire, fire was mainly developed to protect humans; later, fire was refined into a formidable weapon in hunting by perfecting techniques of prescribed or controlled burning. The Aborigines of Australia have skillfully been using controlled burning in northern Australia over an annual area of 30 million ha for more than 40 000 years to maintain the health and vigor of certain ecosystems, to produce seeds, to hunt, for signaling, and for warmth.

Expansion of the Concept of Fire Management

There is a growing awareness that fire needs to be managed at an ecosystem level. Forest fire management is a narrower concept, referring to the management of fires confined to forest areas; however, the majority of fires which currently destroy forests are caused by fires outside forests that spread into forests. Restricting fire management activities to forests is one reason why fire has become an escalating problem and a strong threat to present efforts in sustainable natural resource management.

Global Changes

The increasing global problem of wildfires (fires burning out of control) was first recognized in the early 1970s, when rapid population growth was experienced throughout the developing world; wildfires started to destroy forest vegetation and biomass, resulting in considerable soil erosion by wind and water.

Previously, fire had been used in shifting cultivation, with people frequently moving from one site to another, allowing for fallow periods between cultivations. However, due to population growth, this was no longer possible, and people developed semipermanent agriculture, coupled with traditional annual burning. In parts of Africa, the fire cycle was reduced from once every 10 years to an annual event. Most ecosystems, despite being adapted to fire, could no longer be sustained due to the drastic changes in fire frequency. Fire-adapted ecosystems have adapted to 'fire regimes' that are spaced out over a period of many years to allow for natural regeneration of the forest. If no fire occurs in these ecosystems, then many woody species do not regenerate, and frequent fires can destroy regeneration.

Fire and Food Security

In the savanna ecosystem, where 50% of all global fires occur, the importance of managing fires primarily centers on food security for local people rather than on the traditional concern to protect forest resources in the form of timber and wood products. The hundreds of millions of people living in this environment are traditionally called farmers, and yet they are using hundreds of different non-wood forest products (NWFP) for their daily survival, particularly in the poorest households.

Any uncontrolled fire occurring in this forest environment immediately results in local food shortage. The above areas, where forests are providing a large share of the local food, are largely devoid of global forest as well as fire data (**Figure 1**).

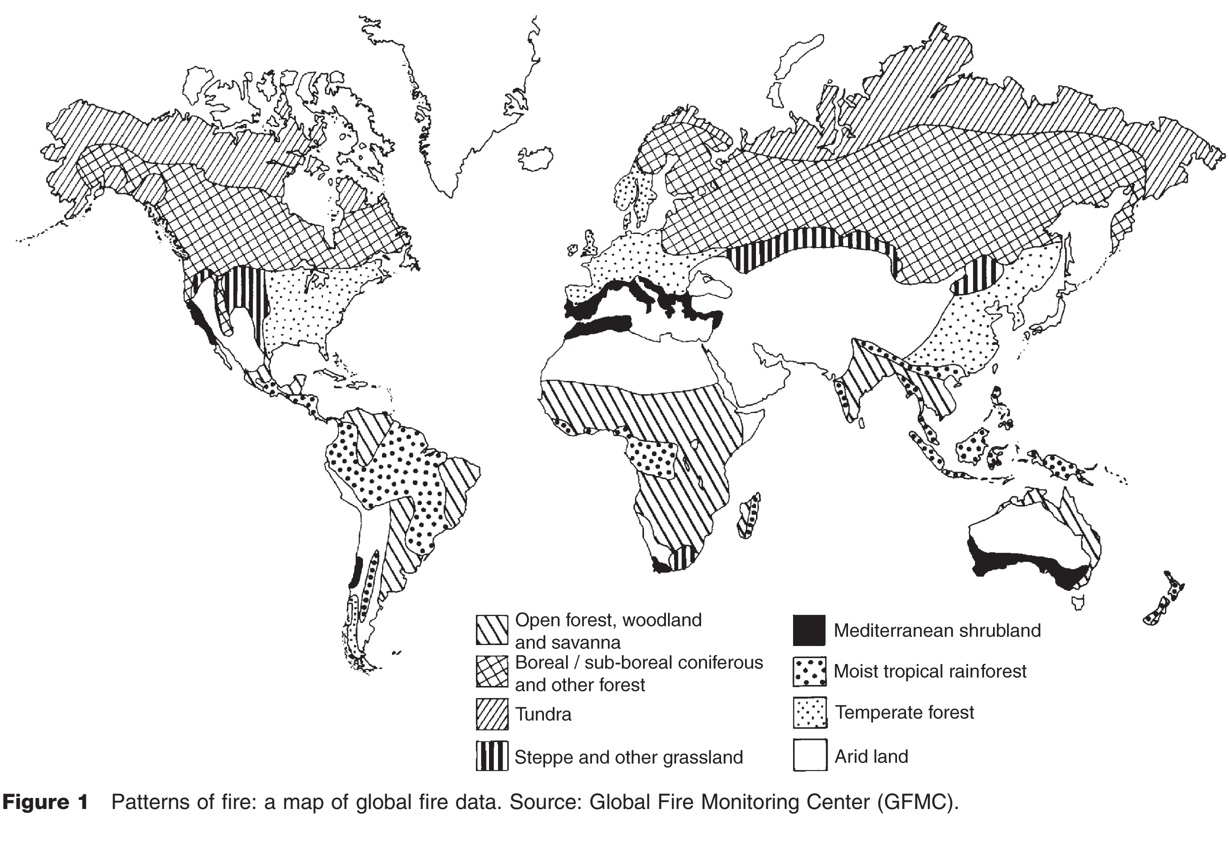

Figure 1 Patterns of fire: a map of global fire data. Source: Global Fire Monitoring Center (GFMC).

Fire Regimes

Fire regimes consist of three factors: fire intensity (severity), fire frequency (how often), and fire season (time of year). For example, the natural cycle of fire in southern Africa is 12 years, decreasing to 8 years towards equatorial Africa. The present almost annual widespread burning has already severely damaged many forest ecosystems in southern Africa, degrading them to bushland and gradually to open eroded seasonal grasslands.

Extensive fire research carried out for more than 45 years in Kruger National Park in South Africa and several other sites confirms the above assumption. The use of fire (silvicultural prescribed burning) needs to be more widely spaced out than the present 7-year cycle applied in the parks and other protected areas to maintain the natural composition of species.

Population Growth

Simultaneously, with the population growth in developing countries, other global changes in the shape of rapid industrialization also took place, resulting in severe industrial pollution and in the extended use of fossil fuels.

The combined effect of these trends resulted in a rapid increase in greenhouse gas emissions which in turn gradually started to change the traditional global weather patterns. This had a negative impact on human life and natural resources, affecting landscapes and livelihoods, causing haze pollution and deposition of unwanted pollutants, drought, insufficient food and widespread flooding.

In the early 1990s global changes reached proportions that led to the global meeting in Rio, Brazil. Changes in global fire dynamics and an increase in weather disturbances such as El Niño have now created a growing awareness that fires are a major threat to many forests and their biodiversity, and directly contribute to the climate change process.

Fire Prediction

Fire prediction used to be an activity carried out by the meteorological institution in each country; in a number of countries it is still the main source of fire information. However, in many countries the national weather service does not have the necessary facilities and field measuring points available for full coverage of the entire country, nor the communication equipment needed to relay information to the central unit. In these cases, fire predictions should be based on the existing database on local fire occurrence.

Silvicultural Factors Contributing to Changes in Fire Prediction

Tropical rainforests, in particular, which were once thought to be resistant to fire, are now experiencing large-scale fires due to unsustainable management practices. Contributing factors include:

- forest operations often prepare for a ready access into the forest in the form of immigration
- lack of management and protection of the forest after harvesting operations
- accumulation of forest debris after logging.

Temperate forests in the USA and eucalyptus forests in Australia, where controlled fires were deliberately suppressed for management and political reasons, are now experiencing devastating wildfires due to an unnatural accumulation of fuel exacerbated by extreme weather conditions. Large-scale fuel reduction programs are now underway in many regions to reduce the potential risk and severity of fires, especially in urban interface areas.

Human-Induced Fires

Globally, 95% of all fires originate from various human activities; these activities can be predicted and to some degree prevented well in advance. The difficulty lies in predicting and minimizing the impact of the remaining 5% of natural fires which are mostly caused by lightning. Predictions of lightning fires can also be made by special sensors measuring all lightning strikes; in recent fires in Australia more than 50 fires caused by lightning were burning simultaneously in Victoria.

Fire Danger Rating

Fire prediction is generally based on an approved national forest fire danger-rating system (FFDRS). The most widely applied system globally is the Canadian danger rating system which consists of two subsystems, fire weather index (FWI) and fire behavior prediction (FBP). Whilst weather application with current remote sensing facilities is quite accurate, FBP is still largely unknown in determining fire danger in many countries. Therefore the international fire community is presently carrying out extensive research in this area to develop reliable prediction systems. Another global dilemma soon crops up once fire prediction is accurately carried out; is the predicted fire a so-called ‘good’ fire that should be allowed to burn, or is it a ‘bad’ fire that should be extinguished? The Canadian FFDRS allows for ‘let burn’ decisions to be made by fire management due to low population densities in some geographic areas.

Fire Prevention

Since 95% of all global fires are caused by human activities it is clear that fire prevention strategies can play a key role in mitigating the global fire situation. There is a need to develop proactive fire management strategies aimed at preventing fires from happening, i.e., allowing fire to burn in useful or good fires, but preventing destructive or bad fires (wildfires) from starting and spreading.

Experience from a number of countries shows that fires cannot be prevented by tightening laws and regulations or by increasing supervision. Sustainable solutions require the ownership of local people in managing fires, including incentive schemes to assist the country in reducing wildfires.

Very little information and research exist about the reasons for forest and biomass fires; natural fires apart, it is difficult to prevent fires if the reasons why these wildfires occur are not known.

Efficient and effective fire prevention work requires networks to be established at global, regional, and national levels to exchange information on best practice raising awareness and training of multiple level and sectoral stakeholders.

Initial Steps in Fire Prevention

The work on forest fire prevention starts by finding out why wildfires burn; when the reasons are ascertained, then strategies for fire prevention can be prepared. Without knowing the reasons for burning, no effective awareness program can be developed, and it is impossible to direct the awareness program to the right target population (such as children, women, men, farmers, hunters, beekeepers, tourists, campers).

There are a variety of reasons why wildfires appear; more often than not, it is a question of ownership or proprietorship of the resource base – land or crop tenure rights can differ between formal laws and customary (traditional) laws. Success points to local management of forest and vegetation fires incorporating the transfer of 'fire ownership' (including land-use rights) from the government to local communities or villages. The term 'fire ownership' implies that, instead of being a top-down government law enforcement activity, fire management becomes a local activity in which fire is used daily as a management tool by the local population.

Integrated (Forest) Fire Management

Transfer of forest fire ownership needs to be coupled with an integrated forest fire management (IFFM) approach, in which a variety of stakeholders each have their agreed roles and responsibilities in managing fires.

The traditional role of agriculturists lighting fires and foresters extinguishing them no longer applies, yet this is still the approach in many countries.

IFFM requires stakeholders to have their agreed roles in fire prevention. At a national level there is a need to involve several ministries outside agriculture, forestry, and the environment, primarily the Ministry of Education and Ministry of Health. The entire population needs to be educated about the environmental functions of trees and forests, about their interdependence with rainfall, soil erosion, harvesting, and global climate. In addition, education and training are needed on the safe use of fire for a multitude of activities, primarily related to managing land and vegetation clearing.

Incentive Schemes

Incentive schemes in managing vegetation and forest are always coupled with the development of methods in how to quantify (in financial terms) the motivation and benefits for local people to participate in managing fires. In the savanna ecosystem, where 50% of all global fires occur, the importance of managing fires primarily centers on food security for local people rather than on the traditional concern to protect forest resources in the form of timber and wood products. These people are using hundreds of different NWFP for their daily survival, particularly the poorest households. The use of prescribed (controlled) fire to protect their resources is a sufficient incentive for the local population to manage their fires. In other parts of the world, people appreciate clean air, scenic beauty, or clean water as an incentive for managing fires, while others appreciate a safe environment surrounding their home, as in the USA lately.

Preparedness

Fire preparedness includes a variety of activities with the aim of improving the capability of reacting in case of fire. Fire preparedness requires the development of reactive fire management strategies.

However, fire preparedness may have a totally different connotation depending on the sociocultural and economic situation at the site of the fire. The preparedness also depends on whether the local people are using fire as a management tool in their daily lives or whether the fires in the area are caused by lightning, as two examples below illustrate.

In the USA

Fire preparedness at a district level may mean that budgets have been approved, funds allocated, staff trained, equipment tested, fuel reductions carried out, firefighters are on standby, the daily fire danger rating is monitored, and the general public have been informed about the fire weather. Satellite and aircraft are being used to monitor and detect any fires at the National Emergency or Alarm Centers. In addition cross-border collaboration agreements have been prepared and signed with a number of countries, such as Canada, Australia, and New Zealand; of annual operating plans/guidelines with these countries have been revised and signed.

In Namibia

The same preparedness at district level means that local communities have been applying prescribed burning or overgrazing using of cattle in strategic areas. Fuel breaks have been constructed in other areas, e.g., around local schools; the traditional chief or leader has been informed about the intention to burn a grass sward around the riverbank at road crossings. Locally, all farmers know the fire weather; additional training means that they understand the implications of fire weather and the skill of using fire in a controlled way, considering the local fire behavior and depending on the type of burn envisaged. Fire detection is generally carried out by local farmers gathering various NWFPs in the forest or herders moving their herds through the silvopastural areas. IFFM approaches mean that the local Council of Chiefs (Khuta) has been informed about the plans to burn some parts of the communal pasture areas at road crossings, thus expanding the activities (from silvicultural forest fire management) to silvopastural fire management. Traditional leaders in neighboring Botswana have also been informed about forthcoming planned burns.

Fire Suppression

Fire suppression or firefighting is the procedure or activity which mitigates the results of a fire that has already started.

Fire consists of three combined components (oxygen, heat, and fuel): removing any one of these components will kill a fire.

In forest fuel the principal inflammable component is carbon. The reaction is expressed as: carbon plus oxygen gives carbon dioxide plus energy ($C + O_2 = CO_2 +$ heat energy).

Suppression (combating fire) can be subdivided into tactics and techniques.

Tactics

Once remote sensing or aerial detection data and images/pictures have been analyzed it is time to start developing the tactical approaches to combat the fire.

Tactics describes how to use human resources, and equipment in the right place at the right time; techniques refers to the technical application in a given fire situation (handtools, pumps, water, foam, aircraft, etc.).

The tactics for extinguishing the fire depend on the resources at hand; it is difficult to remove or reduce oxygen, but it may partly be done. Air contains 21% oxygen; if this proportion is reduced to 15%, it will extinguish the fire. This is most commonly done in the case of light fuels whereby burned gases from the fire are fanned back towards the fire using a fire swatter, thus reducing the oxygen mix; or it may be done by putting sand or soil on top of fire. These methods both remove oxygen and remove heat (applying cold soil onto the source of the heat).

Heat is removed by applying a coolant, usually water, on to the fire; once the heat drops below 220–250°C, the fire will be extinguished.

Fuel can be removed in advance by applying prescribed burning or by other means, or during the fire by manual or mechanical means or by 'back-burning,' i.e., removing the fuel as well as oxygen in the face of the advancing fire.

Tactics will select the combination of activities that together will extinguish the fire. In industrialized countries, fire suppression methologies are well developed, including the use of aircraft, the use of chemical fire retardants mixed with water, and heat-spotting cameras. All these technologies require a high level of sophistication, heavy investment in equipment, and targeting the removal of heat.

In many tropical countries, especially developing countries, the peak fire season usually coincides with a water shortage. Therefore fire management is directly coupled with fuel management, using fire to remove fuel as well as extinguishing fire by lighting another fire. This involves concentrating on removing the fuel as well on a small-scale removal of oxygen, which again is only possible in light fuels.

Incident Command System

In the case of a fire accident or natural cause of fire, a reactive fire management strategy is needed to suppress these fires. Fire suppression is the straightforward action of killing the fire as fast and efficiently as possible.

Therefore it also resembles a military command system; the most efficient system developed for forest fire control is the so-called incident command system

(ICS) which may also be applied to all other kinds of national emergencies whether involving just a few or thousands of people.

Techniques

Firefighting aims to stop the running edge of the fire either by constructing a fire break (a line where all burnable material has been removed) or by applying water or a foam mixture to reduce the surface tension of water droplets for easier penetration into the soil or biomass layer (the same principle as used in dish-washing detergent).

The attack towards the fire may be direct or, if this tactic is not possible, the fire may be attacked indirectly from the flanks of the fire to narrow the moving fire edge. The fire may also be extinguished using another fire either to consume the fuel or the oxygen in front of the advancing fire; this technique is also called backfiring or backburning.

Mopping up

Mopping up is the last step in the process of extinguishing the whole fire. It may also imply that the fire in most of the area surrounding the burning spot is contained in such a way that the fire can no longer escape.

The size of the area to be mopped up depends on the fuel as well as on the location of any smouldering fires in relation to the perimeter of the area.

The failure or success of the entire fire suppression operation may depend on the quality of the mopping-up operation; in addition this may require lengthy patrolling of the burned area, even weeks or months after the initial fire was burning.

Once the fire is 'killed' and the danger is over, one may begin to plan the silvicultural rehabilitation of the burned area.

Hydrological Cycle

L A Bruijnzeel, Vrije Universiteit, Amsterdam, The Netherlands

Introduction

The notion that a good forest cover positively influences climatic and soil conditions, and therefore the amount of water flowing from forested areas, is deeply ingrained in the minds of foresters and the general public alike. Whilst the perceived positive hydrological effects of forests have come under scrutiny in recent decades, the contention that, of all the influences of a forest, that upon the supply of water in streams and upon the regularity of their flow is most important to human economy, remains as valid as ever. With populations rising explosively in some parts of the world, and per capita demands of water increasing in others, optimization of water resources (both streamflow and groundwater reserves) is becoming increasingly important. Also, rising demands for timber products require the establishment of large areas of fast-growing plantation forests, often on land that is currently not forested. Coupled with the continued indiscriminate clearing of the world's natural forests, which in many areas serve as the traditional suppliers of high-quality water, the associated degradation of soil and water quality due to erosion, and the possibility of less dependable precipitation inputs due to climate change, a sound understanding of the hydrological functioning of forests is arguably more important than ever before. In short, water and forests are two natural resources that are inextricably linked. The study of these linkages is called forest hydrology, including any changes in either that are brought about by natural or man-induced forest disturbance.

This article aims to review the current state of knowledge with respect to the chief hydrological processes taking place in forests and how these affect amounts and timing of streamflow. In addition, the effect of forest on amounts of precipitation (a continued bone of contention) is explored. In doing so, the principal focus will be on the more humid parts of the world (both temperate and tropical).

The Forest Hydrological Cycle

The principal features of the forest hydrological cycle are illustrated in **Figure 1**. Rain (P) is the main precipitation input to most forests, supplemented by snow at higher altitudes and latitudes, and by 'occult'

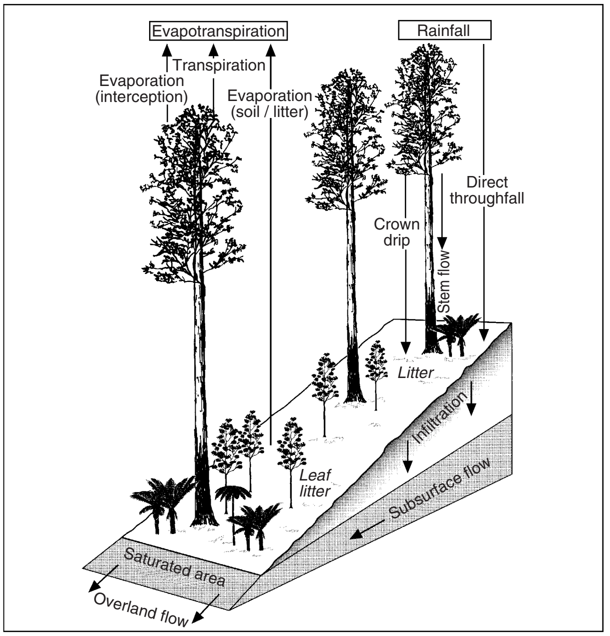

Figure 1 Key hydrological processes on a forested hillslope. Reproduced with permission from Vertessy R *et al.* (1998) *Predicting Water Yield from Mountain Ash Forest Catchments*, CRCCH Industry Report no. 98/4. Canberra: Cooperative Research Center for Catchment Hydrology.

precipitation (fog) in coastal or montane fog belts. A small part of the precipitation reaches the forest floor directly without touching the canopy: the so-called 'free' or 'direct' throughfall. Another (usually small) part travels along the branches and trunks as stemflow *(Sf)*. A substantial portion of the precipitation intercepted by the canopy is evaporated back to the atmosphere during and shortly after the storm (called interception loss, *Ei*), whereas the remainder reaches the soil surface as crown drip once the storage capacity of the canopy has been filled. Because direct throughfall and crown drip cannot be determined separately in the field, the two are usually taken together and referred to as throughfall (*Tf*). The sum of throughfall and stemflow is commonly called net precipitation and is usually substantially smaller than amounts of incident precipitation unless there are significant (unmeasured) contributions by occult precipitation. Thus:

$$Ei = P - (Tf + Sf) \quad (1)$$

If the intensity of net precipitation reaching the forest floor exceeds the infiltration capacity of the soil, the unabsorbed excess runs off as Hortonian or infiltration-excess overland flow (*HOF*). Due to the generally very high absorption capacity of the organic-rich topsoil in most forests, this type of flow is rarely observed in undisturbed forest unless there is an unusually dense clayey substrate or an excessive concentration of stemflow. Not all of the water infiltrating into the soil emerges as streamflow. A large part is taken up by the roots of the vegetation and returned to the atmosphere via the process of transpiration (*Et*). The term evapotranspiration (*ET*) is used to denote the sum of transpiration (evaporation from a dry canopy), interception loss (evaporation from a wet canopy) and evaporation from the litter and soil surface (*Es*). The latter term is often small, especially in dense forests where little radiation penetrates to the forest floor, humidity is high and the air virtually stagnant. Thus:

$$ET = Ei + Et + Es \quad (2)$$

where the respective terms are expressed in millimeters of water per unit of time (hour, day, month, or year).

If unobstructed by impermeable layers, the water not taken up by the vegetation will percolate vertically to the groundwater table and then move laterally to the nearest stream as groundwater (**Figure 1**). Alternatively, percolating water is deflected upon meeting a layer of impermeable subsoil or rock. It is then called 'throughflow.' Such water drains slowly and steadily, thus accounting for the 'delayed flow' or 'baseflow' of streams. In seasonal climates, baseflow reaches a minimum in the dry season and this is usually referred to as dry-season flow or simply 'low flow.' During rainfall, infiltrated water may take one of several routes to the stream channel, depending on soil hydraulic conductivity, slope morphology and soil wetness (**Figure 2**). So-called saturation overland flow (*SOF*) is caused by rain falling onto an already saturated soil. This situation typically occurs in hillside hollows or on

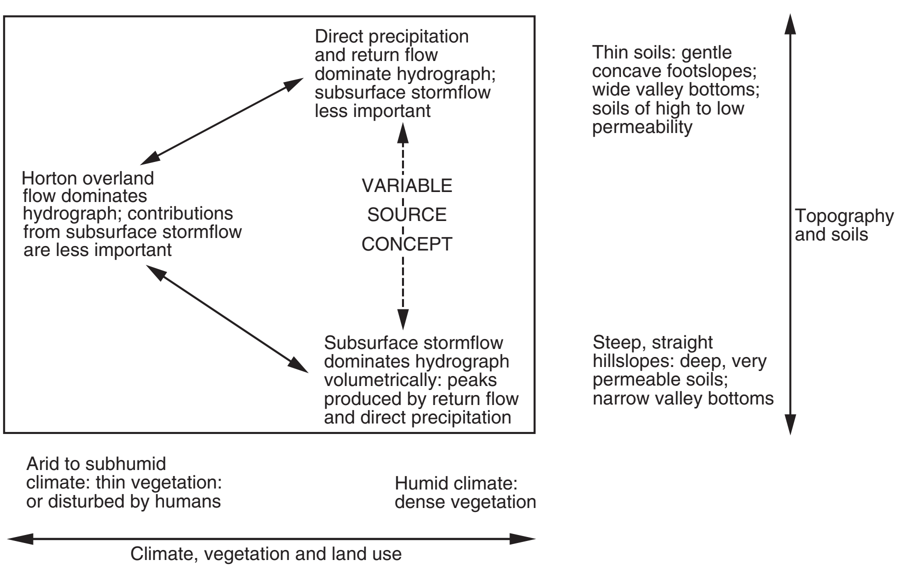

Figure 2 Schematic representation of the occurrence of various streamflow generating processes in relation to their major controls. Note: direct precipitation and return flow are equivalent to saturation overland flow, *SOF*. Reproduced with permission from Dunne T (1978) Field studies of hillslope flow processes. In: Kirkby MJ (ed.) *Hillslope Hydrology*, pp. 227–293. Chichester, UK: © John Wiley and Sons Ltd.

concave footslopes near the stream where the throughflow tends to converge and so maintains near-saturated conditions (**Figure 1**). Occasionally, widespread hillside *SOF* (i.e., outside concavities and depressions) has been observed during and after intense rainfall in the tropics in places where an impeding layer is found close to the surface. Rapid throughflow during storms (subsurface stormflow, *SSF*) usually consists of a mixture of 'old' (i.e., already present in the soil before the start of the rain) and 'new' water traveling through macropores and pipes. As a result of contributions by *SOF*, *SSF*, and in extreme cases *HOF*, streamflow usually increases rapidly during rainfall. This increase above baseflow levels is called 'stormflow' or 'quickflow' whereas the highest discharge is referred to as 'peak flow' (**Figure 3**). Peak discharges may be reached during the rainfall event itself or as late as a few days afterwards, depending on catchment characteristics, soil wetness, and the duration, intensity, and quantity of the rainfall. The total volume of water produced as streamflow from a catchment area over a given period of time (usually a month, season, or year) is called 'water yield.'

The interlocked character of the chief components of the hydrological cycle is summarized by the catchment or site water budget equation:

$$P = Ei + Et + Es + Q + \Delta S + \Delta G \qquad (3)$$

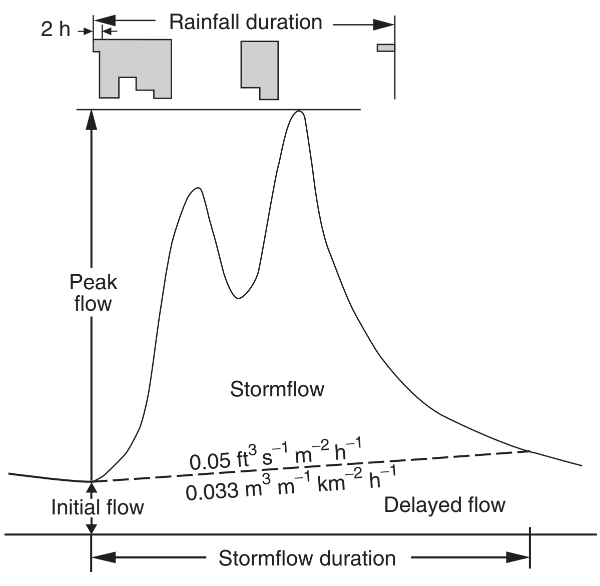

Figure 3 Storm rainfall, stormflow, peak flow, and other variables derived from measured streamflow and rainfall. The dashed line separating stormflow from delayed flow is arbitrary but often used in forest hydrology. Reproduced with permission from Hewlett JD and Doss R (1984) Forests, floods, and erosion: a watershed experiment in the SE Piedmont. *Forest Science* 30: 424–434.

where Q is amount of streamflow or drainage to deeper layers, ΔS change in soil water storage, and ΔG change in groundwater storage, with the remaining terms as defined previously. All values are expressed in mm water per unit of time (hour, day, week, month or year). Note that ΔS and ΔG may assume positive (gain) or negative (loss) values. In view of the seasonal cycle of soil water and groundwater storages in many areas, the values of ΔS and ΔG tend to approach zero on an annual basis. The annual water balance thus often simplifies to:

$$P = ET + Q \qquad (4)$$

Forests and Rainfall

There is a deeply ingrained notion that forests increase precipitation. Indeed, the higher amounts of rainfall that are usually measured in forested uplands or forest clearings compared to adjacent lowlands or agricultural areas would seem conducive to this idea. However, all early reviewers of the subject concluded that enhanced rainfall in forested areas could be attributed either to topographic effects (cloud formation in the uplands being greater simply because of the forced atmospheric cooling of rising air), or to differences in rain gauge exposure to wind (the gauges being more sheltered in forest clearings and usually more exposed in cleared terrain).

Two basic approaches are usually followed to study the effects of land cover on rainfall: (1) trend analysis of long-term rainfall records in combination with simultaneous information on (changes in) land use; and (2) computer simulation of regional (or global) climates under imposed land cover conditions (usually forest versus pasture). Circumstantial evidence for (at least temporarily) decreased rainfall abounds in the literature but such reports have rarely taken into account the large-scale cyclic fluctuations in rainfall that are known to be governed primarily by changes in ocean currents and solar activity. Investigators applying rigorous statistical tests to detect changes in rainfall have usually found trends to be either absent or nonsignificant, or at best only weakly significant. However, although large-scale deforestation has thus never been shown to lead to actual reductions in annual rainfall totals, there is increasing evidence of rainfall being reduced at the onset and end of the rainy season in monsoonal areas. Likewise, changes in the timing of cloud formation during the day and reductions in cloud cover after large-scale forest removal have been detected using satellite images, both under temperate and tropical conditions.

According to atmospheric modeling studies of these phenomena, such changes in cloud formation and rainfall may, at least partly, be caused by the large-scale replacement of forest by agriculture. Forests are aerodynamically rough, which means that they slow down the movement of air. As the air masses behind continue to flow in, the air above the forest is pushed up to greater heights. Also, tall and dark forests absorb more solar radiation than do short grassland or crops and they are therefore capable of returning more moisture to the atmosphere through evaporation. Provided the forested area is large enough (>1000–$10\,000\,km^2$), these two processes lead to enhanced atmospheric humidity and cloud formation over forested terrain.

Since it is impossible to compare differences in rainfall at a site under conditions with and without forest at the same time, computer simulations of the changes in climate associated with land cover change are on the increase. Many simulations have assessed the climatic consequences of the large-scale conversion of the Amazonian rainforest block to pasture. One of the more sophisticated of these simulations predicted an average increase in temperature of 2.3°C over Amazonia and a reduction in annual rainfall of 5–7% (110–150 mm $year^{-1}$), depending on the parameterization of the model. In reality, the actual change in rainfall may be expected to be smaller because the secondary vegetation that often replaces the original forest is much more forestlike than the more extreme grassland scenario used in the simulations. Elsewhere, oceanic influences on climate and rainfall may be more pronounced than in Amazonia (e.g., in Southeast Asia) and this will tend to further moderate the effect of land cover change.

Forests and 'Occult' Precipitation

Where fog impacts a forested area, particularly where the fog persists in the form of a montane cloud belt or coastal fog, additional moisture is intercepted by exposed plant surfaces (or any other obstacle) and precipitation may occur in the form of 'occult' or 'horizontal' precipitation, which is not recorded by rain gauges placed on adjacent open ground (hence the term 'occult'). An extreme example is found along the arid coast of northern Chile where the frequent occurrence of fog drifting in from the ocean has given rise to the development of a patchy forest that, in the near-complete absence of rainfall, thrives almost exclusively on fog water. Similarly, the famous redwood forests of California derive a considerable portion of their moisture (25–50%) from fog blown in from the ocean. At favorably exposed, windy locations the extra inputs stripped from the fog by trees (conifers especially) may reach hundreds of mm per year. Likewise, on wet tropical mountains, so-called 'cloud forests' are found. Net precipitation totals in such forests are often close to, or exceed incident rainfall. Because forest water use (evaporation) under wet, foggy conditions is reduced as well, headwater catchments with cloud forests are veritable water producers. There is circumstantial evidence that the clearing of these fog-ridden forests leads to diminished streamflow totals, particularly during the dry season when inputs by ordinary rainfall are usually low but those by fog at a maximum. Also, ridge-top cloud forests are under siege of global warming which tends to lift the average height of the cloud base.

Quantification of amounts of fog stripped by a forest is notoriously difficult, particularly if the fog occurs together with (wind-driven) rain. The usual approach is to compare amounts of net precipitation (often *Tf* only) beneath the trees with rainfall measured in the open, or to subtract the latter from the catch obtained with some kind of fog gauge. Fog gauge designs are numerous and include wire 'harps,' wire mesh cylinders, polypropylene nets, and louvered metal gauges, but none of these can mimic the complexities of a live forest canopy. As such, they are best used for comparative purposes (site characterization) (**Figure 4**). The throughfall method essentially provides an estimate of net fog drip as it includes an unmeasured amount of water lost to evaporation from the wetted canopy. In addition, the results are site specific. However, progress with the unraveling of fog–forest interactions is being made through the use of physically based deposition models and the often contrasting stable-isotope signatures of rain and fog water.

Forests and Evaporation

Rainfall Interception Loss

Arguably, no subject in forest hydrology has received as much attention as the measurement of interception loss (*Ei*, i.e., the first major component of forest evapotranspiration *ET*), or rather: of throughfall (*Tf*) and stemflow (*Sf*) (see Eqn [1]). The following broad generalizations can be made:

- *Ei* is a function of incident rainfall (*P*) and typically declines more or less hyperbolically when expressed as a percentage of *P*
- both *Ei* and the canopy storage capacity (*S*) are generally larger for coniferous forests than for deciduous forests (growing season)
- winter values of *Ei* and *S* for deciduous forests are roughly half to two-thirds of summer values
- *Sf* generally constitutes only a modest fraction of *P* (typically $<3\%$), with the exception of smooth-barked species such as beech or maple (5–12%) or young trees
- *Ei* and *S* increase with stand density
- snowfall interception storage by coniferous canopies exceeds that for rainfall.

Usually, the results of interception studies are expressed as a percentage of gross rainfall *P*. Comparisons between different studies, even for one and the same species and age class, are rendered difficult, however, because of the more-or-less unique character of each forest stand in terms of density, undergrowth, exposure to prevailing air streams, and rainfall regime. An additional problem is that the notoriously uneven distribution of *Tf* (both in space and time) requires rigorous sampling strategies that are not always achieved. Spatial variability of *Tf* tends to increase with forest density, i.e., it is greater in summer than in winter for deciduous stands and much larger in tropical rainforest than in temperate plantations (**Figure 5**). The vegetation in most natural forests is made up of a mosaic representing different stages of growth, ranging from young rapidly growing trees in gaps to old-growth emergent trees on the decline. Throughfall in coniferous plantations has been shown to decrease with stand age (i.e., *Ei* increases) but in natural forests *Ei* may peak after about 30 years, with a gradual decline as the forest matures. At the micro scale, *Tf* often increases away from the trunks to reach a maximum just within the perimeter of the crown. In view of the high spatial variability of *Tf*, the use of a large number of rain gauges that are placed randomly underneath the forest canopy is usually recommended for adequate measurement. The use of regularly relocated ('roving') gauges is generally considered to give the best results as this allows a more representative sampling of so-called 'drip points' (i.e., places where $Tf > P$, often because of funneling of water by a particular configuration of branches) (**Figure 5**).

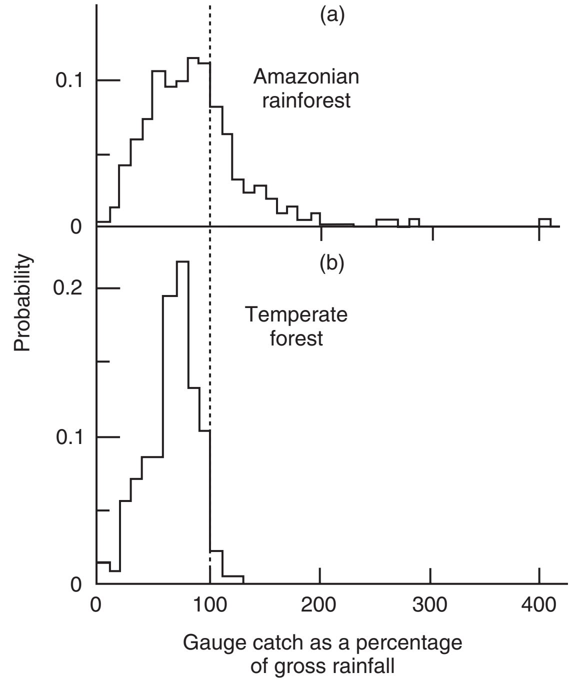

Figure 5 Probability distribution of throughfall gauge catch in a random grid expressed as a percentage of coincident gross rainfall for (a) Amazonian rainforest and (b) a pine forest in the UK. Reproduced with permission from Lloyd CR and Marques AdO (1988) Spatial variability of throughfall and stemflow measurements in Amazonian rainforest. *Agricultural and Forest Meteorology* 42: 63–73.

Figure 6 summarizes results for a number of British interception studies. Despite the large variation encountered within the deciduous forest group, *Ei* in deciduous stands is invariably lower than in coniferous forest for the same amount of *P*. A similar contrast has been noted for coniferous and (semi-) deciduous plantations such as teak and mahogany in the tropics. Although evergreen, the relatively light crowns and smooth stems of (young) eucalypt plantations intercept only modest quantities of rainfall (typically about 10–15%), both in the tropics and in their native Australia. Despite their much greater leaf surface area, lowland tropical rainforests intercept similarly modest amounts of rainfall. This reflects the typically short duration and high intensity of rainfall under such conditions as well as a relative abundance of drip points (**Figure 5**) and small amounts of stemflow (typically $<2\%$). There is reason to believe that interception assumes greater importance under 'maritime' tropical conditions

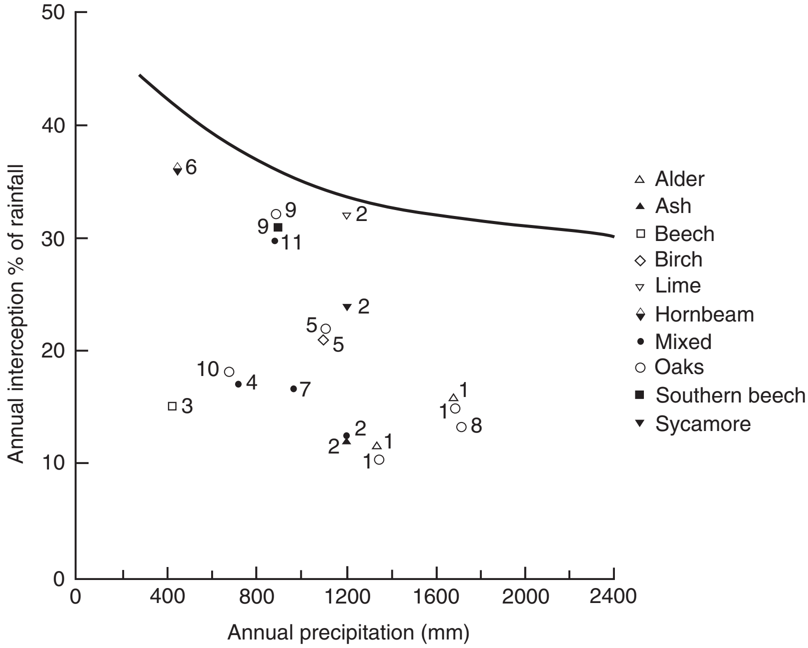

Figure 6 Annual interception loss (%) versus annual rainfall for European broadleaved trees. The solid line represents the annual interception percentage for coniferous forests in the UK. Reproduced with permission from Roberts JM (1999) Plants and water in forests and woodlands. In: Baird A and Wilby R (eds) *Eco-Hydrology: Plants and Water in Terrestrial and Aquatic Ecosystems*, pp. 181–236. London: Routledge.

($Ei > 25\%$), however, although reports to that effect may have been confounded by high spatial variability.

Interception by the Litter Layer

It has been argued that evaporation from the litter layer (*Es*) may constitute a significant component of overall interception loss and should therefore be determined separately. Litter evaporation has been shown to reach 2–5% of incident *P* in hardwood stands in the eastern USA (*c.* 50 mm year^{-1}), with the highest rates being observed in winter when the leafless condition of the forest permits increased ventilation and irradiation as well as maximum amounts of *Tf* to reach the forest floor. High values of *Es* occur mostly in stands with little to no understory vegetation and vice versa. Typical values of *Es* from the thick litter layers associated with temperate and tropical coniferous forests amount to *c.* 10% of *P* (100–150 mm) versus only 1–3% in dense lowland tropical rainforest with a poorly developed litter cover (50–70 mm).

Interception Modeling

Despite the numerous studies of rainfall interception conducted prior to the 1960s, little progress had been made with understanding the physics underlying the observed contrasts and inconsistencies in *Ei*, both between and within species and events. Explanations were usually worded in terms of differences in canopy storage capacity (in turn related to canopy density, deciduousness, etc.) or the intensity and duration of the rain. However, in the mid-1960s the previous largely empirical approach gave way to a more physically orientated process-based approach. This was followed by subsequent improvements in equipment for the measurement of above-canopy climatic conditions and, later, computational facilities. As a result, our understanding of the interception process has increased significantly.

In this more physical approach, evaporation from a vegetated surface is described quantitatively in terms of the amount of energy available for evaporation, other standard climatic parameters governing evaporation (such as temperature and humidity of the air, wind speeds), and various resistances against evaporation. Under dry canopy conditions the prime resistance to evaporation is that exerted at the leaf level (the so-called stomatal resistance), the cumulative value of which for the entire canopy is usually called surface or canopy resistance (r_c). The larger the canopy surface area, the smaller the value of this physiologically controlled r_c and, other variables remaining equal, the higher the resulting evaporation rate. However, when the vegetation surface is (fully) wetted by rain or fog, the canopy resistance effectively becomes zero and the evaporation process is dominated by the so-called aerodynamic resistance r_a. Whilst r_c signifies the resistance experienced by water molecules to transport from within the leaves to the surface of the leaves, r_a denotes the resistance to further upward transport into the overlying air. Unlike r_c, r_a is not controlled by the plants themselves. With increasing vegetation height, however, there is a corresponding increase in surface roughness. For a given wind speed, the associated enhanced atmospheric turbulence is reflected in a decrease in r_a. Also, r_a decreases with wind speed. Approximate values of r_a at a wind speed of $2.5\,\mathrm{m\,s^{-1}}$ measured at 10 m above the surface are 115, 50, and 10–15 $\mathrm{s\,m^{-1}}$ for short grass, field crops, and forest, respectively. Because values of the surface resistance to evaporation from a dry canopy (r_c) for grass and forest are much more similar than those of r_a (**Figure** 7), the net effect of the contrasts in aerodynamic resistance (much lower for forest) and in the degree of reflection of incoming radiation (much higher for grass) result in rather similar evaporation rates for grass and forest, as long as soil water is not limiting (**Figure** 7). This stands in great contrast to the finding that evaporation from a forest canopy under wet conditions (i.e., when the evaporative process is dominated by r_a) will proceed much faster than from a wet grassland (**Figure** 7).

Typically, rates of 0.2–0.5 $\mathrm{mm\,h^{-1}}$ are observed for evaporation rates from wet forest canopies, even in cloudy winter weather when the energy needed to sustain such rates must greatly exceed the available amount of radiant energy. However, temperatures of wet forest canopies have been shown to be slightly cooler than the air passing overhead. This, together with the low aerodynamic resistance of forest that is so conducive to rapid evaporation, allows the development of a downward flux of sensible heat capable of (locally) maintaining evaporation rates well in excess of available radiant energy. The degree to which the phenomenon influences annual interception totals obviously depends on the frequency of wetting of the canopy (i.e., rainfall regime) and thus on the overall setting of the forest. Thus, for a conifer plantation in the relatively dry eastern part of the UK (annual interception total 215 mm or *c*. 40% of total evapotranspiration *ET*), the effect is much less pronounced than for comparable forest in the more maritime setting of wet central Wales with its frequent passage of warm frontal rain (annual *Ei c*. 530 mm or *c*. 60% of total *ET*). Large-scale advection of relatively warm air from the nearby ocean is a likely source of energy for the enhanced evaporation at this and other near-coastal sites. Elsewhere, advection of warmer air flowing in from areas not wetted and cooled by rain may provide the extra energy. An alternative, and as yet insufficiently tested, explanation involves the release of heat that occurs when water that has been evaporated from the forest canopy condenses again. This would suggest a positive feedback of rainfall amount on the magnitude of *Ei* (and thereby condensation) as well as very rapid, local recycling of moisture.

Physically based models may help to elucidate the relative importance of different factors in the interception process which is difficult to assess from an actual interception record. The effect of varying rainfall intensities and wet canopy evaporation rates, canopy storage capacity and the distribution of the rain (continuous versus intermittent) on the magnitude of *Ei* using one such model (the so-called Rutter model) is illustrated in **Figure 8**. The limiting effect of low rainfall intensity at faster evaporation rates is clearly borne out by the simulations, as is the increase in *Ei* at rainfall higher intensities and for

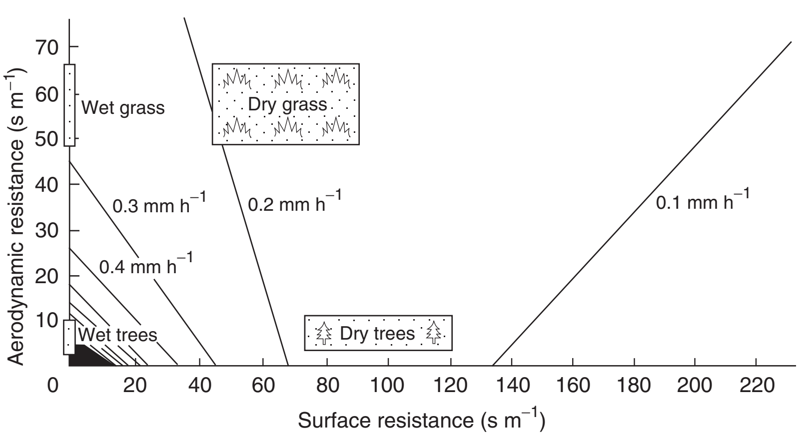

Figure 7 Evaporation rates calculated as a function of the aerodynamic (r_a) and surface (r_s) resistances to evaporation for cool summer daytime conditions. Reproduced with permission from Calder IR (1979) Do trees use more water than grass? *Water Services* 83: 11–14.

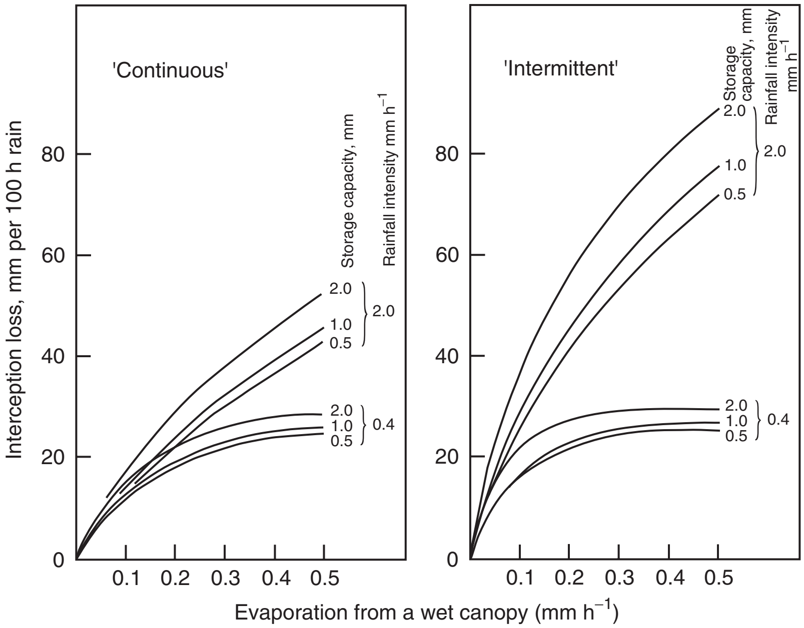

Figure 8 The interaction of wet canopy evaporation rate, rainfall intensity, rainfall distribution, and canopy storage capacity on interception loss from 100 h of rain. higher canopy storages, especially in the case of intermittent rain.

Transpiration

The second major component of forest evaporation is transpiration (*Et*, evaporation from a dry canopy). Like evaporation from a wet canopy, rates of *Et* are governed by the amount of available energy (mostly in the form of sunshine), air temperature and humidity (together determining the so-called evaporative demand of the atmosphere), and wind speed (affecting the rate with which evaporated moisture is carried away). However, unlike evaporation from a wet vegetation, which is largely controlled by the aerodynamic resistance of the vegetation (r_a) as we have seen earlier (**Figure 7**), *Et* is chiefly governed by the physiologically controlled canopy resistance r_c. In its turn, r_c is influenced by a range of environmental and plant variables, including light intensity, leaf area, leaf temperature, and leaf water potential (a measure of plant water stress), but also the humidity of the air and the amount of water present in the soil. The ease with which water molecules are evaporated from within the leaves to the surface of the leaves (as represented by the so-called canopy conductance g_s, i.e., the inverse of resistance r_s) increases with increasing light intensity and temperature (up to a maximum value). However, the conductance decreases as the air or the soil become drier; or, expressed in scientific terms, as atmospheric humidity deficit or soil water deficit increase (**Figure 9**). Although the actual interactions between g_s (or r_s) and the cited plant and weather variables are only partly understood and quantifiable, their combined effect under humid temperate or tropical conditions generally results in distinct daily patterns of g_s (or r_s) that change comparatively little with time as long as soil water stress does not occur.

The distinct response of leaf conductance to changes in atmospheric humidity deficit (**Figure 9c**) has been observed in vegetation types as diverse as northern conifers and tropical rainforests. Coastal species seem to be more sensitive in this respect than continental species, possibly because they are adapted to persistently high humidities. Although the precise underlying mechanism is still unclear, the strong feedback response between g_s and atmospheric humidity results in a significant dampening of instantaneous transpiration rates. Even though potential evaporative demands by the atmosphere may be much higher, daily forest transpiration totals typically remain below 4 mm in most humid climates (both temperate and tropical). There are notable exceptions, however, such as poplars or eucalypts grown in short-rotation coppice systems with unrestricted access to soil water. Although such trees are often called voracious consumers of water and have been used for centuries to help drain marshy areas, it is important to note that they do reduce their water uptake when soils dry out. The planting of eucalypts and poplars, particularly in subhumid areas, should

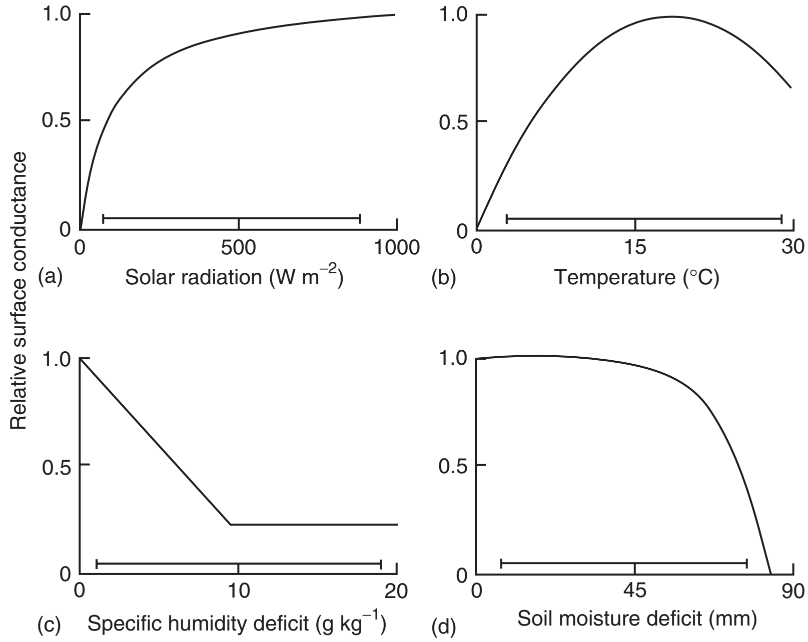

Figure 9 The general form of the dependence of the relative surface conductance on (a) solar radiation, (b) temperature, (c) specific humidity deficit, (d) soil moisture deficit. Reproduced with permission from Stewart JB (1988) Modelling surface conductance of pine forest. *Agricultural and Forest Meteorology* 43: 19–35.

therefore be based on judicious planning if over-exploitation of precious groundwater reserves is to be avoided.

Soil water stress has been shown to have a marked effect on *Et* in seasonally dry climates where the soil tends to dry out considerably. Often, however, the modest transpiration rates caused by the strong physiological sensitivity of the trees to drops in atmospheric humidity (**Figure 9c**) imply that a considerable portion of the soil water reserves (typically two-thirds to three-quarters) can be taken up before surface conductance is reduced further and transpiration starts to fall off (**Figure 9d**). As shown in **Figure 10** for a young eucalypt forest in south-eastern Australia, the soil water deficit at which transpiration becomes reduced tends to be reached earlier when rates of water uptake are high than during times of more modest uptake. As such, critical soil water deficits affecting *Et* will only be rarely attained in humid climates where uptake rates are modest, and may therefore be expected to play only a minor role in generating differences between species and sites.

In contrast to evaporation from a wet canopy (rainfall interception *Ei*) (**Figure 7**), annual totals of transpiration (evaporation from a dry canopy) show comparatively little variation between species and sites within a given climatic zone. For example, the average annual *Et* for coniferous and deciduous forests (excluding poplars) in Western Europe is not significantly different at 300 ± 35 and 335 ± 35 mm. This striking similarity in the water use of deciduous and evergreen species of varying age and habitats can be attributed to: (1) the strong feedback between atmospheric humidity and surface conductance (**Figure 9c**); (2) the relative insensitivity of *Et* to soil water availability (**Figure 10**); and (3) the compensatory effects of the presence or absence of understory vegetation. Indeed, overall transpiration for a dense forest with little to no undergrowth can be similar to that of open forests with much more vigorous understories. Large, deep-rooted trees have been shown to draw their water mostly from deeper layers or the groundwater table whereas small understory trees (whose roots are often unable to reach the groundwater) have to rely on soil water. Interestingly, during periods of drought stress, groundwater taken up by the deeper roots of the larger trees during the night is known to be released from shallow roots into the upper layers of the soil, where it is subsequently used by understory vegetation. This remarkable finding suggests that the water relations of over- and understory trees are more complex and perhaps less competitive than sometimes perceived. The process is known as 'hydraulic lift' and can be explained in terms of soil and plant water potential gradients.

In contrast to the relative abundance of transpiration estimates for humid temperate forests, information for tropical rainforests and plantations is scarce.

Estimates of average annual *Et* range between 900 and 1300 mm (average *c.* 1000 mm) for lowland rainforests versus 500–900 mm for montane rainforests not subject to appreciable amounts of fog. Transpiration in montane cloud forests may be as low as 250–300 mm year^{-1}. Most of these estimates are based on indirect (water budget based) methods, however, which must be considered relatively crude. Fortunately, the number of studies employing direct, micrometeorological techniques to measure evaporation from tropical forests is on the increase. The same holds for the use of physiological approaches measuring the rate of sapflow in individual trees. Whilst tower-based micrometeorological techniques tend to integrate results over larger areas, sapflow measurements need to be scaled up to the stand level. Considerable success has been reported with this approach in a variety of forests.

Total Evapotranspiration

Although it is beyond the scope of the present process-oriented chapter to discuss amounts of total evapotranspiration (*ET*) associated with different forest types and climatic zones, it can be concluded from the previous sections that changes in the interception component of evaporation (*Ei*) will be much more important than those of the transpiration component (*Et*). Taking Western Europe as an example, annual totals of *Et* have been shown to be quite similar for deciduous and coniferous forests over a wide range of soil and rainfall conditions. Conversely, absolute annual totals of *Ei* for these forests (**Figure 6**) range from about 120 mm (oak coppice under low rainfall conditions) to about 700 mm (spruce at a high rainfall location subject to advected heat from the ocean). Similar contrasts between variations in *Ei* and *Et* have been reported for the humid tropics where radiation loads, average temperatures, and rainfall are generally higher than in the temperate zone. As was the case for temperate conditions, the importance of intercepted rainfall to overall *ET* under maritime tropical conditions is tentatively confirmed.

Concluding Remarks

Considerable progress has been made since the mid-1960s in the conceptual understanding and mathematical description (modeling) of such key forest hydrological processes as evaporation from a wet canopy (interception), transpiration (evaporation from a dry canopy), infiltration and forest hillslope hydrological behavior (runoff generation), as well as forest–atmosphere interactions. The precise turbulent transfer mechanisms underlying the much enhanced rates of evaporation from wet forest canopies under maritime climatic conditions or the effects of large-scale deforestation under such conditions are not very well understood, however. Neither is too much known of the hydrological significance of fog interception by forests in montane cloud belts,

particularly in the tropics. Similarly, the data base for tropical forest water use is small. However, with the continued improvement of process-based hydrological models, equipment, data storing, and computational facilities, significant progress can be expected to be only a matter of time.

Impacts of Forest Conversion on Streamflow

L A Bruijnzeel, Vrije Universiteit, Amsterdam, The Netherlands

R A Vertessy, CSIRO Land and Water, Canberra, Australia

Introduction

Trees and forests are valued for timber and forest products, for amenity, for biodiversity, and for the cultural and the spiritual well being we derive from their proximity. Forests and reforestation programs are also widely promoted with regard to their perceived hydrological benefits, although often these expected benefits are not realized. This article reviews the scientific knowledge and the public perceptions of important forest–hydrology links, focusing on the vexed questions of whether, when, and to what extent forests increase or decrease streamflow, reduce floods, and increase dry season flows. The effect of forest on rainfall, the impacts of various forestry activities (thinning, selection logging, clear-felling) on streamflow, and the soil and water impacts of reforesting degraded or agricultural areas are discussed elsewhere (*see* **Hydrology**: Hydrological Cycle; Impacts of Forest Management on Streamflow; Impacts of Forest Plantations on Streamflow). Similarly, effects of forest management and conversion to other land use on water quality, and ways to minimize any adverse impacts accompanying such conversions, are dealt with in other articles (*see* **Hydrology**: Impacts of Forest Management on Water Quality; Soil Erosion Control).

Forests and Water: Received Wisdom

Traditionally forests have been promoted as being ‘good news’ for the water environment. The conventional received wisdom, embodied often in government forest policy and promoted by international and national forestry interests and organizations is that, apart from reducing erosion and maintaining water quality, a good forest cover: (1) increases runoff, (2) reduces or even prevents 'flood,' and (3) boosts dry season flows. Yet when these statements are held against the light of scientific inquiry, the evidence is not always as favorable and sometimes even indicates the opposite.

Put simply, the most widely held view among the general public and, perhaps to a lesser extent, policy-makers and resource managers, is that forests act as 'sponges' absorbing excess rainfall and releasing the water slowly and evenly during lean periods. Because of this, forests are believed to be capable of preventing flooding, and increasing streamflow during the dry season. By analogy, their disappearance invariably brings about havoc (floods, droughts). Likewise, the effect of tree planting on degraded land is expected to result in (rapidly) improved streamflow regimes, i.e., elimination of peak flows and increased low flows. Such views are encountered especially in the tropical and subtropical parts of the world where the adverse hydrological effects of the land degradation that often (but not necessarily) follows forest clearance are felt the most. In the following, the claims with respect to the adverse effects of forest conversion ('deforestation') on streamflow are examined in some detail. The effects of the reverse, i.e., reforestation, are discussed elsewhere (*see* **Hydrology**: Impacts of Forest Plantations on Streamflow).

Forest Conversion and Streamflow: The Scientific Consensus

Forests and Annual Water Yield

It is now recognized worldwide that evaporation from forested areas, with very few exceptions, will be greater than that from alternative land uses, such as pasture or annual cropping (**Figure 1**). Provided the soil is not disturbed too much upon forest conversion, the smaller water use of crops or grassland generally shows up as increases in groundwater recharge, in the volumes of water flowing annually from cleared catchments, and in increased seasonal (dry season) flows. Generally, the larger the proportion of forest removed, the larger these increases in water yield (**Figure 2**).

Whilst the increases in streamflow usually return to preclearing levels within 3–35 years where regrowth of the original vegetation occurs (depending mostly on the vigor with which regeneration takes place), the conversion of native forest to other types of vegetation cover may produce permanent changes in flow. For example, permanent increases in annual water yield are normally associated with the conversion of deciduous or evergreen native forest to agricultural cropping or pasture (cf. **Figure 1**). Depending on the nature of the conversion, degree of surface disturbance (affecting surface runoff), and rainfall, reported increases in flows range from 60–125 mm year^{-1} under humid warm temperate conditions to 140–410 mm year^{-1} in the equatorial tropics. These values are somewhat smaller than the maxima shown in **Figure 2** because the latter mostly refer to increases in flows shortly after forest clearance and before a new vegetation cover is established.

There are two principal reasons for the difference in evaporation between forests and shorter crops (cf. **Figure 1**). In wet climates with frequent rainfall, where the surfaces of vegetation tend to remain wet for long periods, rainfall interception by the canopies of forests is much higher than that by shorter crops. The intercepted water is evaporated back into the atmosphere and therefore does not reach the ground where it could have contributed to soil water reserves. Rates of evaporation from a wet forest canopy are so enhanced because the aerodynamically very rough surfaces of forests assist the turbulent transport of water vapor into the atmosphere much more than the smoother surfaces of grassland or low crops. This is analogous to the clothes-line effect: wet clothes pegged out on a line will dry much quicker than those laid out flat on the ground. Not only does the increased turbulent exchange between forests and the atmosphere increase the rate at which evaporated water molecules are moved up into the air; it also promotes the rate at which heat can be supplied by the passing air to the cooler vegetation surface underneath to support the evaporation process. This source of energy, known as advected heat, is of such significance that annual evaporation rates from forests in some wet climates can exceed those that could be sustained by direct radiation from the sun by a factor of 2. Large-scale advection typically occurs in near-coastal or mountainous regions (where the ocean or adjacent lowlands are the main source of relatively warm air, respectively). At a more local scale warmer air may be drawn in from areas that are not wetted and cooled by rain.

In drier climates or during prolonged rainless periods, forests are able to access and take up more soil water than short vegetation or agricultural crops because forests generally have much deeper root systems. This also contributes to higher evaporation rates overall. However, under conditions of ample soil water availability, the internal physiological resistance to evaporation is often slightly greater for trees than for short crops. As a result, the soil water uptake (transpiration) rates of forest may be *c*. 10% less than those of grassland and other short crops (as long as they are well watered) and this may to some extent compensate for the interception and increased rooting depth effects described above.

Although annual water yields from forested catchment areas can thus be expected to be (much) less than those for cleared areas (**Figures 1** and **2**), there are a few exceptions. The first of these concerns so-called montane cloud forests. These wet and mossy, fog-ridden forests are mainly found in the cloud belts of (mostly tropical) mountains and islands although fog-affected forests also occur along the western margins of the American continent. At favorably exposed locations cloud forests may receive hundreds of millimeters of extra water in the form of wind-blown fog and drizzle that impact on and drip from the canopy. In extreme cases annual amounts of fog drip may exceed incident rainfall totals, thereby more than compensating the losses associated with interception evaporation referred to earlier. Because soil water uptake rates are also low under these humid cloudy conditions, areas with cloud forests are generally considered excellent suppliers of water, especially during periods of low rainfall when fog incidence is often greatest. Concerns have been expressed that the indiscriminate clearing of cloud forests to make way for pasture or vegetable cropping will lead to reductions in streamflow because of the associated loss of the former forest's fog stripping capacity (**Figure 3**). Although evidence from the humid tropics for such declines in flows is circumstantial at best, it has been observed in the Pacific Northwest of the USA after the partial cutting of Douglas-fir forest subject to high fog incidence.

The second exception to the rule of increased streamflows after forest conversion relates to cases where old-growth forests with relatively low water use and vigor are replaced by young, actively growing secondary forest or exotic tree plantations. Examples include rapidly regenerating mountain ash (*Eucalyptus regnans*) forest after a wildfire in southeastern Australia, young secondary growth in Amazonia after the abandonment of agricultural fields or pasture, and (most probably) plantations of *Acacia mangium* replacing rainforest in Malaysia. Likewise, converting deciduous forest to coniferous forest will result in more-or-less seriously decreased streamflow totals, mostly because of the much higher interception evaporation associated with the evergreen conifers.

Figure 3 Converting tropical montane cloud forest to pasture may reduce catchment water yields through the loss of the forest's fog stripping capacity. Photograph courtesy of KFA Frumau.

Although the results of small catchment experiments provide a clear and consistent picture of increased water yield after replacing tall vegetation by a shorter one (and vice versa; cf. **Figures 1** and **2**), such effects are often more difficult to discern in (very) large river basins (>1000 km^2). Apart from continuous changes in the mosaic of different landcover types, each with their own influence on local runoff, there are the added complications of strong spatial and interannual variability in rainfall, and withdrawals of water for municipal, agricultural, and industrial purposes in densely populated areas. Nevertheless, a few studies have demonstrated a significant landcover change effect on the flows from (very) large basins. An increase in annual streamflow of about 110 mm has been reported for the Citarum River basin (4133 km^2) on the island of Java, Indonesia, between the 1920s and the 1980s despite unaltered rainfall totals. The increase was attributed to the replacement of irrigated rice fields (not forest) by settlements and industrial estates. Likewise, the conversion of *c.* 33 000 km^2 (19% of basin area) of so-called cerrado forest (scrub with scattered trees) to pasture in the subhumid Tocantins basin (175 360 km^2) of central Brazil was followed by an increase in streamflow of about 90 mm $year^{-1}$ (+24%).

At an intermediate scale (1100 km^2), increases in averaged annual flow totals occurred over a period of four decades in the Mahaweli catchment in Sri Lanka, despite a weak negative trend in rainfall over the same period. Although both trends were not statistically significant at the 95% significance level due to strong interannual variability in the data, the corresponding increase in annual runoff ratios (streamflow: rainfall) was highly significant (**Figure 4**). The increased hydrological response was ascribed to the gradual but widespread conversion of tea plantations (not forest) to annual cropping and home gardens on steep slopes without appropriate soil conservation measures (see also the section on forest and dry season flows below).

To summarize, despite the few exceptions outlined above, there is overwhelming evidence that streamflow totals from forested catchments are reduced compared with those under shorter vegetation. The effect of enhanced water yield after forest conversion has been demonstrated over a range of scales, including some very large river basins.

Forests and Floods

As long as the soil's water intake capacity is not degraded too much by surface compaction, the lower water use of grassland and crops compared to forest

(**Figure 1**) will manifest itself in the form of wetter soil conditions and thus increased streamflow (**Figure 2**). This overall increase in catchment wetness leads, in turn, to an expansion of storm runoff-producing areas. These are mostly wet, low-lying areas around watercourses and stream heads, but may also include footslopes and hillslope depressions. The consequence of this is that cleared catchments will respond more rapidly and more vigorously to rainfall; both stormflow volumes and peak discharges will be elevated (**Figure 5**).

Under conditions of minimum surface disturbance (e.g., when skyline logging techniques are used), relative increases in catchment stormflow response to rainfall are largest for small rainfall events (up to 300%), declining to less than 10% for large events. As such, the influence of vegetation cover or type is inversely related to the size of the rainfall event generating the stormflow (**Figure 5**). This can be explained as follows: for small storm events the combined storage capacity of vegetation canopies, ground-convering litter, surface microtopography and the soil mantle can be substantial relative to the size of the storm depth. Of these the soil mantle is potentially the largest water store, but its capacity to accommodate additional rain varies as a function of soil wetness. Where previous uptake by the vegetation has depleted soil water reserves, storage capacities will be relatively high but once the soil has become thoroughly wetted by frequent rains (typically at the height of the wet season), opportunities to absorb large additional amounts of rain will be very limited. Furthermore, as precipitation events increase in size, so does the relatively fixed maximum storage capacity of the soil become less influential (**Figure 5**). In other words, under conditions of extreme rainfall and soil wetness, the presence or absence of a good forest cover is no longer decisive. Catchment runoff response to rainfall is then governed primarily by the soil's physical capacity to store and transmit water.

Naturally, the effect of forest conversion on stormflow generation will be much more pronounced if soil disturbance is severe and the catchment's rainfall absorbing capacity becomes structurally impaired. Soils may be compacted by machinery during clearing operations and subsequently by grazing cattle, by exposure to intense rainfall (when no longer protected by vegetation or litter), and by the gradual loss of organic matter and the disappearance of burrowing soil animals during extended periods of agricultural cropping. As a result, total stormflow amounts from intensively grazed tropical grassland catchments are typically 25–45% higher than those associated with the forests they replaced. In the case of seriously degraded cropland (also in the tropics), however, the relative increase may easily be 300–400%. Often, catchment response to rainfall after forest conversion (but also in relation to forestry activities) is influenced most by the construction of roads and drainages, settlements and, in urbanized areas, industrial estates. On such densely compacted surfaces typically more than 70% of the rain is immediately turned into surface runoff. In addition, road construction is often accompanied by increased landsliding and erosion. The associated increases in stream sedimentation may, in extreme cases, cause the river bed to be raised to the extent that flood hazards are increased even further.

At larger scales, the overall effect of landcover change on catchment runoff response to rainfall will depend on the relative proportion of the various landcover types (including roads and settlements) and their hydrological behavior. Recent work in the Pacific Northwest of the USA trying to 'disentangle' the effects of logging and the presence of a road network on peak flow enhancement in the 150 km^2 Deschutes River basin suggests the separate effects of the two to be a rise of about 10% each. In contrast to the forest removal effect (cf. **Figure 5**), the road effect was shown to increase with the size of the flood peak (see also **Figure 6a**). Conversely, in northern Thailand relative runoff contributions from rural roads and trails to overall stormflow production in a largely deforested landscape were greatest for small storms but gradually 'drowned' by contributions from agricultural fields during larger storms.

It is generally found that the adverse local effects of forest removal on all but the largest stormflow response tend to be 'diluted' or even become undetectable at larger scales. This is because peak flows from one part of the basin will usually not coincide with those from other parts due to differences in the timing of the rainfall or in the hydrological response of different landcover types. Arguably the most publicized example of highland–lowland interactions in relation to downstream flooding is the Ganga–Brahmaputra–Meghna river system in northern India and Bangladesh. Disastrous floods in the area are almost always attributed to 'deforestation in the Himalayas' rather than to excess monsoon rainfall occurring at a time when most of the river basin has already been wetted up by previous rains. However, a detailed analysis of the hydrological and climatic records for the area over the past 40 years shows that neither the frequency nor the magnitude of flooding has increased over the last few decades. Indeed, flooding must be considered an unavoidable process given the geoclimatic setting of the Ganga–Brahmaputra river basin. Consequently there is no reason to believe that floods in the Indian lowlands have intensified as a result of human impact in the highlands although the degree of damage has increased because of greater floodplain occupancy.

Nevertheless, there is reason for concern, particularly with respect to tropical river basins. For example, most of the increase in streamflow observed after converting tea estates (not forest) to rainfed cropping on steep slopes in Sri Lanka (**Figure 4**) occurred during the rainy season whereas dry

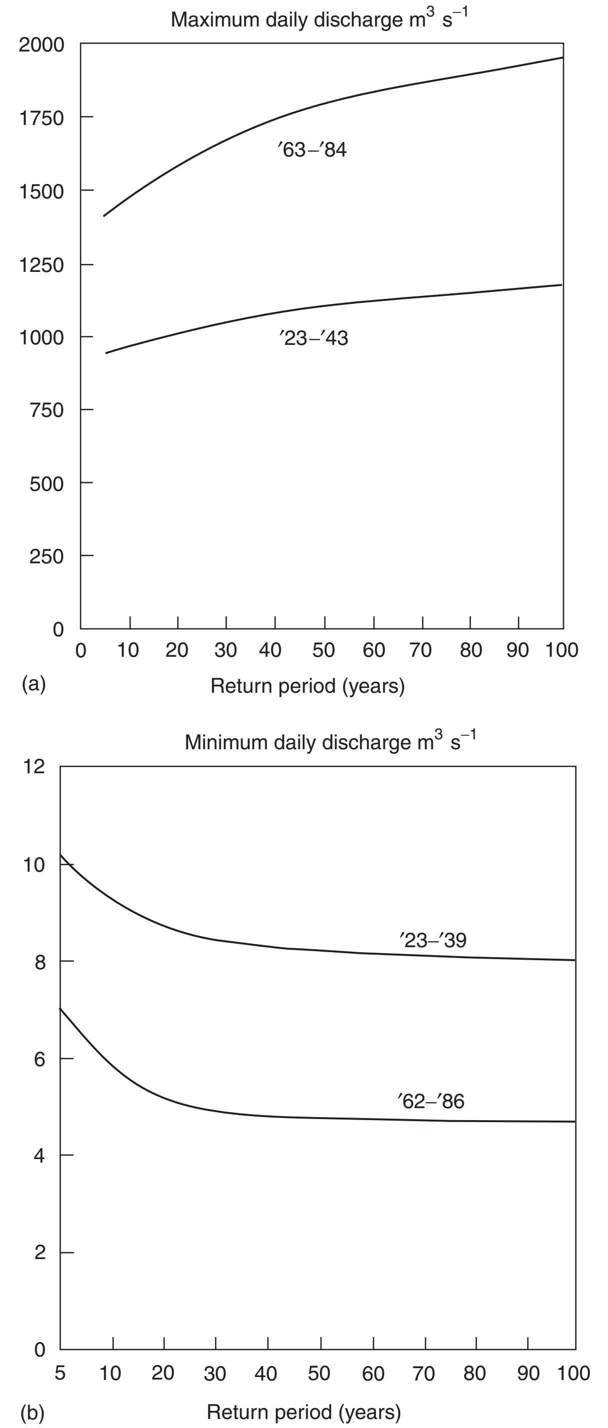

Figure 6 Changes in average maximum and minimum daily flows for the Citarum River basin, West Java, Indonesia between the periods 1923–1939/43 and 1962/63–1984/86. Reproduced with permission from Van der Weert R (1994) *Hydrological Conditions in Indonesia*. Jakarta: Delft Hydraulics.

season flows continued to decline, presumably as a result of steadily worsening surface infiltration conditions (**Figure 7**). Similarly, maximum flows in the densely populated Citarum River basin in

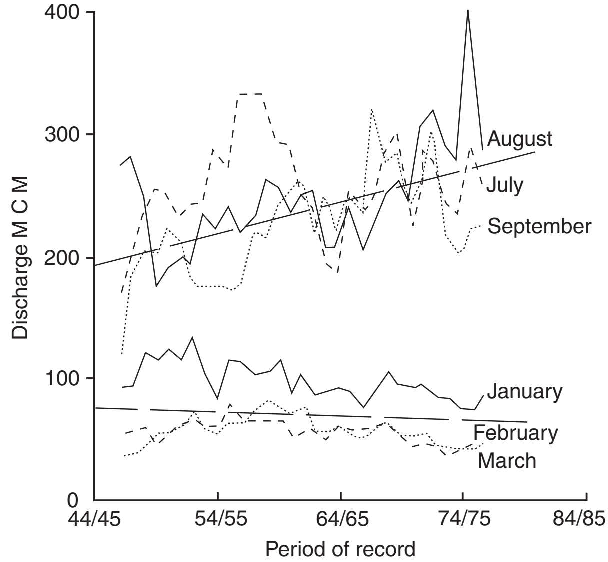

Figure 7 Seasonal trends in streamflow in the upper Mahaweli basin, Sri Lanka. Reproduced with permission from Madduma Bandara CM (1997) Land-use changes and tropical stream hydrology: some observations from the upper Mahaweli Basin of Sri Lanka. In: Stoddard DR (ed.) *Process and Form in Geomorphology*, pp. 175–186. London: Routledge.

Indonesia referred to earlier increased on average by about 50%, with even greater increases for the largest events (**Figure 6a**). This is believed to be caused by the conversion of irrigated cropland to settlements, industrial estates and roads. To make matters worse, dry season flows were also reduced (by about one-third; **Figure 6b**). Although event peak discharges in the much larger Tocantins basin in Brazil referred to earlier were not influenced by the conversion of 19% of its scrubland area to pasture, most of the 24% increase in annual water yield occurred during the wet season. In addition, the seasonal flood peak arrived about 1 month earlier than when the basin was fully forested. Neither urbanization nor altered rainfall patterns could be called on to explain this pattern. The most likely cause is, again, a gradual degradation of soil infiltration capacities, in this case due to the trampling effect of grazing cattle.

To summarize, the role of forest cover in flood mitigation or management is limited to small to medium-sized events. As the severity of the flood increases the impact of land use change appears to be reduced (**Figure 5**). Yet there is increasing evidence that in areas where gradual degradation of catchment infiltration opportunities beyond a critical threshold occurs, peak flows are enhanced considerably, even in (very) large river basins. Finally, there remains a need to better understand the complex relationships between land use change and stream sediment dynamics, including the build-up of river-beds and changes in channel form, and their effect on flood heights.

Forest and Dry Season Flows

In areas with seasonal rainfall, the distribution of streamflow throughout the year is often of greater importance than annual totals. Reports of greatly diminished flows during the dry season after forest conversion to cropping abound in the literature, particularly in the tropics. At first sight, this seems to contradict the evidence presented earlier that forest removal leads to higher water yields (**Figure 2**), even more so because most of the increases in flow after experimental clearing are generally observed during baseflow conditions. However, the controlled conditions imposed during the catchment experiments of **Figure 2** may differ from those encountered in some real-world situations. As we have seen, rainfall infiltration opportunities are often (much) reduced after forest conversion due to soil degradation, compaction or surface pavement. This is usually a gradual process and it is quite possible that many catchment experiments did not last long enough for sufficient degradation to happen. As illustrated by **Figures 4**, **6** and **7**, once infiltration becomes seriously impaired, increases in surface runoff during the rainy season may become so large that the recharging of groundwater reserves is reduced. When this critical stage is reached, diminished dry season flow is the sad result (**Figures 4** and **7**), despite the fact that the removal of the forest should have induced higher baseflows because of the diminished water use of the new vegetation (cf. **Figure 2**).

If, on the other hand, soil surface characteristics after clearing are maintained sufficiently to allow the continued infiltration of (most of) the rainfall, then the effect of reduced water use after forest removal will show up as increased dry season flow (**Figure 8**). This may be achieved through a well-planned and maintained road system plus the careful extraction of timber in the case of logging operations, or by the application of soil conservation measures (such as terracing, planting contour hedgerows, or grass strips) when clearing for agricultural purposes (**Figure 9**).

To summarize, the effect of forest removal on dry season flows will be positive where the infiltration capacity of the soil is maintained sufficiently to avoid excess surface runoff during rainfall. Where infiltration becomes seriously impaired, however, groundwater recharge may be reduced to the extent that dry season flows are decreased.

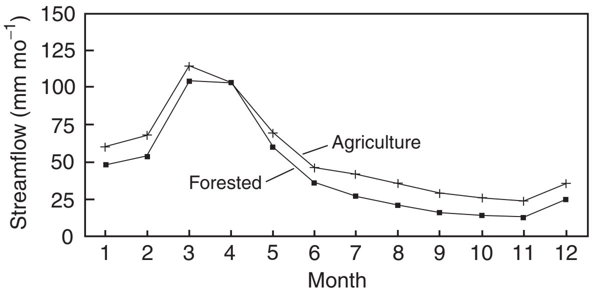

Figure 8 Changes in seasonal distribution of streamflow after replacing montane rainforest by subsistence cropping at Mbeya, Tanzania without significant surface degradation. Based on original data in Edwards (1979); after Bruijnzeel LA (2001) Forest hydrology. In: Evans J (ed.) *The Forests Handbook*, vol. 1, pp. 301–343. Oxford, UK: Blackwell Science.

Reconciling Public and Science Perceptions of Forest – Streamflow Linkages

The most common perceptions of the hydrological impacts of forest conversion ('deforestation') held by many forestry practitioners, policy-makers, and the general public (particularly in the tropics) on the one hand and (most) researchers on the other, are summarized in **Table 1**. Arguably, the contrast between the two is less great than claimed by some. A close inspection of the respective perceptions listed in **Table 1** reveals that in many cases these contrasting views relate to differences in degree or frequency of occurrence rather than representing true differences in kind.

Much of the confusion regarding the increase or decrease of streamflow following forest clearance can be traced to two aspects: (1) the need to distinguish between annual and seasonal water yields, and (2) the fact that most, if not all experimental catchment studies pertain to controlled land use changes, the hydrological impacts of which have been monitored over relatively short periods of time only (typically up to 3 years, occasionally longer). As to the first, in the absence of actual streamflow measurements it is difficult to tell whether the increases in rainy season stormflows and decreases in low flows witnessed by people living in gradually degrading catchments actually add up to increased total annual water yields or not (see **Figure 4**). However, there is little actual difference between the layman stating that 'deforestation' leads to diminished low flows due to the loss of the 'sponge effect' of the forest and the scientist having to agree, provided that surface infiltration characteristics have been degraded sufficiently over time for this to happen. Similarly, the public view that 'floods' invariably increase after

Figure 9 Adverse impacts on streamflow can be avoided largely by applying soil conservation measures following forest clearing. Photograph by LA Bruijnzeel.

forest clearance and that of the scientist acknowledging that stormflows do increase in all but the most extreme cases, and perhaps even then in the case of an extended road network, are not that different anymore either.

Therefore, it is arguably more productive to state that stormflows are increased after forest removal up to a certain threshold (beyond which the effect of landcover is overridden by those of extreme rainfall and limitations in soil water holding capacity), or that low flows will decrease once a certain level of surface degradation has been reached, than to merely dismiss the 'sponge theory' as folklore or an anachronism.

Furthermore, and as hinted at already, in the heated debate on the hydrological role of (especially tropical) forests it is generally overlooked that the circumstances associated with controlled (short-term) catchment experiments may differ from those of some real-world situations in the longer term. No experimental catchment study has lasted long enough, however, to document the long-term effects of increasingly degraded surface conditions on streamflow amounts and regime. As such, both views (diminished or increased dry season flows after clearance) must be considered correct, depending on the situation. Where infiltration is maintained sufficiently, as under controlled experimental conditions or rational land use, the reduced water use associated with forest rsemoval will show up as increased dry season flow (**Figures 8** and **9**). However, where infiltration and groundwater recharge become seriously impaired by surface

Table 1 Common perceptions about the streamflow impacts of 'deforestation'

Commonly held perceptions	*Scientific experience*	*Qualifications*
Forests act like sponges absorbing water during rainy season and releasing it evenly during the dry season. Cutting of forests dries up water supplies, particularly during the dry season, because the 'sponge effect' becomes lost.	Cutting of forests increases total water yield, particularly during low flow periods. Dry season flows reduced if soil water intake capacity seriously impaired (as in severely degraded or urbanized catchments). Clearing of cloud forests may lead to reduced dry season flows and possibly total yield.	Increased total and seasonal water yields under pasture or cropping only manifested as long as surface infiltration capacity is maintained. Fine-textured soils most vulnerable to degradation. Thus, whether the perceived 'sponge effect' remains or disappears depends entirely on postconversion land use practices.
Cutting of forests causes floods as the 'sponge effect' is then lost.	Cutting of forests affects stormflow volumes for small- to medium-sized events and at the local scale ($<10\,km^2$). Little or no impact on size of extreme events (floods) at any scale although adverse effect of extensive roading cannot be excluded. Wet season flows (but not events) from very large basins probably increase due to cumulative effect of reduced infiltration opportunities.	Postforest land use must afford good surface cover. Otherwise stormflows up to medium-sized events much increased (as in severely degraded catchments).

compaction and crusting, as is eventually the case in many real-world situations, diminished dry season flows inevitably follow despite the fact that the reduced evaporation should have produced higher baseflows. In the layman's terms, the 'sponge effect' is lost (**Figures 6** and 7).

A related aspect concerns the fact that long-term fluctuations in rainfall arising from natural climatic variability are not covered adequately by short-term experiments. Such fluctuations have both short- and longer-term impacts on catchment hydrology – notably the (more frequent) occurrence of peak flows during rainier periods or diminished dry season flows during drier periods – which may be attributed erroneously to changes in landcover rather than climatic variability. The massive floods in Central Europe in the summer of 2002 and the extreme drought during the next year are a prime example of the whimsical nature of many climates.

The lack of long-term catchment studies representing actual hydrological conditions experienced by countless people perhaps calls for more modesty on the part of scientists when communicating the results of (controlled) hydrological experiments to practitioners and the public at large. More importantly, it clearly illustrates the need for stepped up efforts to remedy this deficiency.

Impacts of Forest Management on Streamflow

L A Bruijnzeel, Vrije Universiteit, Amsterdam, The Netherlands
R A Vertessy, CSIRO Land and Water, Canberra, Australia

Introduction

The practical overall influence exerted by forests on hydrological processes is most clearly borne out by a comparison of streamflow amounts emanating from catchment areas with contrasting proportions or types of forest. Forestry activities (thinning, selection logging, clear-felling) and natural disturbances (extreme rainfall, hurricanes, fire) have the potential to more or less seriously alter forest water use and thus change the amount and timing of streamflow. Because climatic differences (notably rainfall) between sites or years, and unmeasured transfers of groundwater from one catchment to another, tend to obscure the effect on streamflow of the vegetation, the 'direct' comparison of streamflows from catchments with contrasting forest covers can be problematic. The same applies to a comparison of the flows from a single catchment before and after a change in cover. The classical approach to these problems has been the so-called 'paired catchment experiment' in which the streamflow from two (preferably adjacent) catchments of comparable geology, topography, exposition, and vegetation are expressed in terms of each other (using regression analysis) during a 'calibration phase.' Once a robust baseline calibration relationship has been established, one of the catchments is subjected to a land cover treatment (for example, strip-cutting or clear-felling) while the other catchment remains undisturbed as the control (**Figure 1**). Following the treatment of one catchment, streamflow from both catchments continues to be monitored. Any effects of the treatment are evaluated by comparing the actually measured streamflow totals from the experimental catchment with the flows that would have occurred if the catchment had remained unchanged. This is usually done by inserting streamflow totals determined for the control catchment into the calibration relationship (**Figure 1**). Although a more rigorous comparison between catchments is obtained in this way than in the case of 'direct' comparisons, the tacit underlying assumption of the paired catchment method is that any differences in groundwater leakage from the two catchments remain constant with time, regardless of the status of the vegetation cover. Also, to avoid unjustified extrapolation of the calibration line to accommodate extremes in streamflow during the treatment phase (e.g., because of drought or extreme rainfall), it is important that the calibration period includes both wet and dry years. This makes the paired catchment method a time-consuming (usually at least 5 years) and expensive affair. In addition, the method is essentially a 'black-box' requiring additional hydrological process research to reveal the relative importance of different causative factors to explain the observed changes in streamflow. All this, plus the limited resolution afforded by the paired catchment approach (usually more than 20% cover change is required for effects on streamflow to be detectable), have led to a general decline in the number of such studies in the last few decades and a gradually greater emphasis on computer simulations (modeling).

This article reviews the hydrological effects of (1) various forms of forest management (thinning, selective logging, removal of undergrowth or riparian vegetation, and clear-cutting) and (2) natural disturbances (mostly fire and storms), and subsequent regrowth. Effects on streamflow of converting forest to other forms of land use, and the establishment of forest plantations on former agricultural

land or natural grassland are discussed in the respective companion chapters (see **Hydrology**: Impacts of Forest Conversion on Streamflow; Impacts of Forest Plantations on Streamflow).

Hydrological Effects of Thinning and Selective Logging

Effects on Net Precipitation

A forest canopy intercepts a large portion of the rain that falls on it. This process is called rainfall interception. Usually, the bulk of the intercepted water drips from the canopy as so-called throughfall, whereas a much smaller portion (usually a few percent) reaches the forest floor along branches and the tree trunks in the form of stemflow. The remainder of the intercepted water is evaporated again during and shortly after the storm and thus never reaches the ground. Therefore this term is often referred to as the interception loss. The sum of throughfall and stemflow is called net precipitation. It has long been recognized that amounts of net precipitation tend to be inversely related to the stocking of a forest. In other words, the denser the canopy, the smaller the amount of rainfall reaching the ground. Although this observation may seem trivial, amounts of intercepted water may be substantial, especially in the case of evergreen, coniferous forests (up to 45% of incoming rainfall). As a result, the amount of water available for infiltration into the soil and contributing to soil water reserves is closely related to amounts of interception. Therefore, it is of interest to examine the effect of management-related and naturally occurring changes in forest cover and structure on amounts of precipitation arriving at the forest floor.

In well-stocked coniferous forest (plantations), amounts of crown drip often show a steady decrease with forest age, reflecting the greater leaf surface area and surface roughness associated with older stands. Naturally, a larger leaf area is capable of intercepting and storing more rainfall whereas increased surface roughness enhances atmospheric turbulence and evaporation rates from the wet canopy, and thus total interception. Amounts of stemflow in these forests, on the other hand, decrease with stand age although the overall effect on net precipitation is small due to the relatively small amounts involved anyway. Together with an increased capacity of the litter layer to intercept and store rainfall in older coniferous stands the overall effect on net precipitation is that of a gradual reduction as these forests mature. For example, in stands of white pine (*Pinus strobus*) in the southeastern USA, net precipitation in 60-year-old stands was about 220 mm year^{-1} less than in 10-year-old forest. No such decline with age was found for (natural) deciduous forest in the same area. Apparently, *c*. 10-year-old deciduous forest has already acquired similar leaf biomass and roughess characteristics as the older forests. In evergreen mountain ash forest (*Eucalyptus regnans*) in Australia, on the other hand, an altogether different pattern has been observed. Here, rainfall interception increases rapidly to a value of about 25% of the rainfall during the first 30 years; then it declines slowly to about 15% at age 235 years, a difference of about 190 mm year^{-1} (**Figure 2**). Such changes reflect changes in the structure of the regenerating forest: in younger stands, the trees are closely spaced and there is little undergrowth. In old-growth forest, the trees are much more widely spaced but the understory is well developed.

Naturally, rainfall interception by deciduous forests during the dormant season is lower than during the growing season. However, the typically observed increase in net rainfall of 5–10% when the trees are leafless is by no means proportional to the reduction in leaf area which can be up to sixfold. Likewise, the decreases in rainfall interception that have been observed after forest thinning are typically three to four times smaller than the degree of canopy opening. For example, a 50% reduction in basal area of a Douglas-fir forest in France resulted in only a 13% drop in interception whereas a 13-fold reduction in basal area in a dense Sitka spruce (*Picea sitchensis*) plantation in Scotland (corresponding to a change in planting interval from 2×2 m to 8×8 m) was accompanied by a less than fourfold reduction in interception. Such findings can be explained by the fact that, although canopy cover is reduced by

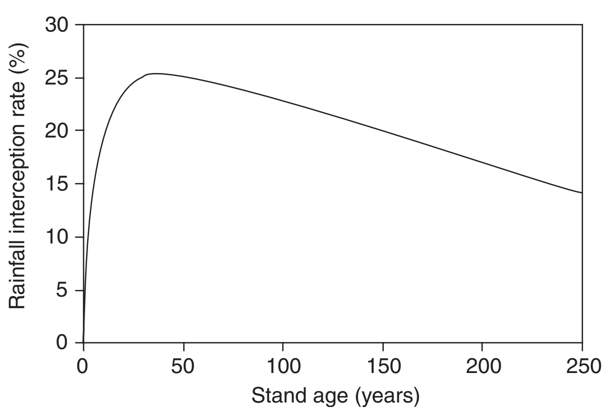

Figure 2 Relationship between mountain ash rainfall interception rate and stand age. Reproduced with permission from Haydon S *et al.* (1996) Variation in sapwood area and throughfall with forest age in mountain ash (*Eucalyptus regnans* F. Muell.). *Journal of Hydrology* 187: 351–366.

thinning or leaf fall, the aerodynamic roughness of the forest is also reduced. As a result, the turbulent exchange between the trees and the surrounding air decreases and rates of evaporation are reduced accordingly. In terms of soil water recharge the effect of forest thinning is even smaller when the felled trees are left to decompose on the site because the slash will intercept part of the gain in throughfall.

To summarize, to achieve significant increases in amounts of net precipitation entering the mineral soil, forest thinning would need to be substantial (up to 70% of basal area). In addition, for maximum effect the slash would need to be removed but this may have adverse implications for soil fertility (erosion and loss of organic matter and nutrients contained in the slash). In areas with snowfall, opening up of the forest will enhance both the rate and timing of snowmelt. Depending on the situation, this may be considered positive (higher water yields) or negative (aggravation of spring flooding).

Effects on Forest Water Use and Catchment Water Yield

Whilst the effect of thinning on interception and net precipitation is thus seen to be rather limited, effects on soil water (and ultimately streamflow) are likely to be smaller still. Opening up of a stand not only enhances the penetration of radiation to the understory vegetation and the forest floor (thereby enhancing evaporation), but also the remaining vegetation will start to compete for the extra moisture supplied by the initially increased throughfall. The magnitude and the duration of such effects will differ between locations, depending on the vigor of overstory and understory vegetation, climatic conditions (including slope exposure), and the configuration of the cutting, as shown by the examples below.

No changes were detected in the streamflow from a deciduous hardwood forest catchment of southeasterly exposure in the southeastern USA (Coweeta) after a selective logging operation had removed 27% of the basal area, whereas only a 4.3% rise in flows was observed after a 53% selective cut. Removing the entire understory (representing 22% of forest basal area) from a catchment of northwesterly exposure in the same area produced an equally modest change. Typically, the moisture gained by removing one component of the forest is rapidly taken up by others. In coastal Douglas-fir forest in western Canada soil water deficits developing during the summer have been shown to be very similar below dense, unthinned stands with little to no undergrowth, and thinned stands with a well-developed understory. After removal of the undergrowth, soil water uptake by the trees increased by 30–50% and the overall effect of the removal on soil water content was insignificant. In an experiment involving two 40-year-old Scots pine plantations of similar tree height but with a more than fivefold difference in stocking in the UK, tree water uptake (transpiration) in the widely spaced plantation was about two-thirds of that of the denser stand. However, relative transpiration rates per tree were more than three times higher in the thinned plot, and intermediate in magnitude between the relative increases in average water-conducting area (so-called sapwood) per tree (2.9 times) and leaf area per tree (4.2 times), compared to the unthinned stand. Therefore, although water use by the thinned forest had not reached prethinning levels yet, the large increases in leaf and sapwood areas of the remaining trees could be seen as representing a tendency towards complete re-equilibration following a set of physiological relationships aimed at maximum site utilization. Finally, in an extreme case from South Africa any positive effects on streamflow of three rounds of thinning (45%, 35%, and 50% after 3, 5, and 8 years) *Eucalyptus grandis* plantations were masked entirely by the continued reduction in flows resulting from the overall vigorous growth (and thus water uptake) of the trees. The message from these examples is a clear one: thinning has to be rather drastic before a marked effect on streamflows can be expected.

Selection logging in tropical rainforest does not produce measurable effects on streamflow for harvesting volumes up to $20\,m^3\,ha^{-1}$ but the much higher logging intensities practised in the rich forests of Southeast Asia have a marked effect. Typical increases in annual water yield under 'average' rainfall conditions (*c.* $2000\,mm\,year^{-1}$) and harvesting intensities (33–40% of the commercial stocking) amount to 100–150 mm but larger increases are possible where harvesting is more intense and disturbance of the soil more widespread. The effect usually disappears within a few years as logging gaps become recolonized (**Figure 3**) although compacted surfaces like tractor tracks, roads, and log landings continue to be sources of enhanced runoff for much longer (decades).

Apart from the degree of cutting, the configuration of the resulting gaps also has an influence. During the first dry season after the creation of differently sized gaps in tropical rainforest in Costa Rica, soil water reserves were depleted most rapidly under undisturbed forest, followed by 6-year-old regrowth, pioneers in an elongated narrow gap, and pioneer vegetation in the center of a large square gap (**Figure 3**). Only 1 year later, however, soil water depletion in the smaller gap already resembled that of the 7-year-old vegetation,

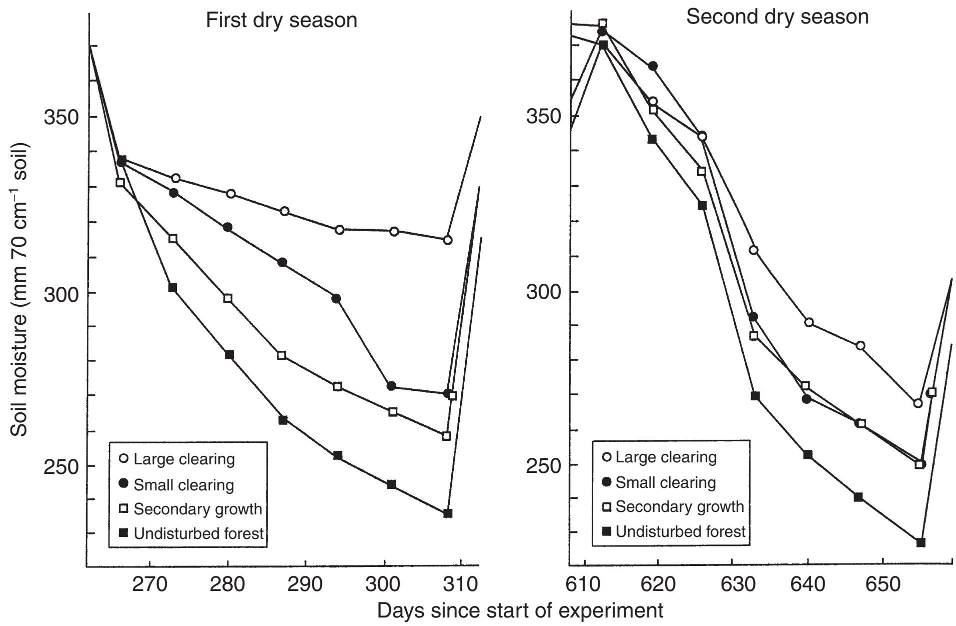

Figure 3 Soil moisture content in the top 70 cm of soil below undisturbed tropical rain forest, 6-year-old secondary growth, and in a narrow (10 × 50 m) and a large (50 × 50 m) clearing in lowland Costa Rica during two consecutive dry seasons. Reproduced with permission from Parker GG (1985) *The Effect of Disturbance on Water and Solute Budgets of Hillslope Tropical Rainforest in Northeastern Costa Rica*. PhD thesis, University of Georgia, Athens, GA.

whereas that for the larger gap had increased considerably as well. The higher water uptake by the vegetation in the smaller gap compared to that in the larger gap reflects the more rapid recolonization of smaller gaps as well as additional uptake by trees from the surrounding forest sending their roots into the gap (**Figure 3**).

The influence of the configuration of the cutting on the magnitude and duration of any increases in streamflow has been investigated in some detail. In the eastern USA the removal of 24% of the basal area from catchment LR 2 at Leading Ridge (Pennsylvania) caused a nearly twofold larger increase in flow than cutting 33% of the forest on catchment HB 4 at Hubbard Brook (New Hampshire) or catchment FEF 2 at Fernow Experimental Forest (West Virginia) (see **Figure 4**). The cutting at Leading Ridge consisted of a single block on the lowest portion of the catchment, whereas the cutting at Hubbard Brook took the form of a series of strips situated halfway up the catchment, and that at Fernow involved harvesting trees from all over the catchment. Therefore, increases in streamflow associated with strip cutting are smaller than for single blocks. This is in agreement with the finding of increased water uptake by surrounding trees upon opening up of the canopy (**Figure 3**) and the limited effect on rainfall interception by thinning described earlier.

No significant differences in streamflow increases were found between the cutting of the upper half of a catchment (such as at catchment 7 at Fernow; FEF 7 in **Figure 4**) or the lower half (catchment FEF 6 in **Figure 4**). Likewise, removal of the vegetation around

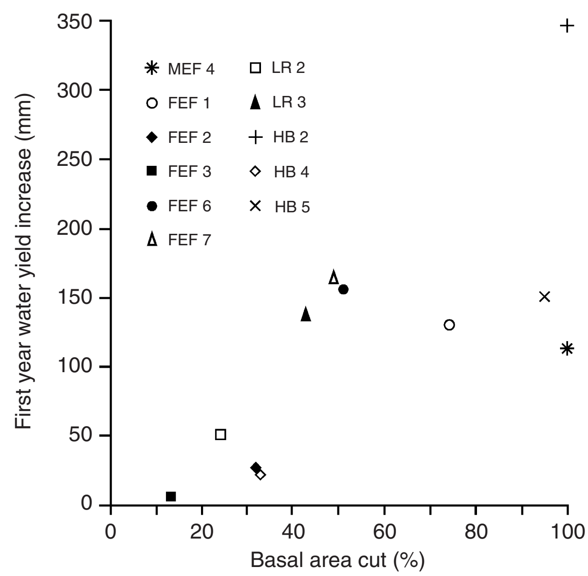

Figure 4 First-year increases in water yield in response to forest cutting in the northeastern USA. Reproduced with permission Hornbeck JW, Adams MB, Corbett ES, Verry ES, and Lynch JA (1993) Long-term impacts of forest treatments on water yield: a summary for northeastern USA *Journal of Hydrology* 150: 323–344. MEF, Marcell Experimental Forest, MN; FEF, Fernow, WV; LR, Leading Ridge, PA; HB, Hubbard Brook, NH.

watercourses in areas with a high rainfall surplus did not produce increases in water yield above those associated with the removal of an equal area of forest elsewhere in the catchment. However, where forest evaporation consumes a much larger proportion of the rainfall and where the terrain is more gently sloping than in the examples shown in **Figure 4**, the effect of cutting trees in the lower third to half of a catchment may well be rather more pronounced than that of cutting the upper third to half. Under such subhumid conditions, water uptake by trees having ready access to groundwater is usually higher than that of trees further up the slopes. High water tables are typically associated with the areas around streams (the riparian zone), footslopes and depressions in the landscape; these, in turn, are mostly found in the lower parts of catchments.

Effects of Forest Clear-Felling and Regrowth on Water Yield and Hydrological Response

Well over 100 (paired) catchment treatment experiments have been conducted (mostly in the temperate zones of the world) to ascertain the nature and extent of streamflow change resulting from forestry operations (mostly clear-felling). Analysis of the literature on catchment treatment experiments indicates that one can confidently generalize about the direction and approximate magnitude of streamflow changes following particular alterations in forest cover. Some of the more robust generalizations are discussed below.

Generalization No. 1: Forested Catchments Yield Less Total Streamflow than Cleared Catchments and the Difference Increases with Mean Annual Rainfall

Almost all catchment treatment experiments have shown that streamflow increases as forest cover decreases, and vice versa (**Figure 5**). The reason for this is that forests evaporate significantly more water than grasslands or crops. Although transpiration rates (soil water uptake by plants) under conditions of ample soil water do not differ much between forests and nonforest vegetation, rates of evaporation from vegetation wetted by rain (rainfall interception) are much higher from tall, aerodynamically rough surfaces like forests. In addition, the deeper roots of trees allow continued water uptake when more shallow-rooted plants have to give up during prolonged rainless periods. Because rainfall interception totals are higher in wetter years, the impact of forest clearance (i.e., after interception falls away) increases with mean annual rainfall (**Figure 6**).

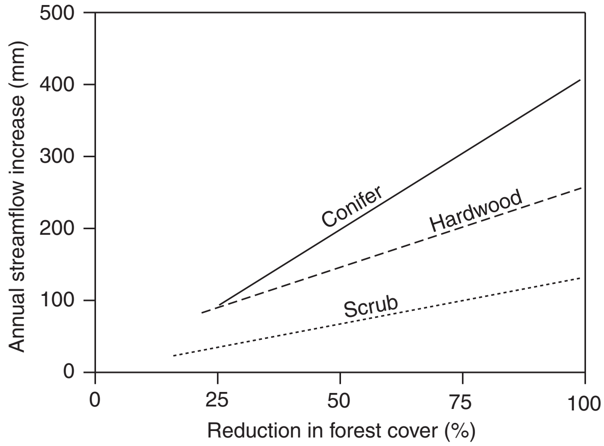

Figure 5 Relationships between reduction in forest cover and increase in annual catchment water yield. The general trend lines show the respective relationships for three types of woody vegetation. Reproduced with permission from Bosch JW and Hewlett JD (1982) A review of catchment experiments to determine the effects of vegetation changes on water yield and evapotranspiration. *Journal of Hydrology* 55: 3–23.

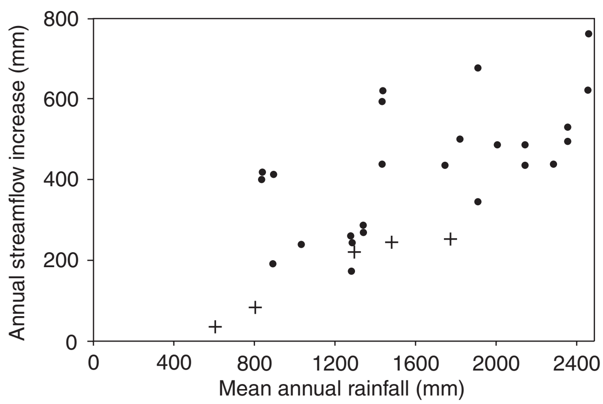

Figure 6 Effect of mean annual rainfall on increases in total water yield caused by total clearance of conifer and scrub vegetation (adapted from Bosch and Hewlett 1982). Crosses denote the expected gains in water yield from converting eucalypt forest to pasture in Victoria, Australia. Reproduced with permission on Holmes JW and Sinclair JA (1986) Water yield from some afforested catchments in Victoria. In: *Hydrology and Water Resources Symposium*, 25–27 November 1986, Brisbane, pp. 214–218. Melbourne, Australia: Institute of Engineers.

Apart from rainfall, the magnitude of the change in annual streamflow is also affected by forest type and slope aspect. Generally, the largest changes are observed in the case of clearing conifers, owing to their dense evergreen habit and high interception, followed by native (but not exotic) eucalypt forests, then deciduous hardwoods (leafless in winter or dry season) and finally woody scrub vegetation (found in low rainfall areas) (**Figure 5**). Mean annual streamflow can be expected to rise by between 10 and 80 mm (but usually between 25 and 50 mm) for each

10% of catchment area cleared of forest, depending on the forest type and rainfall as discussed above (**Figures 5** and **6**). The importance of catchment exposition is illustrated by the difference in first-year streamflow gain after cutting differently exposed deciduous hardwood forest catchments in the southeastern USA. Flows from northerly exposed catchments increased by about 130 mm $year^{-1}$ but increases from southerly exposed catchments (whose forests consumed much more water in response to the greater insolation of their slopes) were as high as 400 mm $year^{-1}$. Most studies indicate that the relationship between treated area and streamflow change is linear (**Figure 5**), although there is some evidence that in subhumid areas the magnitude of streamflow change is reduced if forest treatments take place away from streamside areas.

Generalization No. 2: Streamflow Increases Following Forest Cover Reduction Are Transient and Temporary when Same-Species Regeneration Occurs

In a forest which is cleared or killed by wildfire but permitted to regenerate with the same species, streamflow increases are both transient and temporary. Streamflow increases normally reach a peak within 2–5 years after clearance, then decline to pretreatment levels over a period of between 3 and 35 years (but usually within 10 years), depending on rainfall, soil factors, and forest regrowth rates. This pattern can be explained by the fact that a new vegetation first has to establish itself before water use is gradually increased again. Also, elevated streamflow levels tend to last much longer (15–35 years) when regeneration has to originate from seeds than when massive resprouting occurs (3–7 years).

Part of the increase in streamflow after cutting reflects an increase in catchment response to rainfall. Usually, such storm runoff is generated in wet spots in the landscape, mostly around streams and depressions. Runoff-producing areas are enlarged after forest removal because of the associated increase in water inputs to and reduced uptake from the soil. Once a new vegetation cover is established which starts to actively withdraw water from the soil the extent of the runoff-producing areas is reduced again. However, roads and other compacted areas continue to deliver storm runoff to the streams on a more permanent basis although their areal extent is usually small.

Generalization No. 3: Forest Age Affects Evapotranspiration Rate and Hence Streamflow

A small but significant set of catchment treatment experiments and hydrological process studies indicate that young forests have higher evapotranspiration rates than mature forests, resulting in notable streamflow differences between young and old-growth stands. One of the most comprehensive studies of forest age on streamflows concerns work undertaken in the mountain ash forests of southeast Australia. The ecology of these forests is distinctive, in that they only regenerate after severe wildfire which kills the trees and produces a heavy seedfall. These forests are thus usually even-aged and monospecific, and tend to live for several hundreds of years unless they are killed earlier by wildfire. Significantly, the eucalypts thin out naturally over time, resulting in major changes in forest structure and hydrologic function as stands age. It has been shown that regrowth mountain ash forests aged 25–30 years yield about half the mean annual streamflow of mature stands aged 200 years (i.e., 580 vs. 1195 mm $year^{-1}$ for 1950 mm mean annual rainfall). It has further been shown that it may take between 50 and 200 years before mean annual streamflow in a regenerating mountain ash catchment returns to levels observed in old-growth stands (**Figure 7**).

The effect of stand age on forest water use, and by implication streamflow, is not confined to mountain ash forests. Similar findings have been reported for mixed-species eucalypt forests in the northeast and southeast regions of New South Wales, Australia, in conifer plantations in South Africa, in deciduous hardwood forests in Japan and central France, as well as in coastal redwood forests in California and secondary forests in the Brazilian Amazon.

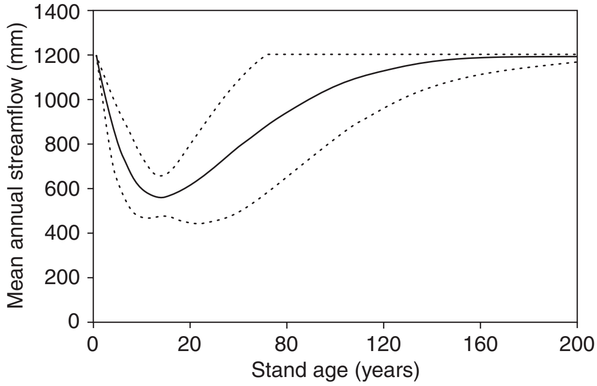

Figure 7 Relationship between forest age and mean annual runoff from mountain ash forest catchments, southeastern Australia. Dotted lines denote the 95% confidence limits on the relationship. Reproduced with permission from Vertessy RA, Watson FGR, and O'Sullivan SK (2001) Factors determining relations between stand age and catchment water yield in mountain ash forests. *Forest Ecology and Management* 143: 13–26.

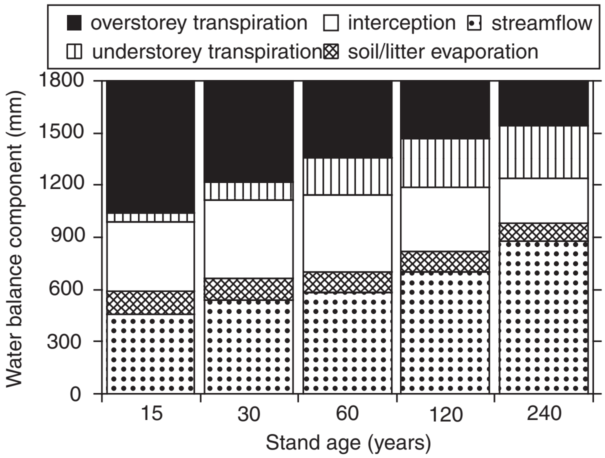

Figure 8 Water balance components for mountain ash forest stands of various ages in southeastern Australia, assuming an annual rainfall of 1800 mm. Reproduced with permission from Vertessy RA, Watson FGR, and O'Sullivan SK (2001) Factors determining relations between stand age and catchment water yield in mountain ash forests. *Forest Ecology and Management* 143: 13–26.

An explanation for the stand age–streamflow relationship in mountain ash forests has been provided by elucidating the leaf area and evapotranspiration dynamics of stands of various ages (**Figure 8**). As the forest matures, total leaf area declines and a greater proportion of the leaf area is allocated to the understory which experiences a gradually more humid and less ventilated microclimate. This results in lower overall water use and hence increased streamflow. Tree physiological measurements indicate that tree sapflow rates decrease with age, owing to increases in the resistance experienced by the flow as stems and branches lengthen and leaf ages increase. Such age-dependent effects on forest water use will tend to be maximized in long-lived, self-thinning, very tall forests.

Generalization No. 4: Forest Cover Affects the Magnitude of Streamflow Peaks for Small and Medium Events

As outlined earlier, the clearance of forests leads to an increase in catchment soil water status which tends to expand wet, runoff-producing areas. Therefore, cleared catchments respond more quickly and more vigorously to rainfall events. Most catchment treatment experiments show that the magnitude of discharge peaks is increased by forest clearance for small and medium-sized rainfall events, particularly when soils are disturbed by logging machinery and the establishment of road networks. However, it is generally accepted that modification of forest cover has little to negligible impact on flood peaks generated by extreme events, say those with recurrence intervals of 100 years and upwards. Under such extreme conditions, catchment runoff response is governed by the capacity of the soil to accommodate additional rainfall. If this capacity has been filled already by previous heavy rainfall, then the presence or absence of a forest cover is no longer decisive. Also, it is important to bear in mind that the local effects of forestry activities on stormflow tend to be diluted at larger scales by more modest flows from other areas receiving less rain or being less disturbed. Generally, the overriding factors in extreme flooding are the duration and intensity of the rain and the spatial extent of the rainfall field.

Nevertheless, there is reason for caution. Recent work in the Pacific Northwest region in the USA has demonstrated that forest clear-felling and the presence of an extensive road network each increased average stormflow volumes by *c.* 10%. Whilst the relative effect of the clear-felling diminished with the size of the stormflow generating event, the effect of the road network increased with event size.

Modeling the Hydrological Impacts of Forest Manipulation

As shown in the preceding sections, different forest manipulations affect the water flows through catchments differently. Traditionally, forest hydrologists have relied on costly and time-consuming paired catchment experiments to evaluate such effects. Whilst this approach enabled the construction of general curves from which changes in annual streamflow totals can be read as a function of annual rainfall (see **Figure 6**), or first-year increases in flow as a function of percentage basal area reduction and catchment aspect for particular areas at best, the results are often so variable as to render their applicability for more detailed water resources planning rather limited (**Figures 5** and **6**). Also, the black-box nature of the paired catchment technique is unable to evaluate the relative importance of the governing factors underlying the observed changes in flow, and this severely limits the possibilities for extrapolation of results to other areas or years.

Process-based hydrological models represent an alternative way of predicting how catchments might respond to different forms of management. Because many practical forest management questions have a spatial dimension to them, and because landscapes are usually made up of a complex mosaic of different land uses, such models should preferably be 'distributed,' that is: capable of taking into account spatial variations in topography, soils, vegetation, and climate. During the last 10–15 years, considerable progress has been made with the modeling of forest hydrological and ecological processes over a range of spatial and temporal scales. Within-catchment applications of such models relevant to forestry include the prediction of wet zones in the landscape (governing machine access) and the delineation of areas especially prone to surface erosion, gullying, or landsliding. Another example concerns the evaluation at the hillslope scale of the water balance and growth performance of different tree planting configurations (e.g., block planting vs. strip planting) under subhumid conditions. Whole-catchment applications include the simulation of changes in tree growth and water yield after clear-felling during forest regeneration or of a conversion of forest to pasture. To address forestry-related questions of catchment water management at larger scales (100–1000 km^2), simpler (but still spatially distributed) models have been developed and used to simulate (for instance) long-term changes in water yield due to forest fire and subsequent regeneration in a spatially distributed manner. Such models, if applied properly, can lead to more rational land and water management decision-making. However, whilst distributed models represent the only class of simulation models capable of capturing the complex feedback mechanisms that occur upon disturbing hydrological systems, they are also data-demanding. In addition, at larger scales there is the problem that good results require equally good data on the spatial distribution of rainfall. However, there is reason for optimism as various remote sensing technologies that are currently still in their infancy can be expected to become widely available within the next decade. This will greatly facilitate data acquisition and upscaling of hydrological results over larger areas.

The last decades have seen the waning of the 'empirical age' of catchment treatment experimentation and ever more rapid developments in our ability to model complex natural systems in a spatially explicit way. Although the arrival of process-based distributed hydrologic models and ongoing improvements in measurement equipment, remote sensing technology and computing power guarantee that there are exciting times ahead for forest hydrologists, continued field experimental efforts will remain important for model calibration and testing.

Characteristics of Plantation Forests

Tree plantations for the production of timber have been established for more than a century (tropical teak and mahogany plantations, for instance, date back to the mid-nineteenth century), but it is mainly in the last few decades that an exponential expansion of this form of land use has occurred. Taking one of the most popular tree types for plantations as an example, eucalypts have been planted on an estimated 17 million ha worldwide, of which more than 90% have been established since 1955 and roughly 50% during the last decade. The total plantation area around the globe is 187 million ha of which over 60% are in Asia, with Europe having the next largest share (17%). *Eucalyptus* and *Pinus* are the dominant genera within the broadleaved and coniferous plantations, respectively. Although forest plantations only occupy about 5% of the world's forest area, they are estimated, as of 2000, to supply 35% of all roundwood, a figure that is expected to rise to 44% by 2020 as natural forests continue to decline and demands keep rising.

Plantations are typically established at a regular spacing (1000–2000 stems ha^{-1}), and individual stands (compartments) have the same age and are composed of a single species or clone. Often plantations are particularly productive because the tree species being grown are exotic to the area and thus free of their native pests and diseases. Generally, a distinction is made between industrial plantations (aimed at producing wood for commercial purposes, including construction timber, panel products, furniture timber, and paper pulpwood) and nonindustrial plantations (aimed at fuelwood production, protection of catchment areas for soil and water conservation, provision of wind- or fog breaks, etc.).

Scope

There appears to be a significant disparity between public and scientific perceptions of the hydrological role of forests in general and of plantations in particular. Arguably, the contrasts in views are especially pronounced in tropical regions where calls for massive reforestation programs to restore reduced dry season flows or to suppress flooding and stream sedimentation are heard more frequently. Often, however, these expected hydrological benefits are not realized and in a number of cases forest plantations have even been observed to aggravate the situation. This article recapitulates the current understanding of how forest plantations affect the hydrological functioning of catchments. Other articles outline the principles of the forest hydrological cycle (*see* **Hydrology**: Hydrological Cycle) and indicate the hydrological effects of various forest management activities and forest conversion to other land uses (*see* **Hydrology**: Impacts of Forest Conversion on Streamflow; Impacts of Forest Management on Streamflow). Strictly speaking, the term 'reforestation' should be used to describe the planting of trees in areas that were once covered by natural forest whereas 'afforestation' applies to plantation establishment in areas that are too dry, or for other reasons, do not support natural forest vegetation. To avoid semantic problems, the term 'forestation' is used mostly in the following to denote either type of planting.

The Forest Plantation Water Budget

The hydrology of tree plantations is most easily discussed with the aid of a simple water budget equation, most simply expressed in equivalent units of water depth (mm per unit of time):

$$P = ET - Q + \Delta S$$

where P is total precipitation (mostly rainfall, sometimes also fog or snow), ET the sum of various evaporation components (often referred to as evapotranspiration), Q the surface runoff or streamflow, and ΔS the change in (subsurface) storage of water in the catchment (soil water and groundwater reserves).

Evapotranspiration ET dominates the water balance of all but the most humid forest plantations. Beyond an annual precipitation of *c.* 2000 mm and under conditions of lowered evaporative demand (e.g., montane or coastal fog belts) the balance between evaporation and streamflow tips toward streamflow. There are two main components to forest ET: transpiration (the water which is taken up from the soil by roots and passes through the trees to be transpired from the stomata of the leaves, E_t) and interception (the water that is caught in the canopy and evaporates directly back into the atmosphere without reaching the ground, E_i). Under closed canopy conditions, usually rather minor additional components of evaporation are evaporation from the soil surface (E_s), which in a forest includes interception by the litter layer, and evaporation from understory vegetation. The presence or absence of a forest cover has a profound influence on the magnitude of *ET*, and by implication, also on streamflow *Q*.

Rainfall Interception

Compared to short, simple vegetation canopies (grassland, agricultural crops), tree plantations increase evaporation losses by intercepting a larger portion of incident rainfall. Generally, annual interception totals associated with the dense canopies typical of evergreen coniferous plantations are higher than those of deciduous broadleaved forests. Interception is also particularly high (expressed as a fraction of total precipitation) where rainfalls are frequent but of low intensity, especially where the evaporation process is aided by the influx of relatively warm air striking a cooler vegetation surface, as is often observed in near-coastal areas. An example of this effect comes from the UK where conifer plantations have been established in upland heath and grasslands in Scotland and Wales. Here the nature of the precipitation, proximity to the ocean, and the change in canopy density may increase interception losses to as much as 35–40% of annual precipitation.

At the other end of the interception spectrum (E_i *c*. 6%) are the *Eucalyptus* plantations of the humid, subtropical eastern escarpment in South Africa. This is an area of high seasonal rainfall (1200–1500 mm), much of which falls in the form of infrequent storms of short duration but high intensity. Interception losses from pine plantations in the same area are somewhat higher (13%), reflecting their denser canopies compared to the more open canopies of the eucalypt stands. In the cooler southwestern part of South Africa, an area of winter rainfall of lower intensity, interception losses from pine plantations are higher again (18%) than in the pine plantations in the subtropical areas. In the case of both pine and eucalypt plantations, though, there is a net increase in interception over the grasslands and scrub vegetation they replace because of the higher leaf area, greater depth of canopy, and aerodynamic roughness associated with timber plantations.

Rainfall interception in tropical tree plantations ranges from relatively low values in eucalypt stands (*c*. 12%) (**Figure 1a**), to *c*. 20% for broadleaved hardwood species such as teak and mahogany (**Figure 1b**), and 20–25% for pines (**Figure 1c**) and other conifers (*Araucaria, Cupressus*), with the higher values usually found in upland situations where rainfall intensities are generally lower. Well-developed dense stands of the particularly fast-growing *Acacia mangium*, on the other hand, may intercept as much as 30–40% of incident rain. Typical interception values for the rainforests replaced by these plantations range from 10–20% in most lowland situations to 20–35% in montane areas.

Transpiration

Transpiration (soil water uptake) is the second large component in the evaporation budget of forest plantations. Usually, plantation water uptake rates are similar to those of natural forest occurring in the area of planting but under certain conditions water use of the (usually exotic) newcomers may be higher, particularly under subhumid conditions where the natural vegetation consists of more open woodland or scrub. Examples include the replacement of dry forest/scrub by fast-growing plantations of *Eucalyptus camaldulensis* and *E. tereticornis* in South India, and by *E. grandis* in southeastern Brazil and South Africa. Likewise, water uptake rates reported for (vigorously growing and densely stocked) stands of *Acacia mangium* in Malaysia and for various species planted in the lowland rainforest zone of Costa Rica are such that they must exceed the water use of the old-growth rain forests they are replacing, possibly by 100–250 mm year^{-1}. Even greater differences in transpiration can be expected where plantations are established in areas with (natural) grassland or degraded cropland. For example, whilst forest water uptake under humid tropical conditions typically exceeds that of pasture by about 200 mm year^{-1}, the difference may increase to as much as 500–700 mm year^{-1} under more seasonal conditions. Such differences reflect the contrasting rooting depths of trees and grassland as well as the tendency for natural grasslands to go dormant during extended dry periods while the (exotic) trees continue to take up water.

Total Evapotranspiration (ET)

It follows from the above increases in rainfall interception and transpiration that are typically associated with the establishment of tree plantations in areas of (natural) grasslands or (degraded) cropland that overall *ET* totals can be much increased after forestation. As shown in **Figure 2**, total *ET* values for actively growing plantations may approach 1500 mm year^{-1} and, occasionally, as much as 1700–1900 mm year^{-1}. Such very high values must be considered the exception rather than the rule, however, and probably reflect the advection of

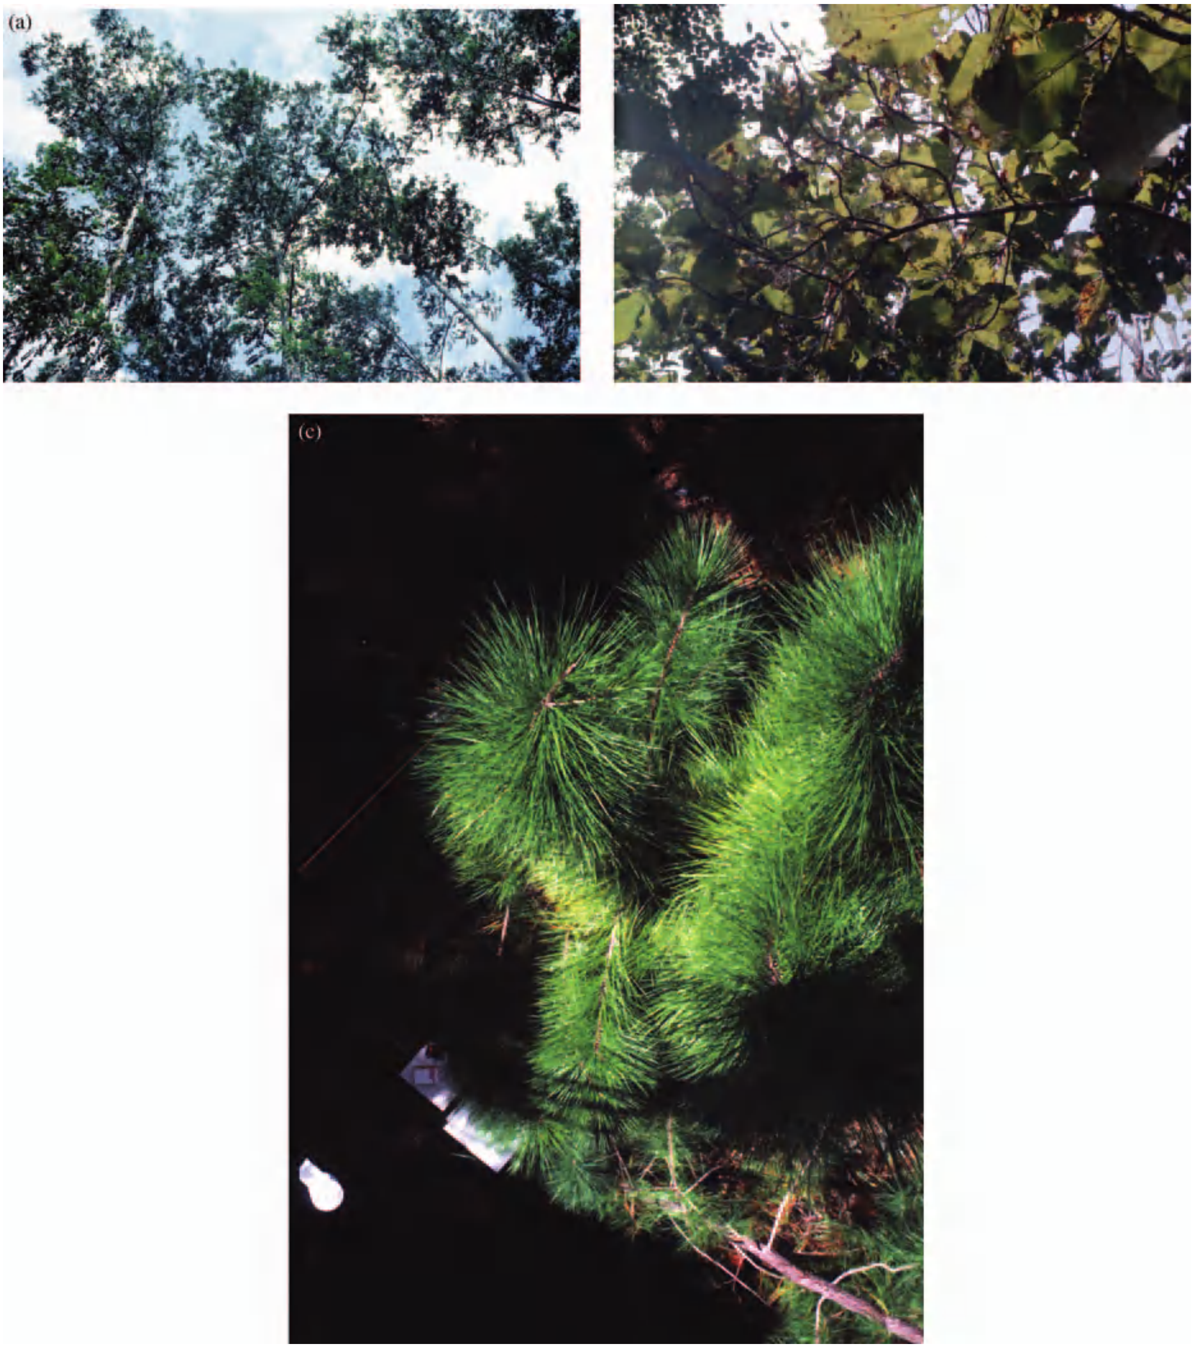

Figure 1 The contrasting canopies of (a) *Eucalyptus* spp., (b) teak (*Tectona grandis*), and (c) pines (*Pinus caribaea*) lead to differences in amounts of rainfall interception and in the drop size spectra (and thus eroding power) of water dripping from the canopy. Photographs by LA Bruijnzeel.

warm, dry air flowing in from adjacent grassland areas which tends to greatly enhance evaporation rates. Nevertheless, the fear is justified that the much increased water use of tree plantations compared to the grasslands and crops they replace will lead to substantial reductions in catchment water yields, particularly during the dry season, if entire catchments are planted.

Effects of Tree Plantations on Streamflow

Effects of Associated Land Management

In discussing the hydrological effects of establishing timber plantations, it is important to be clear about the site-specific conditions and management practices associated with the land-use change and their contribution to the effect of a change in land use.

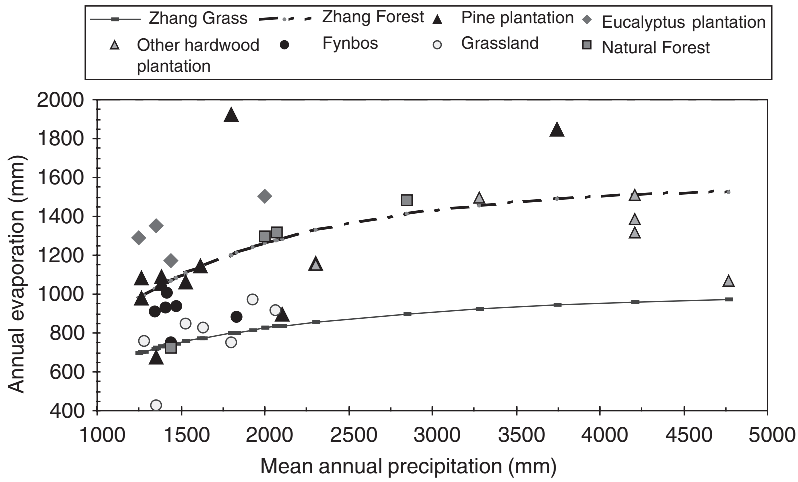

Figure 2 Total evaporation (*ET*) from forest plantations and other vegetation types as a function of precipitation. Data mostly from humid tropical (Bruijnzeel 1997) and South African plantations (courtesy of D Le Maitre, CSIR, South Africa, unpublished compilation). The curves define average forest and grassland water use in southeastern Australia (adapted from Zhang L, Dawes WR, and Walker GR (2001) Response of mean annual evapotranspiration to vegetation changes at catchment scale. *Water Resources Research* 37: 701–708), and have been extrapolated for rainfall >2000 mm.

Such background information may be very important in assessing the overall hydrological effect of the plantations. The following examples illustrate the need to specify more than simply the change in vegetation cover itself.

Firstly, a forest or plantation would be expected, normally, to have a continuous groundcover of leaf or needle litter and some shade-tolerant shrubs. In parts of southern China and adjacent countries, however, all litter and understory plants may be collected for fuel, a practice that has a profound influence on the occurrence of surface runoff and erosion in the plantation (**Figure 3**). Elsewhere (as on the Indian subcontinent) forests and plantations are used to graze cattle, a practice that requires regular burning to stimulate the growth of fresh grass shoots. The combined effect of burning and trampling by livestock may promote massive surface erosion, sometimes to the extent of initiating gullies.

Contrary to popular belief, it is not the interception of rainfall by the main tree canopy that protects the soil underneath against the erosive impact of the rains. Rather it is the combined protection afforded by the understory vegetation and a well-developed litter layer that prevents the soil from being eroded. In fact, the erosive power of rain dripping from the canopies of tall trees is often greater than that in the open, because of the associated increases in drop sizes. The largest increases in drop diameters are observed for drip from large-leaved trees such as teak or *Gmelina*, whereas those falling from eucalypts or pines are more modest in size (**Figure 4**). Such findings underscore the importance of maintaining a good groundcover in plantations if runoff and erosion problems are to be avoided (cf. **Figure 3**).

A final example of the importance of management comes from the wet and peaty hill country of Scotland and the English borderlands, where surface drains are usually excavated prior to the planting of coniferous trees (mostly Sitka spruce, *Picea sitchensis*), to improve the success of tree crop establishment. However, the influence of the drainage ditches on streamflow has proved more important than the vegetation change from heath and moorland to tree plantation itself.

Forestation and Water Yield

The increased evaporation from timber plantations replacing shorter vegetation types (**Figure 2**), not unexpectedly, translates into decreases in annual streamflow totals after plantation establishment. Although there are no stringent (paired) catchment experiments in the humid tropics proper, there is overwhelming evidence to this effect from the subhumid tropics (notably India), the subtropics (mostly South Africa), and the temperate zone (including southeast Australia and New Zealand). Considerable differences have been observed between species but these are not necessarily the same in different areas. For example, in southeast Australia and New Zealand greater reductions in flow were observed after planting pines (*Pinus radiata*) on grassland than in the case of planting eucalypts (**Figure 5**). Conversely, in South Africa, other variables being equal, the effect of planting *Eucalyptus*

Figure 3 The practice of repeated removal of needle litter from coniferous forests in parts of mainland southeast Asia often leads to dramatic increases in surface runoff and erosion. Photographs by courtesy of C Cossalter.

grandis was more pronounced than that of *P. radiata* or *P. patula* (see **Figure 8** below). Such contrasts mainly reflect differences in growth performance between regions and to a lesser extent differences in rainfall interception dynamics.

Published experimental results often represent the maximum possible impacts on streamflow. In the real world, variations in site characteristics and plantation management may exert a moderating influence on the hydrological impacts of forestation. Moderating factors include the fraction of the catchment planted, planting position within the catchment (upstream or downstream parts, close to or away from the streams, blocks vs. strips, etc.), and variations in stand age and productivity between species. These factors are elaborated upon briefly below.

Catchments are rarely completely planted with trees because some land is usually reserved for other uses or it may be inaccessible or otherwise

unsuitable. The classical forest hydrology literature suggests that the magnitude of the change in catchment water yield is linearly proportional to the percentage of catchment planted or cleared, with increases in flow after forest removal and reductions after forestation (**Figure 6**). Hence, in the case of plantations, one could assume that if only half of a grassland catchment would be forested then the estimated reduction in mean annual runoff would also be about half of the maximum reduction predicted by **Figure 5** for a given annual rainfall total (assuming that plantation position in the catchment does not influence the result).

Few experimental data are available on the influence of plantation position on catchment water balance changes. Under humid conditions in the eastern USA, the reverse operation (i.e., forest clear-cutting) did not show a significant difference in streamflow response after cutting the upper half of the catchment or the lower half. Also, elimination of the vegetation around streams in one experiment in the summer-rainfall zone of South Africa did not lead to greater increases in streamflow than when removing an equal area of forest away from the stream. However, several other experiments in South Africa showed that an area of plantation near streams had roughly double the effect of the same area of mid-slope planting.

Such contrasting results may be explained in terms of average soil water surplus or deficit, depth to the groundwater table and slope morphology. All these factors influence hillslope hydrological behavior. Where rainfall is plentiful, slopes steep and convex, and the groundwater table rather deep (say, more than 3 m), no major spatial effect is expected. This is because rainwater infiltrating into the soil percolates more or less vertically to the water table, then moves laterally as groundwater to the nearest stream without being taken up again by the roots of the trees. Conversely, where soil water is scarcer, slopes gentle and concave, and depth to the water table shallow, a more pronounced effect is possible because trees located closer to the stream will have more ready access to the groundwater table. As such, they are likely to consume more water than trees further away from the stream that have less direct access to groundwater to supplement diminished soil water reserves.

Furthermore, there is the intuitive notion that the further away one gets from a stream, the smaller the probability that water infiltrating into the soil will actually contribute to streamflow. These ideas have been tested in modeling experiments in the context of southeast Australia, the results of which lend support to the notion that plantation position could indeed affect catchment water yield under conditions of low rainfall (700 mm), gentle slopes, and high water-tables (**Figure** 7). Indeed, the predicted effect on streamflow of tree planting differed strongly depending whether forestation started at the top of the hillsides and progressively moved downslope or vice versa. The curves of **Figure** 7 also suggest that under the prevailing conditions planting of the lower 30% of the catchment would have a much greater impact than planting the uppermost 30%. Similarly, a related modeling study indicated that planting trees in strips about 40 m wide parallel to the contour with bands of pasture in between leads to greater tree water use and better growth than when the same number of trees are planted in a single block at mid-slope position.

More work is needed to ascertain optimal plantation positions to minimize the hydrologic impacts of forestation under contrasting climatic and topographic conditions. Process-based, spatially distributed hydrological models can be used to assess how different planting strategies would impact on catchment flow regimes. Whilst such models are difficult to set up and apply, the effort is surely worthwhile given the level of investment that goes into planning any significant forestation initiative.

Much can be learned on the effects of species, plantation age, and vigor from a particularly comprehensive series of long-term paired catchment studies of the hydrological effects of afforesting natural grasslands and scrublands in subtropical South Africa. Ten paired catchment experiments have studied the effects of afforestation with *Pinus radiata*, *P. patula*, and *Eucalyptus grandis* within catchments. The research sites are all in the high rainfall zone of South Africa (mean annual precipitation 1100–1600 mm). Experimental control was provided by catchments kept under native vegetation. Although generally steep, the catchments have deep, well-drained soils and show very low stormflow response to rainfall. The catchments are all in good hydrological condition (i.e., no significant surface erosion); thus, the experimental comparison is between the two vegetation covers, reflecting, ultimately, the differences in total evaporation.

The resulting streamflow reductions over time after planting follow a sigmoidal pattern comparable to a growth curve (**Figure** 8). There are clear

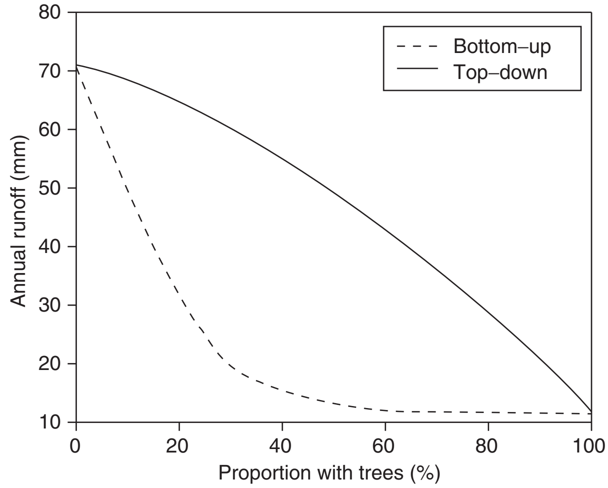

Figure 7 Results from a numerical modeling experiment showing two sets of predictions of annual streamflow after planting trees on a catchment under pasture in central New South Wales, Australia (mean annual rainfall 700 mm). The upper curve (solid line) shows changes in annual flow with forestation starting at the top of the catchment and progressing downslope. The lower curve (dashed line) shows the comparative response when forestation starts at the bottom of the catchment and progresses upslope. Reproduced with permission from Vertessy RA, Zhang L, and Dawes WR (2003) Plantations, river flows and river salinity. *Australian Forestry* 66: 55–61.

differences between the effects of eucalypts and pines, but there is also a large amount of variation from year to year within a single experiment and between different experiments, even in comparable catchments in one locality. The highest flow reductions occur once the tree crop is mature, and range, for a 10% level of planting, from 17.3 mm or 10% year^{-1} in a drier catchment to 67.1 mm or 6.6% year^{-1} in wetter catchments (**Figure** 8). As such, relative streamflow reductions (%), for a set age, are greater in drier catchments but absolute reductions (mm) are greater in wetter catchments. In other words, the reductions are positively related to water availability. The lower of these reductions in streamflow are similar to results obtained after planting *E. globulus* in high elevation grassland areas in the subhumid South of India (*c.* 20 mm per 10% forest year^{-1}) whereas the highest reductions in South Africa rather resemble the changes observed after planting *P. caribaea* on seasonal grasslands in Fiji (50–60 mm per 10% year^{-1}). Similar effects on streamflow have been recorded under the more temperate conditions of New Zealand (see also **Figure** 5), where conversion of pastures and tussock grassland to *P. radiata* plantations, over a range of climates, led to streamflow reductions of 20–45 mm year^{-1} per 10% of catchment planted, the amount again being dependent on water availability.

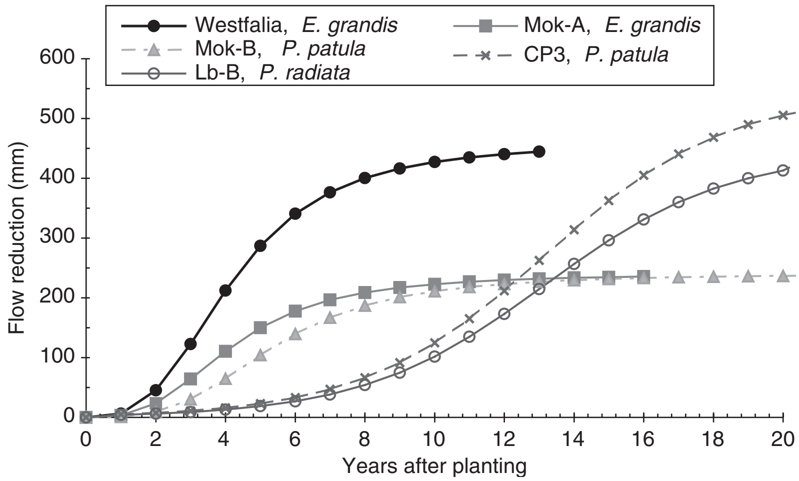

Figure 8 Reductions in streamflow as measured in five catchment afforestation experiments in South Africa. The curves are scaled for 100% planting of the catchment and smoothed to the mean annual runoff (MAR) prior to planting. Based on Scott DF and Smith RE (1997) Preliminary empirical models to predict reductions in total and low flows resulting from afforestation. *Water SA* 23: 135–140.

The timing of the first significant reductions in flow after planting varies quite widely depending on the rate at which catchments are dominated by the plantation crop. The pine plantations in the high altitude grasslands at Cathedral Peak in South Africa (CP in **Figure 8**) usually took several years to have a clear impact on streamflow. However, the same species of pine had an earlier effect on streamflow (within 3 years) under the drier conditions prevailing in the Mokobulaan B catchment in Mpumalanga Province (Mok-B in **Figure 8**). Other conditions remaining the same, eucalypts have a slightly earlier impact on streamflows than pines in South Africa, normally within 2–3 years.

A key factor influencing the degree of streamflow reduction after forestation is the vigor of the trees. Usually, there is a close link between the growth rate of a plantation and its overall water uptake. A new finding from the South African afforestation experiments is that the flow reductions are diminishing again during the postmaturation phase of the plantations, both in the case of pines (after about 30 years) and in at least one of the two eucalypt experiments (after 15 years). This undoubtedly mirrors the gradually decreased vigor of older trees as has also been observed in old-growth native eucalypt forest in southeast Australia and tropical rainforest in Amazonia. In industrial plantation forestry, short- and medium-length tree rotations will tend to keep the trees in their peak water use phase, but longer rotation crops, such as those aimed at producing good quality saw timber, are more likely to have a smaller effect on water yield later on in the rotation.

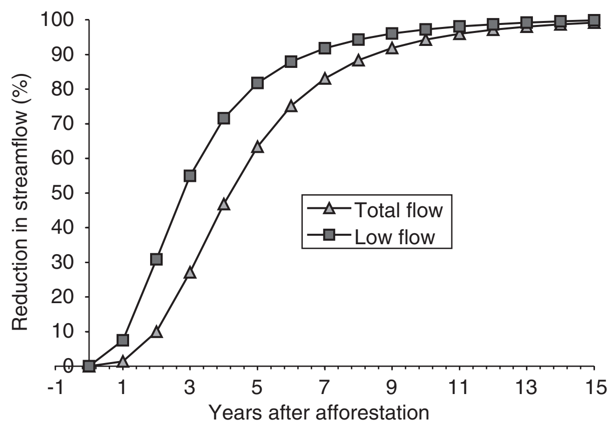

Figure 9 Pooled results from two eucalyptus afforestation experiments in South Africa, showing the pattern of flow reductions as a function of plantation age, and illustrating the greater and earlier effects on the low flow component (both catchments fully afforested). Reproduced with permission from Scott DF and Smith RE (1997) Preliminary empirical models to predict reductions in total and low flows resulting from afforestation. *Water SA* 23: 135–140.

Forestation and Low Flows

Declines in streamflow following the establishment of plantations are recorded in all components of the annual hydrograph (i.e., stormflows and baseflows). In South Africa, effects on total and low flows follow the same pattern, but low flows are decreased more than are total flows at the same age (**Figure 9**). Similar effects have been found in the temperate zone as well as in Fiji, India (even more so after coppicing and resprouting), and Malawi. The effect of forestation on low flows in subhumid areas has two supposed sources. First, exotic plantations, in contrast to the native grasses or scrub vegetation they replace, do not go dormant in the dry season. The second cause, though less easily quantified, is that of steadily reducing soil water reserves as the trees mature. Low flows are a reflection of the amounts of soil water and groundwater stored in the catchment and as these are steadily depleted by tree water uptake so low flow will diminish correspondingly. It is clear from the South African experiments that total water use by the tree crop can exceed annual rainfall in many years and that, once dry season flow has ceased altogether, the occurrence of rainstorms may not easily cause the streams to flow again.

Strongly reduced baseflows after forestation of (nondegraded) grassland or scrubland can thus be expected to be a generally occurring phenomenon. The magnitude of this effect is probably related to the capacity of the soils to store water and to the extent that this water can be accessed by the roots of the tree crop. Thus, where the new trees are able to occupy a much greater volume of soil through their deeper roots, reductions in baseflows following forestation can be expected to be proportionately larger than in situations where rooting volume is restricted.

Finally, it is important to bear in mind that the above examples concern situations where the soil is not degraded and rainfall infiltration generally proceeds unimpaired. Under such conditions, streamflow amounts will simply reflect the change in vegetation water use and low flows will be thus (much) reduced (see **Figures 2** and **6**). However, in areas with degraded, compacted soils where much of the rain may run off along the surface as overland flow (and therefore does not contribute to soil water reserves), the planting of trees can be expected to ultimately have a positive effect on infiltration. Theoretically, the extra water entering the soil through improved infiltration after forestation may moderate or, in extreme cases, even reverse the adverse effect of the larger water use of the trees on streamflow. In all cases, the net effect of tree planting on the baseflow from degraded areas will reflect a trade-off between these two effects. Where infiltration is already sufficient to accommodate most of the rainfall, any further improvements by forestation will not tip the balance. Rather, water yield will be reduced even further (**Figures 6** and **9**). However, where soils are deep but overland flow during rainfall is rampant and much is to be gained from improved infiltration (**Figure 10a**), it cannot be excluded that a net positive effect on low flows may occur. The

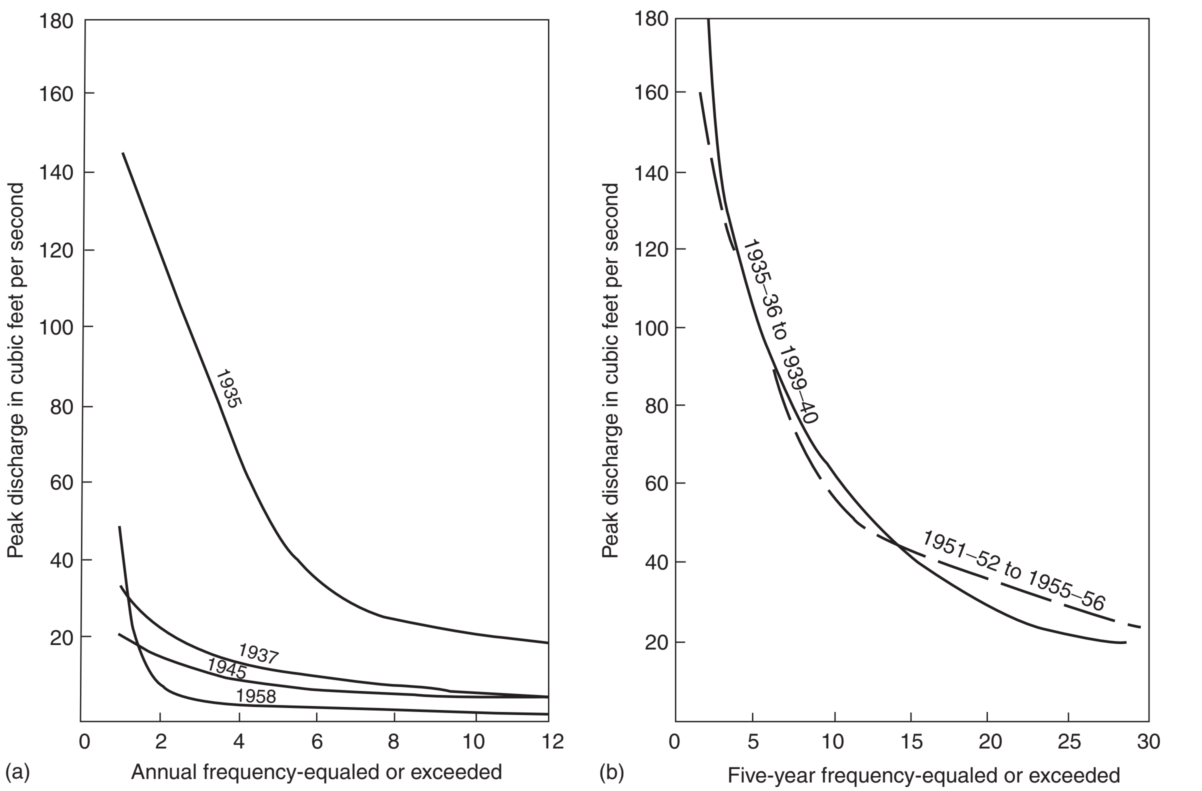

Figure 10 Frequency distributions for peak discharges during (a) summer and (b) winter in the While Hollow catchment, Tennessee, USA before (1935) and after (1937–1958) reforestation. Modified from Tennessee Valley Authority (1961) *Forest Cover Improvement Influences upon Hydrologic Characteristics of White Hollow Watershed, 1935–1958*. Report no. 0-5163A. Knoxville, TN: Tennessee Valley Authority.

experimental evidence for this contention is only indirect, however, and based on a comparison of observed reductions in stormflow response (having a positive effect on soil water reserves) (**Figure 10a**) vs. increases in vegetation water use (having a negative effect on soil water reserves) (**Figure 2**).

Forestation and Stormflows

Forest hydrological research has shown that the influence of vegetation cover or type on catchment runoff response to rainfall ('stormflows') is inversely related to the size of the rainfall event that generates the flows. This can be explained as follows: in small to medium storm events the combined water storage capacity of vegetation layers, litter, surface depressions, and the soil mantle will be considerable relative to the amount of rain delivered by the storm. As a result, the associated catchment response will be much reduced in the case of a good forest cover. The soil mantle is potentially the largest water store, but its capacity to accommodate additional rain varies as a function of soil wetness. Where previous uptake by the vegetation has depleted soil water reserves (as is often the case during summer), storage capacities, and thus stormflow reduction, will be relatively high (**Figure 10a**). However, once the soil has become thoroughly wetted by previous rains (typically during winter or the main rainy season), very little opportunity to store additional water will remain, regardless of vegetation type (**Figure 10b**). In addition, as rainfall events increase in size, so does the relatively fixed maximum storage capacity of the soil become less important in determining the size of the stormflows. In other words, the presence or absence of a well-developed forest cover has a significant effect in the case of small events but this typically makes very little difference (less than 10%) in the case of truly large events (floods) generated by extreme and prolonged rainfall (**Figure 10b**). Under such conditions, runoff response is governed almost entirely by the capacity of the soil to accommodate and transfer the rain.

However, where degradation of a catchment's soils has produced strong reductions in canopy and groundcover (including litter), and above all in infiltration capacity and soil depth through continued erosion (and thus overall soil water storage opportunity), reforestation could clearly lead to an improvement of most or all these factors over time. These ideas are conceptualized in **Figure 11**.

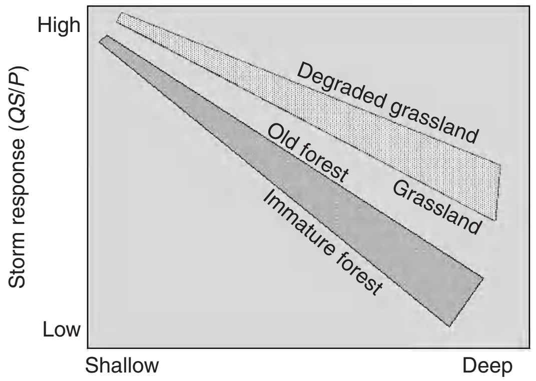

Figure 11 Postulated generalized relationship between catchment storage capacity and stormflow response to rainfall, as affected by vegetation cover. Reproduced with permission from Scott DF, Bruijnzeel LA, and Mackensen J (2004) The hydrological and soil impacts of forestation in the tropics. In: Bonell M and Bruijnzeel LA (eds) *Forests–Water–People in the Humid Tropics*. Cambridge, UK: Cambridge University Press.

Concluding Remarks

Catchment experiments all over the world have demonstrated convincingly that total amounts of streamflow emanating from catchments where forest plantations have replaced (natural) grassland or scrubland, or (degraded) cropland, are invariably much reduced. In addition, the reductions in baseflows during the dry season are relatively greater than during the wetter season. Small to medium-sized stormflows are also reduced significantly by forestation but the effect on occurrence and size of flood peaks associated with truly large rainfall events is very limited.

These observations differ strongly from the popular view held by many foresters, policy-makers, and the public at large that forestation will lead to (more or less rapidly) increased streamflows and the elimination of flooding. Although the establishment of forest plantations on degraded land will improve the soil's capacity to absorb rainfall, this is likely to take at least several decades. However, because water use by the trees is much increased within a few years compared to that of the former vegetation, the balance of probability is that low flows will also be reduced in this case. Establishing the precise hydrological effects of reforesting areas in various stages of soil degradation constitutes a prime research need.

Impacts of Forest Management on Water Quality

S H Schoenholtz, Oregon State University, Corvallis, OR, USA

Introduction

In forested catchments the hydrologic cycle, involving precipitation, interception, evapotranspiration, overland flow, subsurface flow, groundwater flow, and stream flow (**Figure 1**) is closely linked to water quality in that water movement through the forest ecosystem also transports sediment, and dissolved nutrients, as well as fertilizers, and pesticides if they are present. Understanding relationships between forested ecosystems and quality of surface and subsurface water associated with these systems is a key component of sustainable forest management because changes in water quality may result from forest management practices. These changes can reflect either positive or negative outcomes of forest practices. For example, logging road construction and harvesting of timber with improper consideration for erosion control can cause increased sedimentation of stream water and a degradation of water quality. In contrast, conversion from agricultural crop production to forestland can improve water quality by decreasing erosion rates and creating long-term storage pools (e.g., forest floor, woody biomass) for carbon and nutrient retention. This article provides a synthesis of our current thinking regarding (1) the concept of water quality, (2) the role of forested watersheds in providing water of relatively high quality, and (3) commonly evaluated water quality parameters and potential effects of forest practices on these parameters. The primary focus is on the relationship between water quality characteristics of streams draining forested watersheds and forestry practices. Where information is available, effects of forestry practices on groundwater quality are also addressed.

Water Quality: The Concept

The concept of water quality is largely based on value judgments developed in relation to the beneficial or intended use of the water resource of interest. For example, water quality standards – comprising selected physical, chemical, and biological characteristics of water (**Table 1**) – developed for domestic use are likely to be different from water quality standards developed for other beneficial uses such as recreation, habitat for aquatic biota, or irrigation. As such, water quality standards are relative values that are dependent on the intended use of the water. The key to assessing whether or not change in a water quality parameter is a pollutant concern depends on its impact on beneficial uses.

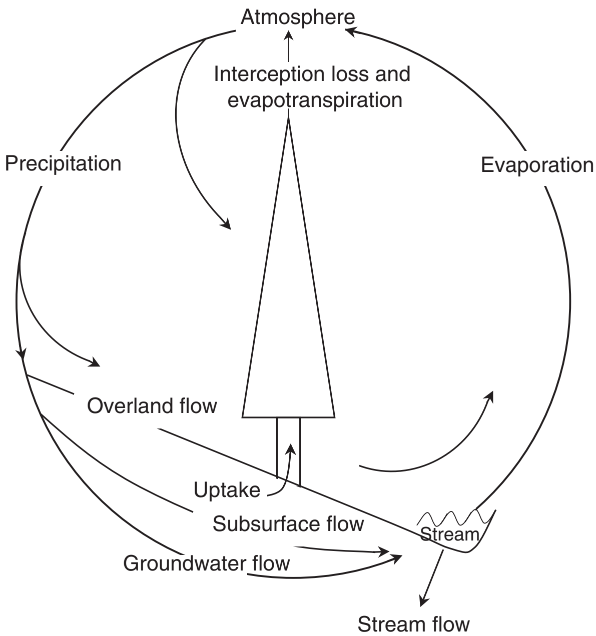

Figure 1 The hydrologic cycle for a forest. Adapted with permission from Brown GW (1988) *Forest and Water Quality*, Corvallis, OR: Oregon State University.

In cases where water quality is diminished because of anthropogenic influences, then pollution of the water resource has occurred. However, water quality can also be degraded by natural phenomena such as wildfire, volcanic eruptions, earthquakes, hurricanes, floods, and landslides. It is therefore important to consider anthropogenic influences on water quality in the context of the natural variation that is characteristic of water quality parameters. At times, changes in water quality resulting from natural causes can overwhelm effects of land use practices. Examples of this natural variation are provided by landslides, which often dramatically increase sediment loads in streams or by severe wildfires, which can also increase sediment loads as well as nutrient concentrations in stream water.

Importance of Forests for Water Quality

Water draining from undisturbed forested watersheds is generally of the highest quality, particularly with regard to beneficial uses including drinking water, aquatic habitat for native species, and contact recreation. A survey of the literature shows consistent patterns of relatively high water quality draining forested catchments in comparison to other land uses such as agriculture or urbanization (**Figure 2**). Recognition of the relative role of forests for providing water supplies of the highest quality has

Table 1 Commonly measured water quality parameters in forested watersheds

Parameter	*Influence on water quality*
pH	Influences chemical and biological reactions; toxic at extreme high or low values
Acidity	Capacity to neutralize base; affects chemical and biological reactions
Alkalinity	Capacity to neutralize acid; affects chemical and biological reactions
Conductivity	Estimate of total dissolved solids
Suspended sediment	Restricts sunlight and photosynthesis; smothers benthic communities; covers spawning gravels
Turbidity	Measure of water clarity; often surrogate measure for suspended sediment
Dissolved phosphorus	Essential nutrient; excess can cause eutrophication
Dissolved nitrogen	Essential nutrient; excess can cause eutrophication; forms can be toxic to stream biota and humans
Dissolved oxygen	Required for aerobic metabolic processes; affects chemical reactions
Temperature	Affects dissolved oxygen and metabolic processes
Biochemical oxygen demand	Measure of decomposable organic loading in water
Pathogenic bacteria and protozoa	Potential human health hazard
Pesticides	Forms can be toxic to stream biota

Figure 2 Undisturbed, forested watersheds generally produce outstanding water quality.

been one of the driving factors for establishment of forest reserves and for development of forest management practices designed to protect this high quality.

In some cases forest management activities such as road construction, harvesting, site preparation for regeneration of forest tree species, and fertilization of existing forests have been shown to alter water quality, primarily by causing changes in sediment loads, stream temperature, dissolved oxygen, and dissolved nutrients, particularly nitrogen. Fortunately, the wealth of literature addressing forest management impacts on water quality reports that, if impairment of water quality resulting from forestry practices is observed, it is relatively short-lived, diminishing rapidly as vegetation is re-established, and occurs at infrequent intervals because forest practices on a given site may only occur once or twice during a forest rotation (i.e., several years for intensively managed, fast-growing trees in the tropics to several centuries for unmanaged forests in areas of low productivity).

Effects of Forestry Practices on Water Quality

Suspended sediment, turbidity, stream water temperature, dissolved oxygen, and dissolved chemicals including nutrients and pesticides are the most studied characteristics of streamwater in relation to effects of forestry practices. Biological characteristics including pathogenic bacteria and protozoa in surface water have also received attention in forested watersheds because of their potential to impair human health and restrict water use. Other constituents that are commonly assessed for water quality characterization but have received less attention in relation to forestry practices to date include biochemical oxygen demand (an index of the oxygen-demanding properties of biodegradable material in water), pH, acidity, alkalinity, and conductivity (**Table 1**). The following subsections discuss (1) erosion and resultant sedimentation, (2) water temperature and dissolved oxygen, (3) dissolved nutrients in relation to nutrient cycling and fertilization, (4) application of pesticides, and (5) pathogenic microorganisms and their impacts on water quality in response to forestry practices.

Suspended Sediment

In general, forest lands produce very low sediment yield compared to other rural land uses (e.g., cropland). In many cases, much of the sediment observed in streams draining forested watersheds is the result of geologic weathering and erosion that are natural processes. Stream channels (including the stream banks) are also an important natural source of suspended sediment and are probably the dominant contributor of suspended sediment in undisturbed forested watersheds (unless in geologically unstable terrain prone to landsliding). For example, concentrations of suspended sediment measured during storm events may result from redistribution of sediment previously stored in the streambed or from the collapse of an unstable section of the stream bank. Nevertheless, excessive suspended sediment loads in streams are the major water quality concern for forest management because poorly planned forest management activities on hillslopes or in the vicinity of the stream channel that cause erosion can add to naturally derived levels of suspended sediment.

Increases in suspended sediment levels resulting from erosion and soil mass movement (i.e., landslides) can degrade drinking water quality, detract from recreational values, decrease stream depth, fill pools in the stream channel, increase stream width, and cause sedimentation of gravel beds which lowers their permeability and degrades their habitat quality for spawning fish (**Figure 3**). Furthermore, large accumulations of fine sediment can restrict sunlight and smother benthic communities thereby disrupting the aquatic food chain. Sediment also increases turbidity

Figure 3 Landslides and debris flows can cause downstream sedimentation.

Table 2 Factors commonly affecting rates of erosion in forested watersheds

Factor	*Characteristic*
Climate	Timing, intensity, duration, form of precipitation
Site	Forest floor composition, structure, depth
	Soil water content, infiltration capacity, texture, structure, depth
	Slope length and gradient
Vegetation	Composition, structure, age
	Rate of interception, evapotranspiration
Forestry practices	Road construction and maintenance
	Skid trail construction
	Mechanical site preparation
	Prescribed fire

and carries nutrients and anthropogenic chemicals (i.e., pesticides) that can degrade water quality.

Responses of suspended sediment concentrations are a function of the effects of climate, site characteristics, and forest practices on soil erosion (**Table 2**). More specifically, climate influences erosion rates through its effects on timing, quantity, intensity, and form of precipitation. Climate also affects erosion indirectly through its influence on soil properties and plant communities. The interaction between rainfall intensity and soil infiltration capacity plays a major role in controlling runoff. Soils with high infiltration capacities rarely have surface runoff and subsequent high rates of soil erosion unless rainfall intensity exceeds infiltration capacity. In most cases, forest soils have infiltration capacities in excess of common rainfall intensities, and therefore, surface runoff and erosion are often relatively insignificant in undisturbed forested catchments.

The interaction between rainfall and infiltration capacity is further modified by the composition and structure of the vegetation through its effect on transpiration, interception of precipitation, and resulting soil moisture. Vegetation also contributes organic matter through deposition of litter to the forest floor which provides a protective layer above the mineral soil surface. Plant roots help stabilize soil to further minimize soil erosion and soil mass movement. Additional factors affecting erosion rates and subsequent delivery of sediment to stream channels include slope length and steepness, and stream drainage density. Erosion rates are highest on long, steep slopes and delivery of sediment to stream channels is more probable (i.e., high sediment delivery ratio) where stream drainage density is high.

Even in forested watersheds that are not subjected directly to human disturbances, erosion rates are often highly variable both spatially and temporally. Natural events such as large storms, landslides, and fires can cause dramatic elevation of suspended sediment that exceeds water quality objectives. This natural variability is an important consideration in ascertaining the effects of forest management on suspended sediment.

Timber harvesting Accelerated erosion caused by forestry practices such as road construction, logging operations, and intensive site preparation can cause increased levels of suspended sediment as demonstrated by reports from timber producing regions worldwide. As such, excess sediment in streams is the most widespread water quality concern associated with forest management. Removal of vegetation and disturbance of soil, two activities that are inevitable at some level during forest harvesting, are driving factors that promote the erosion process. If mineral soil is exposed to rainfall through removal of the forest floor via machine disturbance or fire, then surface erosion can occur through detachment of unprotected soil particles and degradation of soil surface structure.

There is general agreement in the literature that forest road networks and skid trails developed to extract timber are the greatest threat to water quality because they are frequently a source of erosion and sedimentation. Compacted surfaces of logging roads and skid trails reduce infiltration and often carry surface runoff and suspended sediments during storms (**Figure 4**). The amount of sediment delivered to streams is often (1) proportional to the density of logging roads and skid trails within a watershed and (2) inversely proportional to the time since road and skid trail construction. Erosion rates are generally highest immediately after road construction and at times when roads are used during wet conditions. Water reduces frictional resistance and cohesion between soil particles making it much easier to

Figure 4 Improperly designed logging roads are often the source of increased levels of suspended sediment in streams.

dislodge soil particles via mechanical action of traffic on wet roads. These dislodged particles are immediately available for suspension and transport. Compaction and concentration of flow in tire ruts created in wet conditions can also concentrate flow and accelerate erosion on road surfaces. As roads age and vegetation becomes established, erosion rates decline. Therefore, minimizing the density of these disturbances through planned road and skid trail systems, followed by rapid revegetation of disturbed surfaces, which are not required for continued access, are likely to minimize stream sedimentation. Additional techniques commonly used to reduce road erosion and stream sedimentation include surfacing the road with gravel, decreasing the spacing of cross drainages, avoiding stream crossings, locating the road farther from streams to minimize direct drainage of roadside ditches into the stream, and limiting road gradients (*see* **Harvesting:** Roading and Transport Operations).

Soil mass movement such as landslides and debris flows can be triggered by improper road construction that disrupts drainage patterns and concentrates water flow under conditions of high rainfall in steeply sloped terrain. In cases where soil mass movement occurs, sediment delivery to streams far exceeds that from surface erosion and can cause extremely high levels of suspended sediment.

Increased sediment yields have also been noted as a result of ditching to provide drainage of peatlands and mineral soil wetlands. Drainage of these wetland soils is commonly utilized for commercial forest production and resulting changes in runoff as a result of drainage often increase sediment delivery to streams.

Soil disturbances and erosion caused by moving logs from the stump to a loading area vary with the type of skidding and yarding equipment. The most soil disturbance generally is caused by crawler tractors, followed by wheeled skidders. Cable logging systems are more expensive than ground-based systems but result in less soil disturbance because machinery is not traversing the site. Helicopter and balloon logging systems generally cause the least soil disturbance but are often prohibitively expensive for most operations. Logging systems designed to minimize compaction and disturbance of the forest floor generally result in minimum sediment delivery to streams.

Studies have shown that clear-cutting sites without the use of skid trails to transport trees to loading areas does not cause significant increases in sediment yield via surface erosion. In timber harvesting operations, contributions of felling, limbing, and bucking of trees do not contribute directly to sediment levels in streamflow because these activities do not often expose the mineral soil surface. However, clear-cutting often leads to greatly increased water yield and thus to the potential for enhanced streambed and bank erosion.

Increases in sedimentation from timber harvesting are commonly short-lived. Revegetation usually minimizes continued soil loss at rates first observed after the disturbance. Speed of revegetation is variable, depending on harvesting intensity, site preparation for re-establishment of trees, soil properties, and climate. In most studies, if elevated concentrations of suspended sediment are observed after logging activities, they return to preharvest levels within 1-5 years.

Fire Forest management practices sometimes utilize prescribed fire to control vegetation, reduce fuel loads, or to prepare sites for replanting after harvesting. Effects of fire on erosion and sediment yield are directly related to fire severity and degree to which the forest floor is consumed. Low-severity fires that do not completely remove the organic layer of

Figure 5 Surface erosion occurring after a severe forest fire.

the forest floor often do not cause significant increases in erosion and sedimentation. However, if fire severity is sufficient to remove the protective litter layer of the forest floor, thereby exposing mineral soil to raindrop impact, then increased erosion and sedimentation are likely (**Figure 5**). An additional concern that often causes accelerated erosion after fire is development of water-repellent hydrophobic layers in the soil surface that impede infiltration. Increases in suspended sediment after fires are most pronounced in steep watersheds with severe fires. Finally, fire lines that are established by bulldozers to control the spread of fire can be potential sources of sediment in streams. If fire lines are established under emergency circumstances, concerns for proper planning, avoidance of sensitive areas (i.e., very steep or excessively wet), and erosion control are not always paramount and accelerated erosion and sedimentation may result.

Temperature and Dissolved Oxygen

Water temperature is a key water quality parameter because of its direct effect on chemical and biological processes and properties in the stream. It is also a determinant of the amount of dissolved oxygen available for aquatic fauna (**Figure 6**). Solubility of oxygen decreases rapidly with rising temperature. Increases in water temperature generally accelerate biological activity and place greater demand on dissolved oxygen. Metabolism, reproduction, and other physiological processes of aquatic biota are controlled by heat-sensitive proteins and enzymes. A 10°C increase in temperature will roughly double the rate of many chemical reactions and the metabolic rate of cold-blooded organisms. Furthermore, the inverse relationship between water temperature and

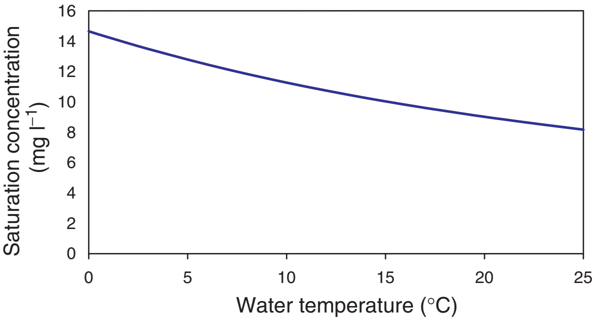

Figure 6 Solubility of oxygen as a function of temperature.

dissolved oxygen exacerbates the consequences of increased temperature. As such, temperature has a strong influence on composition of aquatic communities and maintaining stream temperature is a primary concern to many forest land managers.

Clearing of riparian vegetation is the primary forest management practice that can cause elevated stream temperature, particularly in small headwater catchments. This is the result of increased stream exposure to direct solar radiation. Temperature increases of as much as 15°C have been observed in forest streams when riparian vegetation has been removed. However, the magnitude of the response is tempered by stream discharge, streambed characteristics, channel morphology, stream surface area, and degree of hyporheic exchange and groundwater influx along the stream length. For example, streams with high degrees of hyporheic exchange and/or groundwater inflows may have less of a temperature increase when exposed to direct solar radiation.

Maintaining shade in riparian zones by retention of riparian buffers is a management practice that can be used to avoid most temperature increases in small streams. The key consideration in maintaining stream temperature is to maintain shade conditions that do not alter direct solar radiation from that of undisturbed conditions. However, as stream width increases, more of the water surface is exposed to direct sunlight and the influence of riparian canopy on stream temperature decreases.

Maintaining stream temperature at levels observed in undisturbed conditions is vital for aquatic organisms because of their dependence on dissolved oxygen. Use of streamside buffers to protect from temperature changes will also generally protect streamwater from corresponding changes in dissolved oxygen. However, dissolved oxygen is a function of its solubility in water (largely temperature driven) as well as the balance between oxygen consumption (e.g., respiration, decomposition) and oxygen replenishment (e.g., photosynthesis of aquatic plants, turbulent mixing of streamwater). Levels of dissolved oxygen are influenced by chemical oxidation of organic matter and decomposition of organic matter by aquatic microorganisms. Thus, addition of nutrients and logging debris to streams in response to logging practices has the potential to increase oxygen demand through increased decomposition. However, this demand generally decreases exponentially with time as decomposition proceeds; and if oxygen is readily available and the organic loading is not excessive, then oxidation proceeds without detrimental decreases in dissolved oxygen levels. Presence of streamside buffer zones generally prevents excess delivery of logging slash to stream channels, thereby helping to maintain dissolved oxygen levels similar to prelogging conditions.

Critical periods for water temperature and dissolved oxygen are during summer low-flow conditions when discharge is at a minimum and solar radiation is at or near a maximum, resulting in conditions of maximum stream temperature. Lethal levels of dissolved oxygen vary with aquatic species. For example, dissolved oxygen levels of $<1\text{–}2\,\mathrm{mg\,l^{-1}}$ are lethal for juvenile salmonid species and growth of these species is inhibited in the range of $5\text{–}8\,\mathrm{mg\,l^{-1}}$. In contrast, species occurring in warmwater streams are adapted to low levels of dissolved oxygen.

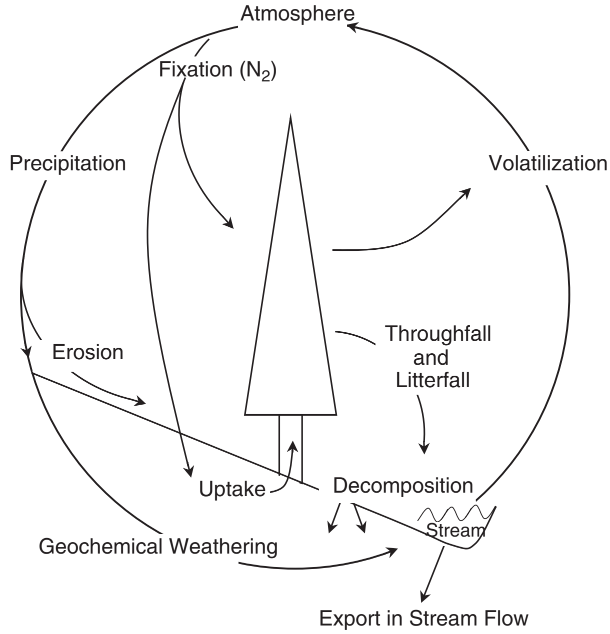

Figure 7 Nutrient cycling in a forest. Adapted with permission from Brown GW (1988) *Forest and Water Quality*, Corvallis, OR: Oregon State University.

Dissolved Nutrients

Nutrient concentrations in surface and groundwater draining undisturbed forest are generally very low because nutrients are used rapidly by ecosystem biota. Because of this limited nutrient availability, inputs of nutrients, particularly nitrogen (N) and phosphorus (P), in excess of background levels often lead to increased primary production, altered aquatic food webs, and potential eutrophication. Dissolved nutrient concentrations are a function of nutrient cycling processes that include (1) inputs from weathering of geologic parent materials (primary source of P, calcium (Ca), magnesium (Mg), sodium (Na), and potassium (K)) or directly from the atmosphere (primary source of N), (2) storage in the soil, (3) plant uptake from soil and storage in biomass, (4) release of organically bound nutrients via decomposition, and (5) outputs of nutrients via streamflow or leaching to groundwater (**Figure 7**). Precipitation and leaf fall are two additional important sources of dissolved nutrients to streams in forested ecosystems.

The two primary dissolved nutrients of concern to forest managers are phosphate-P (PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$) and nitrate-N (NO_3^-) because they often limit productivity of aquatic plants and both can be elevated by forest practices such as harvesting, fertilization, and prescribed fire. Changes in stream P are uncommon after logging, but can increase after fertilization or high-severity fires. Both N and P are commonly applied as fertilizer in intensively managed forests and thus have the potential to alter nutrient cycling processes and affect water quality.

Dissolved N also exists as nitrite (NO_2^{2-}), ammonia (NH_3), ammonium (NH_4^+), and organic N. Dissolved P also occurs as complexes with metal ions and as sorbed phosphate on colloidal organic and inorganic particulate material. High concentrations of dissolved nitrate are a concern because of potential risks to human health if the water is used for drinking. The US Environment Protection Act and Canadian drinking water standard is $10\,\mathrm{mg\,l^{-1}}$ NO_3-N, whereas the World Health Organization and the European Union use a standard of $11.3\,\mathrm{mg\,l^{-1}}$ NO_3-N. Dissolved ammonia can be toxic to aquatic organisms, with concentrations as low as $0.03\,\mathrm{mg\,l^{-1}}$ NH_3-N being potentially toxic as acute concentration and toxicity associated with chronic concentrations of $0.002\,\mathrm{mg\,l^{-1}}$ NH_3-N. Nontoxic ammonium forms from ammonia at pH levels commonly observed in forested streams and is the predominant form observed. Phosphate is not toxic. The range of suggested water quality standards for P is 0.025–$0.1\,\mathrm{mg\,l^{-1}}$ as total P.

Worldwide, pristine rivers have average concentrations of ammonia-N and nitrate-N of $0.015\,\mathrm{mg\,l^{-1}}$ and $0.1\,\mathrm{mg\,l^{-1}}$, respectively. The concentration of nitrate-N averages approximately

0.23 $mg\,l^{-1}$ for large forested watersheds in the USA. Nitrate-N concentrations $>1.0\,mg\,l^{-1}$ generally indicate anthropogenic inputs. Because N is essential for plant growth, seasonal differences in plant uptake can cause variations in the concentration of N in soil and surface waters. In addition, rate of removal of N from forest streams is generally high. As water flows downstream, N compounds may be removed by biotic uptake, movement into sediments, or conversion to gas. Finally, the literature on synoptic patterns of streamwater chemistry suggests that influences of vegetation type, vegetation age, geologic substrate, stream order, basin size and morphology, and climate are controlling factors of dissolved nutrient levels. As a result, water chemistry can be highly variable within and among streams. For example, conifer forests tend to have more dissolved N in the organic form and hardwood forests tend to have more dissolved N in the inorganic form. Some regions, such as the red alder (*Alnus rubra*)/Douglas-fir (*Pseudotsuga menziesii*) forests of the Oregon Coast Range in the USA have high levels of nitrate naturally from N fixation provided by the alder stands that dominate the riparian zones. This interaction among controlling factors of streamwater chemistry illustrates a fundamental challenge in detecting significant responses to anthropogenic influences.

Timber harvesting Despite the confounding factors described above, studies throughout the world show that following intensive timber harvesting on well-drained soils, there is frequently an increased loss of nutrients from the logged area. Increased nutrient export from intensively logged watersheds is often partly caused by increases in water yield that usually accompany removal of vegetation. When trees are harvested from a site, a sequence of alterations in nutrient cycling occurs that can lead to loss of nutrients from the terrestrial ecosystem. Removal of vegetation results in less nutrient uptake, increased soil temperature, and increased soil water content. Accelerated release of nutrients occurs as decomposition of logging slash is stimulated by warmer, wetter soil conditions that generally favor decomposition. Enhanced decomposition increases mineralization of organic matter and nitrification, resulting in release of cations and nitrate that are available for leaching loss to streams and groundwater in the absence of adequate nutrient uptake and soil retention.

Nitrate-N concentrations in streams have received the most study and have shown increases in response to harvesting in some cases. However, extent of nutrient loss from sites disturbed by timber harvesting is highly inconsistent because of variable climate, geology, soils, plant community composition, and revegetation dynamics. Losses are generally lowest in deep soils with high clay contents which have a high capacity to fix leaching nutrients on exchange sites within the soil profile. The most susceptible sites to nutrient loss occur on shallow soils with low exchange capacity in systems where relatively high levels of nutrients are supplied to the site via precipitation and/or weathering. For example, in areas that are subject to N saturation from deposition of N compounds in air pollution, forest harvesting, or fertilization can produce significantly elevated concentrations of nitrate-N in streams and groundwater. Nutrient mobility from disturbed forests generally follows the order $N > K > Ca = Mg > P$. Thus forest practices such as timber harvesting generally produce larger responses in N concentrations in streamwater and groundwater than other nutrients. In contrast, P is delivered to streams primarily adsorbed to fine-textured sediments via erosion.

Fertilization Fertilization of managed forests is a common practice in the northwestern and southeastern USA, Canada, Japan, Australia, New Zealand, and regions of Europe and South America. Young commercial forest stands (~15–40 years) are commonly fertilized with N at $\sim 200\,kg\,N\,ha^{-1}$ as urea, ammonium nitrate, diammonium phosphate, or ammonium sulfate. Various forms of phosphate fertilizers are applied less commonly and at lower rates. In most cases, increases in dissolved phosphates after fertilization have not been observed in streamwater or groundwater.

The potential for negative effects of fertilization on streamwater quality has long been recognized and has resulted in considerable research and review in the literature. Studies have reported that applied fertilizer N can affect N concentration in streams, with losses to the stream ranging from 0% to as much as approximately 30% of applied N. Losses from the site of application depend on numerous factors, including amount and form of fertilizer, timing of application, weather during and immediately following application, stand composition and age, width of riparian buffers, amount of direct input to streams, N status of soils, quantity of organic matter in the soil, hydrologic processes (e.g., groundwater residence time, hyporheic exchange), and land use history (**Table 3**).

Fertilization of forests with urea-N often shows subsequent elevation in stream nitrate-N concentration, but not until nitrification of the urea-N has proceeded in the soil and several rainstorms have occurred to transport the resultant nitrate to the stream. As such, maximum nitrate-N concentrations

Table 3 Factors affecting nitrogen loss from forested watersheds via leaching or streamflow after nitrogen fertilization

Factor	*Characteristic*
Fertilizer	Form, amount, timing
	Amount of direct input to stream
Weather	Conditions during and immediately following application
Stand	Composition, age
	Width of riparian buffers
Soil	Nitrogen status
	Nitrification potential
	Quantity and properties of soil organic matter
	Soil depth, texture, cation exchange capacity
Hydrologic processes	Hyporheic exchange
	Groundwater residence time
Watershed geology	Landforms, soils
Land use history	Previous fertilizer applications

in streamwater are sometimes not observed until the winter after fertilization with urea. Most fertilization studies have shown peak concentrations of nitrate-N of $<2.0\,mg\,l^{-1}$. In cases where high nitrate-N has been observed (e.g., Fernow Experimental Forest in West Virginia, USA and in Sweden), N-saturated soils are present and excess atmospheric N deposition is well-documented. Most occurrences of elevated nitrate are short-lived, lasting for a few days to several weeks, because of uptake within the soil profile as well as N processing within the stream. Instream pathways for N processing include downstream transport and dilution, hyporheic retention and processing by microbial communities, uptake by benthic algae, and downstream transport and recycling via sloughed, particulate forms of algae.

Inadvertent application of fertilizer to unintended areas occurs to some extent during most aerial applications. Highest concentrations of streamwater N occur where fertilizer is applied directly to streams. Typically, pulses of dissolved urea, ammonia, or nitrate resulting from direct application quickly decline in concentration and are short-lived – usually lasting less than 1 month and often only a few days. Even under conditions of direct application, nitrate-N concentrations rarely exceed the standard of $10\,mg\,l^{-1}$ and ammonia toxicity is rarely observed because of rapid conversion to non-toxic ammonium.

Fire Numerous studies have reported increases in streamwater nutrient concentrations after wildfires and prescribed management fires, but these increases are usually limited in magnitude and duration. Nutrient loss to streams following prescribed fire is generally undetectable or very low. However, as fire severity increases, organic materials are oxidized creating oxides of metallic cations such as Ca, K, Mg, and Fe, which react with water and CO_2 to become soluble and more susceptible to leaching. This process increases potential for leaching loss of nutrients from the ash into and through the soil. Nutrients in the ash are also susceptible to loss by surface erosion. Overland flow from a rainfall event of high intensity following a severe fire can move large quantities of soluble ash compounds into streams, especially during the first year after the fire. This effect quickly diminishes as vegetation is re-established.

The potential for increased nitrate concentrations in streamflow is generally a function of accelerated mineralization of organic N, followed by nitrification in soils after burning. Where severe fires have removed vegetation, plant uptake of N is diminished and available nitrate resulting from the fire is susceptible to loss via leaching or erosion. This effect is also usually short-lived, and generally declines as revegetation occurs.

Pesticides

Applications of pesticides to forest lands are just a fraction of those applied to agricultural lands and pesticide concentrations associated with forest management practices are generally many times less than those used on agricultural lands. However, there are circumstances where forestry applications can cause degradation of water quality and potential impacts on stream biota. Pesticides, including herbicides for vegetation control and insecticides for control of damaging insects, are often used for intensive forest management.

Herbicides are used to control competing vegetation during forest stand establishment. This practice eliminates on-site soil and organic matter displacement, prevents deterioration of soil physical properties (i.e., compaction), and minimizes erosion when compared with mechanical means of site preparation and vegetation control. In most cases, these chemicals are distributed aerially and therefore a portion of the aerial spray can fall directly on surface water and create immediate contamination. Amount of spray drift is influenced by the pesticide carrier, size of spray droplets, height of spray release, wind speed, temperature, and humidity. Concentration of pesticide chemicals in streams is often a function of whether the stream originates in or flows directly through spray areas.

Pesticide risk to aquatic systems depends on persistence characteristics of the pesticide, hydrologic processes (i.e., leaching, surface runoff), and properties of the site. Rainfall rates, soil infiltration capacity and hydraulic conductivity, soil texture, soil depth, amount and character of organic matter, and slope can all affect pesticide transport. Conditions that slow rate of surface runoff and leaching will minimize stream contamination because a longer residence time in the soil provides more opportunity for volatilization, plant uptake, adsorption to soil colloids and organic matter, and chemical or biological degradation. Most currently labeled pesticides degrade rapidly and are available for overland flow for a short period (hours or days). Furthermore, in most forest soils, infiltration capacity exceeds most common precipitation intensities and overland flow rarely occurs. As a result, pesticide delivery to streams via runoff in forested settings is uncommon and water contamination is generally precluded.

Pathogenic Organisms

A broad spectrum of disease organisms can be transported by water. Of particular interest are waterborne pathogenic bacteria (e.g., *Escherichia coli*) and protozoal parasites (e.g., *Giardia* spp. and *Cryptosporidium* spp.) which can cause gastrointestinal illnesses in humans. Water samples are often tested for fecal coliform as an accepted surrogate for potential presence of pathogens. In general, there is a direct relationship between increased human and animal use of forested watersheds and concentrations of bacteria which indicate fecal contamination of water resources. However, most forest management practices with the exception of livestock grazing do not affect the occurrence of these pathogens directly.

Converting Farmland to Forestland

In cases where marginal farmlands (supporting either crops or pastures) are being converted to forestlands through afforestation efforts or simply through abandonment of the farmland, there is growing evidence that water quality improvements are likely to occur after the land use is altered. However, impacts of this type of conversion on water quality have received limited evaluation because there is limited documentation of comparisons between farmland and forestland on the same site. Net impacts on water quality depend on prior land use and crop management, current forest management practices, soil type, local hydrology, and climate. In general, conversions to forestland have the potential to reduce erosion and subsequent sedimentation (**Figure 8**), as

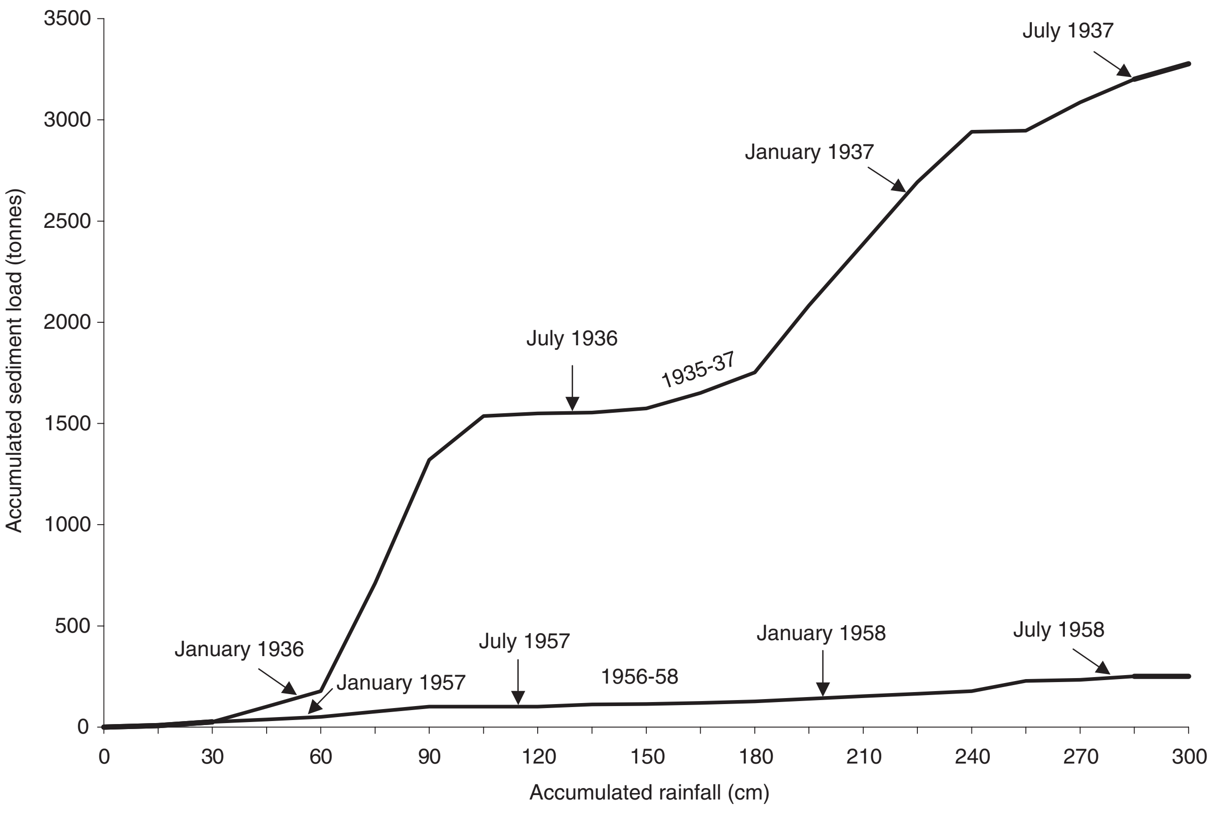

Figure 8 Cumulative sediment yields from White Hollow Watershed, Tennessee, USA, before and after reforestation. Adapted from Tennessee Valley Authority (1961) *Forest Cover Improvement Influences upon Hydrologic Characteristics of White Hollow Watershed, 1935–1958*. Report no. 0-5163A. Knoxville, TN: Tennessee Valley Authority.

well as reduce levels of dissolved nutrients and pesticides in surface runoff and groundwater. These improvements in water quality are a function of lower amounts of runoff and leaching as well as lower concentrations of potential pollutants that are expected to result from the conversion to forestland. For example, declines in quantities of runoff and leaching have been observed in response to increased interception and evapotranspiration occurring as forests become established. Increases in infiltration capacity also occur via increased litter cover, and resultant improvement in soil structure and porosity. Fertilizer and pesticide applications are eliminated or drastically reduced after conversion to forestland and thus, these potential sources of water quality degradation are eliminated or minimized. Establishment of new forests and sustainable management of existing forests are widely viewed as management practices that will improve or retain high quality water resources.

Soil Erosion Control

J Croke, University of New South Wales, Canberra, Australia

Introduction

Soil erosion control in managed forests is undertaken, and best achieved, for two main reasons. The first relates to soil protection for the sustainable productivity of the forest resource. The second relates to the protection of valuable water resources located in forested catchments. The potential impacts of increased soil erosion and the subsequent delivery of this material off-site, include a general reduction in water quality, adverse health effects on aquatic species, and an increase in the delivery of nutrients and sorbed chemicals to watercourses. This article discusses soil erosion control in managed forests from this twofold perspective. It uses a conceptual framework that emphasizes the link between on-site erosion and the subsequent delivery of this material off-site to the stream channel. The importance of adopting erosion control practices that encourage the reduction of surface runoff, and thereby off-site sediment delivery, is emphasized. The role and effectiveness of selected best management practices used in the control of soil loss and sediment delivery in forestry environments is also discussed within this framework.

General Principles of Soil Erosion

Soil erosion is the detachment and movement of soil by the physical agents of gravity, water, and wind.

The dominant agent of erosion in many forests is water, which describes the detachment of soil particles by raindrops and overland flow, and their transport and deposition as sediment. Water erosion is further categorized as rill, interrill, gully, and channel bank erosion. Rills, which may evolve to form gullies, are erosional features characterized by concentrated flow to a depth of <0.3 m (**Figure 1**). Interrill is the term used to describe the adjacent areas. As the hydraulic shear stress exerted by the flow in the rill is sufficient to overcome the binding forces between the particles, it is often seen as the primary detachment agent. The flow also acts to transport detached soil from both the rill and interrill areas. Detachment on interrill areas is primarily induced by raindrop impact, as flow depths are shallow and have limited erosive power.

The above forms of water erosion occur naturally in all environments, and can act singularly or in combination to determine the overall soil loss. Soil loss is defined as the amount of soil removed in a specified time period over an area of land that has experienced net soil loss (expressed in units of mass per unit area, $kg\,m^{-2}$). It is different to the other frequently used term, sediment yield. Sediment yield refers to a mass of sediment that leaves a boundary, such as the edge of a plot, bottom of a hillslope, or the outlet of a catchment (expressed in units of mass per unit area, $kg\,m^{-2}$ or $t\,ha^{-1}$, or total mass, kg). The sediment delivery ratio (SDR) describes the proportion of detached soil particles relative to the gross erosion of the basin that are delivered to a stream edge or catchment outlet. Mass wasting, although specifically not a form of erosion as it does not involve agents like wind or water, generates huge amounts of stream sediment and thus affects the SDR. Logging operations, especially clear-cutting, and the construction of cut-and-fill roads have been shown to affect the occurrence and frequency of shallow slips, which in some catchments dominate sediment delivery rates.

Key Factors in Soil Erosion Control

Much of the understanding of soil loss and the effect of various conservation practices is derived from research in agricultural areas. However, many of the factors remain the major determining influences of water erosion in other environments. One of the most commonly applied soil erosion models, the universal soil loss equation (USLE) incorporates the effect of factors such as soil erodibility (K), slope steepness (S) and length (L), rainfall erosivity (R), surface cover (C), and conservation support practice (P). These factors have been used in the USLE in the following factorial form;

$$A = RKLSCP \tag{1}$$

Only A, K, and R have dimensions. Rainfall erosivity (R) refers to the ability of rainfall to cause erosion. Soil erodibility (K) reflects a soil's ability to withstand the forces of detachment, a function of soil composition, and structure, and prevailing climatic factors, notably rainfall intensity and energetic loading.

Figure 1 Rills are regarded as the primary detachment agent in water erosion processes. Rill development can be exacerbated in forestry operations due to compaction and vehicular traffic on road and track surfaces. Photograph courtesy of estate of TC Whitmore.

Hillslope length (L) and slope (S) are expressed relatively to values from a standard 22.1 m and 9% hillslope used in the original experiments; cover (C) and conservation practice (P) vary between values of zero (full cover and conservation works in place) and 1 (no cover nor conservation).

Soil erosion strategies often aim to influence some of these factors, especially cover and conservation support, which are manipulated more effectively than topographic or climatic variables. Soil loss in many environments is managed, therefore, by controlling the rate of particle detachment through either maximizing surface cover or minimizing surface runoff. Surface cover management involves practices that aim to protect the soil from detachment by raindrops and water. Surface runoff reduction aims to minimize the accumulation of water into concentrated flows to reduce the detachment and transport of sediment in rills. Traditionally, on-site soil erosion has been managed through surface cover practices (e.g., mulching) and off-site soil erosion by reducing surface runoff (e.g., by terracing or bunding). However, large amounts of sediment cannot be moved off-site without sufficient discharges to transport this material. Surface cover management alone, for example, may reduce the erosional effects of raindrop impact but do little to reduce runoff accumulation, which may have a greater impact upon erosion processes both at a site and downstream in the catchment. This off-site delivery component of soil conservation is not well accommodated within empirical soil loss equations, which do not explicitly consider off-site sediment yield. Significant contributions from landslides and channel bank erosion are also not well considered in empirical approaches such as the USLE, although recognized to be major contributors to overall sediment supply in some cases. Research has highlighted the importance of sediment storage and redistribution which are often poorly represented in small plot scale studies of erosion. The deposition of sediment as runoff moves down the hillslope and in concavities has been recognized as an important, but largely unquantifiable component of the SDR. Spatial patterns of disturbance caused by logging, compaction, cover removal, and regeneration lead to complex patterns of erosion and deposition frequently leading to high rates of sediment redistribution within a compartment or hillslope but low overall rates of sediment yield. Our understanding of these processes and their contribution to catchment sediment yield is improved through larger scale plot studies incorporating sediment storage and redistribution terms together with the application of some sediment 'fingerprinting' techniques such as radionuclides that are used to trace the source and depositional history of sediment.

The following discussion of soil conservation practices in managed forests thus uses a conceptual framework that considers the need to conserve soil on-site both for the sustainable production of forests and for off-site water protection.

Soil Erosion and Forestry Operations

In pristine or undisturbed forests, soil loss due to the erosional effects of water, wind, and gravity is typically low due largely to the protective cover of abundant over- and understory vegetation, and, above all, a well-developed litter layer promoting infiltration of rainwater and the slowing down of any surface runoff that may develop. Soil loss is exacerbated by disturbances associated with tree removal. The opening or removal of forest canopies during harvesting or land clearing results in potentially large areas of bare soil being exposed to the erosional processes of raindrop splash, overland flow, and, under certain conditions wind (**Figure 2**). The extent of bare soil exposed to these processes understandably is greatly influenced by the nature of the logging operation, and varies significantly between selective logging and the more intensive clear-cutting operations. Some of the more commonly described, and somewhat universal impacts associated with logging include soil compaction, increased volumes of runoff, both surface and subsurface, and enhanced erosion. In some environments, the dominant hydrological regime will be dramatically altered due to compaction of the surface soil, in some cases changing subsurface dominated hydrological regimes to overland flow dominated regimes. Associated with these are corresponding

Figure 2 Canopy removal during harvesting exposes large areas of bare soil to the erosion processes of overland flow, raindrop splash, and wind. Photograph courtesy of LA Bruijnzeel.

reductions in soil permeability, soil fertility, and organic matter content.

Relative differences in the rate of soil loss are often the result of variations in the intensity of forest disturbances, quality of management and the prevailing climatic characteristics, notably rainfall erosivity. In both pristine and managed forests, rates of erosion and soil loss can be several orders of magnitude higher in areas characterized by high-intensity, short-duration rainfall events. Such intense rainfall events, typical of many lowland tropical environments, are characterized by large raindrop sizes that distribute high kinetic energy on impact, further exacerbating erosivity in areas of unprotected soil.

A recent advance in our understanding of water erosion processes in forestry environments has been recognition of the importance of the road and track network both in the generation and delivery of sediment (**Figure 3**). Forests roads and tracks are both a significant source of overland flow and sediment which if constructed and drained poorly often form a direct connection or pathway to the stream network. This coupling of the on-site erosion process with the subsequent delivery of the material off-site is a necessary advance in both the conceptualization and implementation of soil conservation practices in forests. Soil conservation practices should explicitly consider both the reduction of erosion on-site and the delivery of this material off-site through specific delivery pathways. Recognition of the importance of runoff-generating mechanisms in this process is paramount to the successful design of effective on- and off-site erosion control strategies.

Figure 3 Overland flow develops rapidly on compacted road surfaces that have infiltration rates in some environments as low as 1 mm h^{-1}. Photograph courtesy of A Malmer.

Runoff Production and Erosion Control

The first priority in designing effective erosion control strategies in managed forests is to develop an understanding of the dominant runoff production mechanisms and their potential alteration due to the harvesting regime. For example, infiltration-excess or Hortonian overland flow (HOF) is rare in undisturbed forests typically due to the generally very high infiltration capacity of the soil in most cases. In disturbed forest environments, overland flow generation, and especially HOF, is common because compaction from logging equipment and road building create areas of reduced hydraulic conductivity. Increased areas of compacted soil and altered groundcover due to timber harvesting and roading have been shown to alter hillslope hydrological processes, and overall catchment stream flows, to varying degrees.

Road surfaces may occupy less than 1% of the catchment area but contribute a disproportionate amount of water and sediment during low to moderate rainfall events. Infiltration rates as low as 1 mm h^{-1} have been reported on road surfaces which means that they respond very quickly to rainfall events and generate overland flow faster and in greater volume than other landscape surfaces. During long duration and higher intensity rainfall events, runoff contribution from other surfaces will be more dominant, simply because of their greater areal extent.

General harvesting areas (GHA) or logged hillslopes represent the largest land surface by area within a commercially logged forest. Although partially disturbed during selection harvesting operations, the retention of a high degree of forest vegetation contributes to reduced surface runoff accumulation and consequently limited sediment transport. Under such conditions, runoff generation on GHA is usually restricted to some Hortonian overland flow development, predominantly from bare or the more disturbed parts of the hillslope. Thus, widespread sheet flow is not common on the GHA and this is reflected in the relatively small volume of overland flow generated even under extreme rainfall events. Channelized flow in rills is also rarely reported within the GHA, limiting the ability of runoff to transport large amounts of sediment. A clear priority is to reduce the potential for run-on of overland flow onto these areas from the more disturbed and compacted areas. For example, runoff from tracks and roads which is discharged onto the GHA may increase the shear stress of the flow above some critical level and cause erosion of the surface soil layer. This will lead to rill and potentially gully development in these areas. In addition, increased runoff from compacted sources can contribute to the development of saturation-excess overland flow (SOF) on footslopes, in riparian zones, and other areas of near-surface flow convergence. The effective management of high runoff producing areas is paramount to the success of traditional on-site erosion control strategies. The hazard of managing high runoff production areas increases as the area of forest removed is increased, as is the case between a total clear cut operation compared with selectively logged slopes.

On-Site Soil Erosion Control

On-site control of soil erosion is designed to minimize the detachment and subsequent removal of soil from a range of disturbed land surfaces in a managed forest. There is a hierarchy of sediment sources in these environments ranging from the highly disturbed and compacted areas such as roads and tracks, logged hillslopes to the undisturbed streamside riparian areas (**Figure 4**). The greatest source of sediment in a managed forest is the road and track network, especially those used frequently by vehicles during logging operations. Logging tracks used by machinery during logging only and then often abandoned and regenerated tend to generate less sediment than primary roads. Sediment yields from logging roads show increases from twofold to 50-fold over background levels in undisturbed forests. As such, priority will be given here to discussing soil conservation strategies that may effectively reduce the generation and delivery of this material.

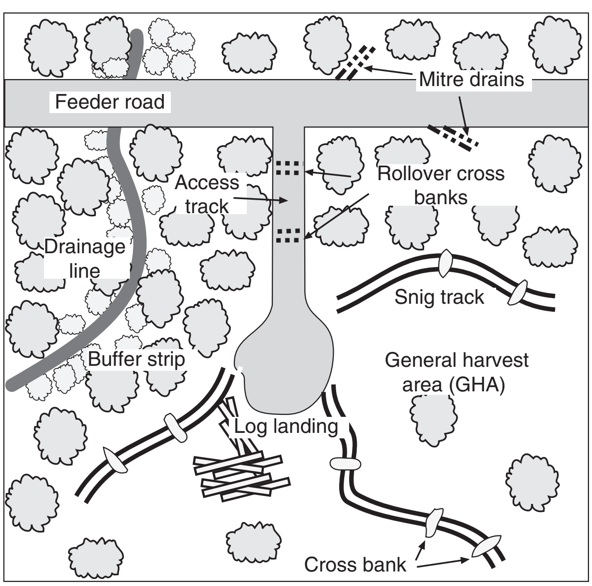

Figure 4 Range of sediment and runoff sources within a typical managed forest. Priority should be given to high runoff and sediment production areas such as roads and tracks.

Numerous strategies, including revegetation, graveling, regulation of use or traffic volume, and regular maintenance have been found to be successful in limiting sediment generation from forest roads and tracks. For example, the discontinued use of tracks and logging roads between cutting cycles is seen as a significant factor in limiting sediment availability for transport. The intensity of traffic usage is also seen as a key factor in the persistence of these areas as a sediment source (**Figure 5**). Sediment yields have been shown to decrease rapidly after road use is discontinued and logged areas regenerate (**Figure 6**). Road yields measured 5 years after logging produced less than five times the background values. Thus controlling vehicle access during wet weather conditions and limiting recreational use of roads in close proximity to streams should be considered integral to any erosion control strategies in the forest. The remobilization of previously deposited sediment during extreme events may pose a major problem in heavily disturbed areas, especially around hollow log culverts which tend to decompose over time.

The spacing of road drainage features is a key design variable for the effective management of overland flow on roads and tracks. Redistributing runoff at water bars or water diversion structures

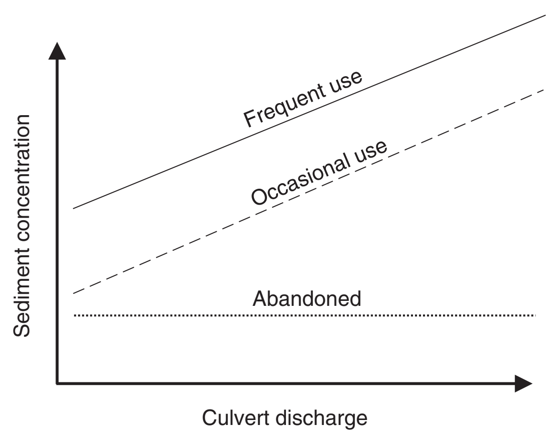

Figure 5 Generalized relationship between sediment concentration in road runoff and road usage. Well-used roads may have up to four loaded logging truck passes per day with lower-frequency traffic usage on the remaining use.

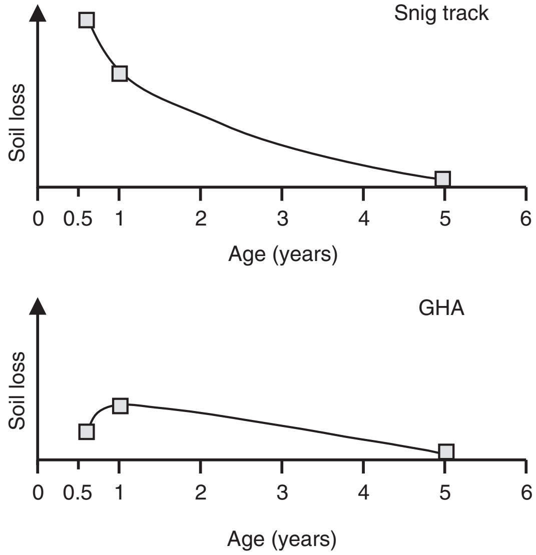

Figure 6 Generalized relationship between soil loss and time since disturbance typical of a humid temperate environment. Studies confirm the notable reduction in soil loss within a period of less than 5 years since harvesting. Erosion control strategies are essential in this period immediately post-logging when soil is exposed and natural regeneration has not occurred.

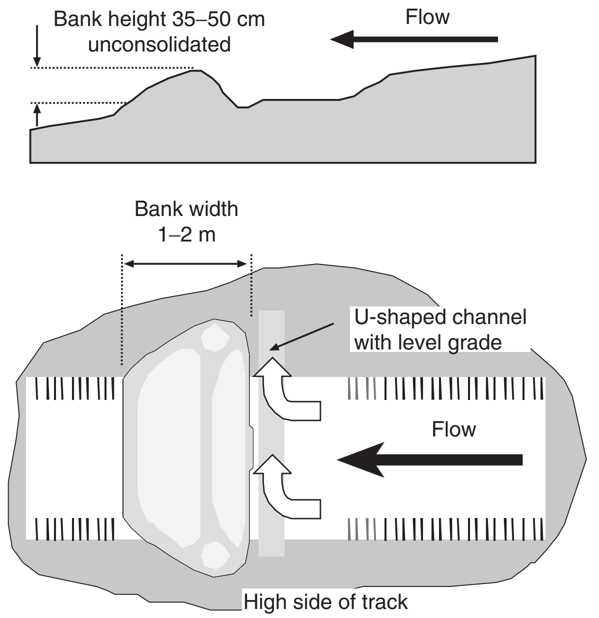

Figure 7 Construction of cross-banks or water bars at regular intervals along forest tracks is an effective control of overland flow development and sediment transport. These features do not need to be great tall mounds and are designed primarily to divert track runoff onto an adjacent hillslope so that roughness and cover can be effectively used to promote infiltration and sediment deposition.

along tracks immediately after logging is a successful method in reducing the contribution of water and sediment to streams, particularly during small to medium-size rainfall events (**Figure 7**). Design principles to guide the spacing of water bars and road drains have been developed based on maximum contributing track lengths and track slope (**Table 1**). Although not highlighted in the example provided in **Table 1**, rainfall intensity, frequency, and duration are important additional variables in determining the appropriate spacing of road drainage features for any given climatic area, but especially in tropical environments. The objective of these drainage features is to minimize the contribution of runoff and promote infiltration into the rough surface of the adjacent GHA. The high infiltration properties and roughness of these hillslope areas should be used as a natural erosion control strategy. The velocity and sediment transport capacity of runoff from tracks and roads passing through these areas will be reduced, promoting deposition and limiting sediment delivery to streams. Poor construction of these features can lead to the destruction of banks and water bars, especially under extreme rainfall events, resulting in catastrophic consequences for sediment supply and delivery.

Another important design variable is the position of the drainage outfall point in the landscape. For example, a culvert discharging into a stream head or first-order stream (gully) will greatly increase the impact of road runoff and sediment on the stream (**Figure 8**). In contrast, if a culvert directs road runoff onto a large divergent slope, surface erosion will be minimized, thereby reducing sediment delivery to the stream. In some instances, however, prevention of concentrated runoff on hillslopes at culvert outlets will also require implementation of protective measures such as masonry, grassed waterways, stone drops, etc. to provide resistance to scour at the culvert outlet.

Surface cover management provides an effective measure for the reduction of erosion and soil loss. Numerous studies confirm that surface cover of between 30–50% is effective at significantly reducing soil erosion processes at a site (**Figure 9**). There is also the potential to use effective time management in the harvesting process or provide artificial cover (e.g., straw bales, grass seeding) to protect more disturbed or bare areas until natural regeneration occurs. Natural or artificial regeneration procedures such as ripping or plowing up and fertilizing log landings have been used successfully to enhance the return of roughness and surface cover in these bare areas.

Off-Site Soil Erosion Control

Controlling the generation and delivery of sediment and attached nutrients is an important process in

Table 1 Example of road drain spacing guidelines, giving distance (m) between drainage structures varies with road travelway slope and the gradient of the hillslope at the discharge point. This table is developed for a forested catchment in Australia and can not be applied in other environments

Figure 8 Erosion of the hillslope at road drainage outlets is a significant contributor to off-site sediment delivery in forested catchments. Large volumes of overland flow from road surfaces are discharged at single outlet points, often causing increased shear stress and the development of rills or gully erosion. These features form efficient transport pathways to streams enhancing the risk of off-site impacts to water quality.

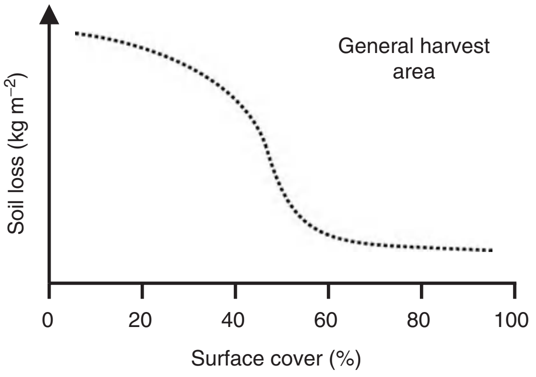

Figure 9 Generalized relationship between soil loss and surface cover. Most studies confirm that surface cover of >50% is sufficient to reduce surface erosion.

minimizing off-site impacts of forestry operations. The most effective measures of reducing sediment delivery for off-site protection in forestry environments include:

1. Reducing the volume of overland flow.
2. Minimizing direct connectivity of sediment sources with the stream network.
3. Promoting vegetative filtering.

Volume of Overland Flow

Reduction of the volume of overland flow can be achieved by reducing the contributing area of disturbed surfaces draining to a particular point in the landscape. This is effectively managed through conservation planning and practices that limit the size of harvesting coupes or include some strategy for alternate-coupe or patch harvesting. Likewise, adequately planned and constructed road and track drainage plays a key role in minimizing the volume of overland flow generated from compacted surfaces.

Minimizing Connection of Sediment Sources with Streams

The term connectivity is now commonly applied to describe the level of interaction between disturbed areas such as roads and tracks and the stream. There are a variety of degrees of connectivity that express whether a sediment source is fully or partially connected to the stream. For example, a road network is fully connected to a stream at a stream crossing or when there is a continuous gully that extends the full length from the source to the streams (**Figure 10**).

Opportunities to reduce overland flow through vegetated hillslope areas and streamside buffer strips are plentiful in forested catchments, as long as gully erosion does not occur. Runoff from roads and tracks can disperse in vegetated areas where flow is not concentrated and shear stresses remain low. The risk of gully development is increased as a result of poor road and track drainage and this should be avoided where possible. Once initiated, gully erosion is difficult to halt and these features then effectively bypass the potential filtering effect of vegetation in reducing runoff and sediment fluxes.

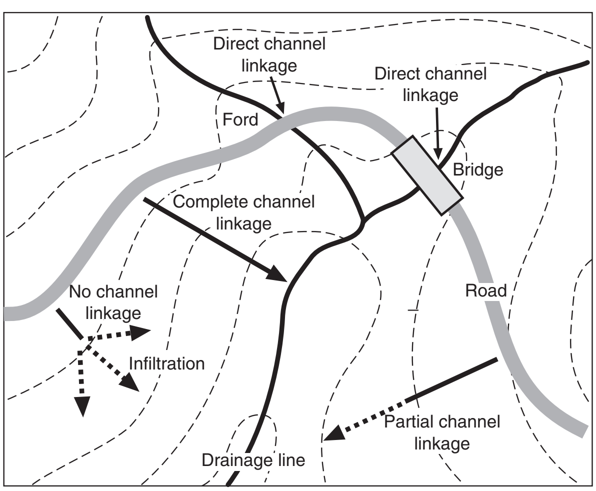

Figure 10 There is a range of degrees of 'connection' between sediment sources such as roads and receiving waters. Sources may be fully connected to a stream, as occurs at stream crossings or where a gully has formed at a road drainage outlet. Partial or nonconnected pathways also exist. Direct connection between a sediment source and stream should be avoided by appropriate planning of road location and drainage.

Connection between sediment sources and the stream can also be minimized by appropriate road and track planning. Minimizing the number of stream crossings by the location of roads along ridge-tops is preferable to the distribution of roads along valley bottoms where the distance to streams is short. The procedure of uphill yarding or snigging is also a key measure in minimizing connection between compacted surfaces, sediment sources, and the stream. This encourages the location of roads and tracks away from the streams and results in a downslope divergence of the associated skidder track pattern.

Vegetation Filtering

Riparian or streamside vegetated zones are recognized worldwide as having a key role in moderating the impact of land use on stream water quantity and quality (**Figure 11**). Riparian zones have several functions and the emphasis placed on each of these functions depends on a wide range of environmental and organizational issues. This riparian zone or buffer strip has a range of functions including maintaining the stability of the stream channel, providing riparian habitat and a long-term recruitment of woody debris, regulating light and water temperature in the stream, and acting as a vegetative filter for runoff between the areas of disturbance and the stream network. This final function may be considered as the last line of filtering as sediment generated on roads, tracks, and other compacted areas frequently pass through the general harvest areas prior to entering the buffer strip.

In terms of their sediment trapping ability, riparian zones have several characteristics that encourage deposition. Riparian zones are normally characterized by a very rough soil surface, often with an intact litter layer. Hence, the soil is porous, with many macropores; and the rooting zone is frequently deep. Sediment deposition occurs as a result of a decrease in flow velocity and volumes as the flow moves into areas of relatively high infiltration and dense vegetation. The very porous nature of the undisturbed riparian zone soil assists in this process, although the presence of a wet zone from a water table may inhibit total sediment deposition. Nevertheless, the surface roughness of the riparian zone continues to aid in trapping sediments even if saturated.

Overall, the literature confirms that vegetated areas perform well in relation to sediment deposition. Consensus on their ability to trap the very fine-grained silt and clay material under certain

Figure 11 Location of riparian or buffer strips along streams in a logged catchment. Vegetative filtering as runoff passes through these areas, often demarcated a set width from a major watercourse is an effective control strategy for reducing sediment delivery to streams.

hydrological conditions is less conclusive. The ability of the buffer strip to reduce the volume of overland flow by infiltration processes is sensitive to the prevailing hydraulic properties of the area and to the moisture-holding properties of the soil. Streamside buffer strips may also act as runoff sources themselves due to rising groundwater levels in wet areas immediately adjacent to the stream. The trapping of very fine-grained material is likely to be highly dependent upon runoff infiltration mechanisms within the buffer strip.

Soil Erosion Strategies for Off-Site Protection

Several best management practices (BMPs) are used in forestry operations to mitigate the potential impacts of logging on stream ecology and water quality. Some of the more universally applied practices include the use of riparian buffer strips, patch harvesting, siting and design of roads and road crossings to minimize sediment inputs, and restrictions to logging activities in relation to slope and soil type. There is little doubt that the effective implementation and construction of these practices can significantly reduce sediment delivery to streams in managed forests. While the positive effect of catchment-scale BMPs has been widely observed, the relative contribution of specific on-site practices is rarely reported. However, there are two erosion control strategies that are imperative to reducing off-site delivery of sediment in forested catchments. These are:

1. The standard implementation of an undisturbed vegetated area adjacent to the stream network.
2. The proper planning of the road network to avoid source-to-stream connectivity.

Riparian or buffer strips in forests Forest management practices in many countries are now obliged to leave an undisturbed vegetated buffer strip immediately adjacent to the majority of streams and drainage lines (**Figure 11**). The placement and width of buffer strips in catchments is a contentious issue due to potential economic loss of harvestable timber from streamside reserves. There are two possible approaches for locating buffer strips to mitigate the inflow of sediment and associated pollutants from the upslope areas; one is based on determining appropriate sediment transport distances through the buffer strip; and the other is predicated on protecting wet areas in the landscape as these are more liable to overland flow generation through saturation excess from rising water tables during rainstorms. In the case of the former, a 30 m buffer is typically regarded as effective in trapping most of the sediment from cleared areas, although absolute width is dependent upon specific site. In general, significant impacts of logging are more likely to occur where buffer widths are less than 30 m. However, the application of a universal buffer width remains a contentious issue as large parts of the forest resource can be locked away. For example, in many upland situations with high rainfall, drainage density is so high that the blanket application of 30 m buffer zones severely limits the area available for commercial logging.

Road planning and position Given the recognized importance of the road network in both the generation and delivery of runoff and sediment, emphasis should be given to these areas during the planning stages of forest harvesting. The connectivity concept as outlined above (**Figure 10**) provides a useful conceptual framework for forest managers to incorporate with other factors such as economical and topographic constraints. Maximizing the distance between the road and track network can be readily accommodated at the planning stage through the location of roads away from streams and by yarding the logs uphill (**Figure 12**).

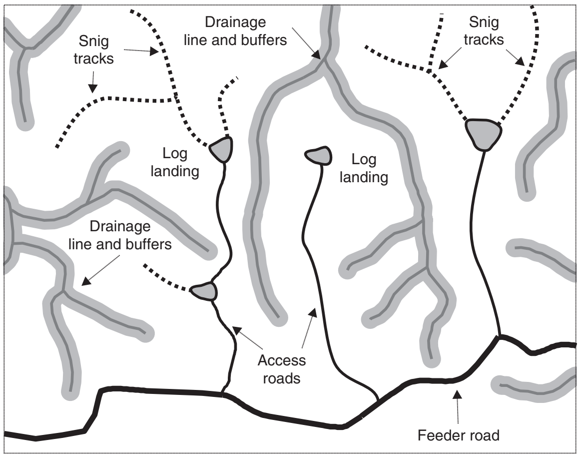

Figure 12 Road network in a logged catchment. The distribution of road networks throughout the catchment is best achieved during the planning phases where roads can be located along ridge-tops or at maximum distances from the stream. Uphill skidding and yarding is to be strongly encouraged as it results in a network of tracks that are divergent and away from the main stream network.

In many countries, forest managers are dealing with the legacy of an old road and track network that was constructed relatively close to the stream network. Rehabilitation of these surfaces or their removal from the catchment though expensive rehabilitation programs has been adopted in some countries. Ideally, many of the best strategies to minimize the potential for off-site impacts should be considered at the forest planning stages and optimum decisions made regarding the location and rehabilitation of these surfaces during the post-logging phase.

Summary

The understanding required to implement effective soil conservation strategies to manage surface erosion now exists. In many countries, harvesting and vegetation clearance is taking place at an alarming rate and the conservation and protection of many forest environments, and the associated water resources, are in jeopardy. Traditionally erosion control strategies have focused only on minimizing the detachment of soil particles through approaches such as surface cover management and runoff minimization. This review has examined both the generation and delivery of sediment in forests with a view to protecting the sustainable use of forests for future generations and the water resources located in these catchments. Effective erosion control strategies must be approached with this twofold objective in mind. Priority should be given to high runoff and sediment producing areas such as roads and tracks in both the planning and protection phases of forest harvesting. The combined beneficial effects of BMPs such as maintaining riparian buffer zones, the proper planning and construction of roads, and patch harvesting are now widely reported. The principles and processes for managing sediment delivery in forestry environments are basically understood. The effective implementation of these practices is thus often limited by economics or political pressure. Continuing development of practical and economical forest code prescriptions should be an ongoing focus of erosion research in forestry environments.

Snow and Avalanche Control

M Schneebeli and P Bebi, WSL Swiss Federal Institute for Snow and Avalanche Research, Davos, Switzerland

Introduction

Snow has a strong effect on the hydrology of forests. In contrast to rain, much more snow is intercepted by the branches and temporarily stored on the forest floor. Snow also modifies the radiation balance of trees. Snow–forest processes are much more complex and important due to the increased three-dimensionality of trees than in open land (**Figure 1**). Management practices can strongly influence the snow storage capacity of forest, and therefore significantly contribute to runoff and runoff timing. This is especially important where water from mountains is used for irrigation and water supply (e.g., the Sierra Nevada in California, southern slopes of the Himalayas). Another locally very important effect in mountain regions concerns the prevention of snow avalanches. The preventive effect of forests on the formation of snow avalanches was recognized in different Alpine regions in Europe as early as the Middle Ages. By then, the intensified logging and clearing of mountain forests for timber and the creation of pastures had caused the formation of new starting zones and avalanche paths and required the relocation of farms and primitive measures for the protection of buildings. In addition, mountain forests were protected and declared untouchable by decree of local authorities. The physical processes underlying the formation of snow avalanches and the most effective ways of reducing their occurrence and intensity were investigated more intensively in the latter part of the twentieth century, mostly in the European Alps and the Rocky Mountains. The effect of forests on avalanche formation is limited; forests are unable to stop avalanches as soon as their size exceeds a few hundred square meters. In fact, avalanches carrying trees in their debris often cause larger damage than 'clean' snow avalanches. In this article an overview is presented of forest–snow relationships, which are important for the understanding of the hydrology of forests in regions where snowfall occurs, and snow avalanche formation in forested areas. In addition, the implications for forest management with respect to snow hydrology and avalanche protection are discussed briefly.

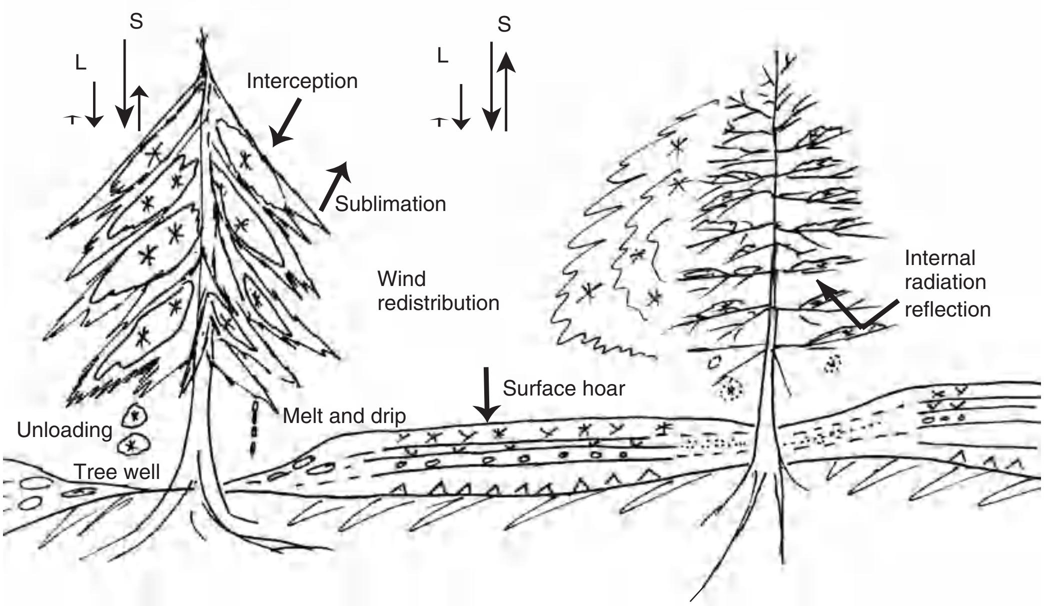

Figure 1 Processes in a snowy forest. The snow precipitation is unevenly deposited. Part of the snow is retained by interception on the trees, and later unloaded by mechanical shaking, melting and dripping as water, redistributed by wind, or sublimated back into the atmosphere. The intensity of these processes depends on weather and tree species. Incoming and outgoing shortwave solar radiation (S) and longwave radiation (L) depend on tree species, amount of interception, and topography. This modifies the condition for snowmelt and snow metamorphism.

Forest–snowpack Interactions

Snow changes the climate of a forest in winter and early spring through its high albedo and energy storage capacity (**Figure 2**).

Snow as the solid phase of water is stored at the surface of the forest floor, and because of the high energy necessary to melt it, its release as liquid water is delayed. These properties can be used to influence regional hydrology by specific forest management schemes. Snow deposition occurs in a forest at different heights and intensity, leading to a snowpack that varies spatially in terms of depth and water equivalent. Snow depth normally decreases with decreasing distance to the stem. Snow depth and water equivalent are usually higher beneath deciduous trees compared to coniferous species. In dry winter climates up to one-third of the intercepted snow is sublimated, thus reducing the amount of water available for melting in spring. Clearings with a diameter of up to seven times the height of the surrounding trees can increase the water equivalent of the snowpack, with maximum values around two to fives times tree height (**Figure 3**). However, the effect of wind erosion and redistribution of snow in alpine terrain can completely invert this behavior, such that the water equivalent of snow deposited in a spruce forest is 120% compared to that in shrub tundra.

The main effect of trees and forests on avalanche formation is through the modification of the snow's mechanical properties. Relevant processes include the interception of falling snow by the trees, the modification of the radiation and, therefore, temperature regimes beneath and around the trees,

Figure 2 Snow-covered branches of a spruce (*Picea* sp.). Solar radiation reflected by the highly reflective snow surface is absorbed by the dark underside of the branches, causing higher temperatures and melting or increased sublimation from the bottom.

and the reduction of near-surface wind speeds. External topographic factors are slope aspect and steepness. Direct support of the snowpack by tree stems is relevant in the case of dense forests and especially snow gliding. Continuous snow layers of low internal mechanical strength often show preferential fracture planes that favor so-called slab avalanche formation. The formation of such unstable layers is reduced in forests through the processes and factors mentioned earlier, i.e., snow interception (reducing the amount of snow reaching the ground) and the moderation of the radiation regime (reductions in both incoming shortwave radiation and outgoing longwave radiation), but also by increased unloading of intercepted snow from the trees by wind.

Snow Interception

Interception of falling snow by the branches of the trees is usually followed by partial unloading in the form of irregular lumps of snow caused by warming and wind. This tends to result in a highly irregular snowpack around the trees. The direct effects of this are typically visible within a distance of about 1.5 times the crown projection (see **Figure 4**). Such tree-induced disturbances of snowpack layering are most pronounced below evergreen trees; the effect is less visible in the case of deciduous trees which tend to intercept less snow due to their much reduced trapping capacity in winter. The overall stability of the snowpack as determined by mechanical tests is similar, however, between snowpacks in evergreen coniferous and deciduous forest.

Radiation

The energy balance within a forest is very different from that in the open. Both amounts and duration of solar radiation are much reduced beneath a tree cover whereas outgoing longwave radiation (mostly at night) is reduced as well (see **Figure 1**). Snow has a strong effect on the reflection of incoming radiation, as it is almost perfectly reflecting in the visible part of the spectrum and represents a near-perfect black body in the thermal infrared part of the spectrum. The associated fluctuations in surface temperatures cause the rapid formation of surface hoar frost in open fields. Surface hoar frost is a major cause of slab avalanche formation because this type of snow crystal is very brittle and can fracture after later burial by new snow. Surface hoar (and therefore slab avalanche formation) is much less probable in forest where fluctuations in snowpack surface temperatures are much more moderate because of the shielding effect of the canopy.

Wind

Wind is a major factor in the formation of avalanches in open areas through snow redistribution. Even the presence of rather open forest already causes a significant reduction in wind speed such that only minor relocation of snow occurs. This results in a more homogeneous distribution of the snow, and prevents extreme accumulation in gullies and depressions, as tends to occur in open areas.

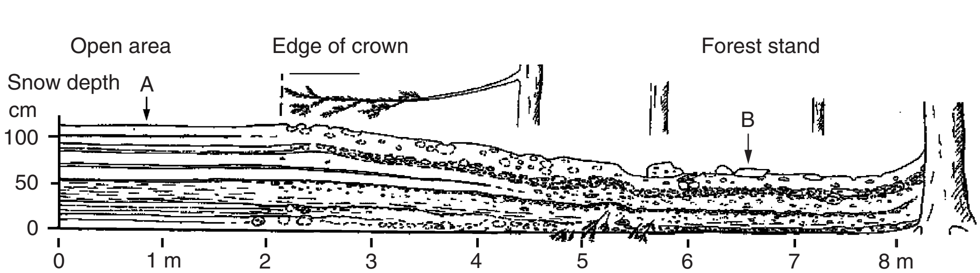

Figure 4 Snow profile in the forest. Reproduced with permission from Imbeck H (1987) *Schneeprofile im Wald*, Winterbericht Eidgenössisches Institut für Schnee- und Lawinenforschung 1985/86, no. 50.

Forests and Avalanche Control

Avalanche formation is also intimately linked to terrain features, notably slope exposure, steepness, and surface roughness. Trees and the associated modifications of the various physical processes described above form an additional modifying element compared to open, non-wooded slopes.

Terrain: Slope Angle, Aspect, and Roughness

A necessary condition for snow avalanche formation is a slope gradient exceeding 20°. In the Swiss Alps, avalanche formation on forested slopes has only been observed on slopes exceeding 30°. This value is probably valid worldwide, as the underlying mechanical processes will be similar. Slope aspect is especially relevant for the type of avalanche that occurs. Wet-snow avalanches occur mostly on sun-exposed slopes, while dry slab avalanches have only been observed on shaded sites. The frequency of avalanche releases is also higher on convex slopes (which tend to become steeper as one goes downslope) than on concave slopes where gradients generally decrease going downslope.

The roughness of the terrain underneath the snowpack is decisive for the occurrence of snow gliding and subsequent wet-snow avalanches. Grassy, abandoned meadows are especially prone to snow gliding. Fallen logs, remnant stumps of logged or snapped trees, root plates of upturned trees, and large rocks can all prevent the formation of small avalanches, but not extreme ones. Such surface features also promote regrowth by preventing subsequent mechanical damage by new avalanches to the young trees, and by providing favorable microsites for tree seedling establishment.

Effect of Forest Structural Properties

The density of a forest cover (both in terms of the number of trees per hectare and percentage canopy cover) and the size and distribution of forest gaps are often regarded as the chief forest structural parameters influencing the triggering of avalanches in forested areas. Although quantitative data on the minimum size for this 'gap effect' to happen are scarce, a first estimation of the quantitative relationships between stand structural and topographical variables may be derived from pioneering work conducted in the Swiss Alps. **Figure 5** shows the relationship between gap width and crown cover density for different categories of slope steepness based on a multivariate analysis of 112 avalanches triggered in coniferous forests in Switzerland. As gap width increases, the neighboring forest has to be increasingly dense so as to decrease the risk of avalanche formation. For a crown cover density of 60%, which is typical for subalpine forests in the Swiss Alps, a minimum gap width of approximately 20 m is expected to be sufficient to enable the triggering of avalanches on a 35° forested slope. When crown cover density decreases below 35%, the minimum gap width decreases to 10 m (see **Figure 5**).

Other important variables for avalanche control include gap length and the distance between the starting point of an avalanche in an open area and the nearest downslope forest edge. In contrast to gap width and crown cover density, which control the microclimatic influence of the forest (cf. **Figure 1**), these distances also affect the speed and, therefore, the destructive force of an avalanche. Generally avalanches with acceleration distances of more than 150 m cannot be stopped by forests, and the trees will be destroyed (**Figure 6**). For shorter acceleration distances, the efficiency of the forest's resistance to

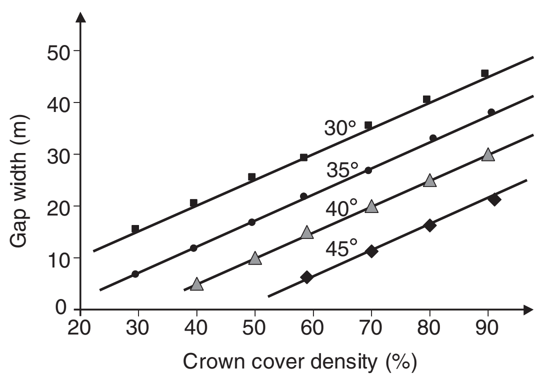

Figure 5 Relationship between critical gap widths and crown cover densities for the triggering of avalanches for different categories of slope steepness. The correlations are based on a multiple linear regression model of 112 avalanches in subalpine coniferous forests of Switzerland. R. Pfister, Swiss Federal Institute for Snow and Avalanche Research, unpublished data.

Figure 6 The devastating effect on a forest caused by an avalanche starting high above the tree line. Photograph by Swiss Federal Institute for Snow and Avalanche Research.

disturbance and the resulting degree of damage are mainly a function of slope angle, avalanche size and capacity, and the distribution and size of the trees.

Stand structural requirements for the triggering of avalanches in forests differ between evergreen forest types (mostly conifers) and broadleaved forests (mostly deciduous). The minimum gap widths required for avalanche formation are smaller in deciduous broadleaved forests. For example, in beech (*Fagus*)-dominated forests in the European Alps, a gap width of 5–10 m may already reduce the forest's snow interception capability below a critical threshold (see **Figure** 7). However, in contrast to the general perception, deciduous coniferous trees, such as larch (*Larix* spp.), are almost equally effective when it comes to preventing avalanche formation as are evergreen coniferous trees (spruce, fir), as long as stand densities are comparable. Deciduous trees are less effective in reducing avalanching than evergreen trees when the temperature during snowfall is lower. Under such conditions the snowflakes do not stick to twigs without needles.

Open-structured forests, which are more susceptible to the triggering of avalanches, are often more frequent at higher elevations and near the timberline. This is particularly valid in the case of coniferous forest in the northern hemisphere, where scattered, single trees and small clusters of trees tend to dominate in the subalpine timberline zone. Elsewhere, dense broadleaved forests (such as the *Nothofagus* forests in New Zealand) may continue all the way up to the timberline whereas under dry montane conditions open forests may form well below the temperature-controlled timberline (e.g., *Pinus ponderosa* forest in the Rocky Mountains).

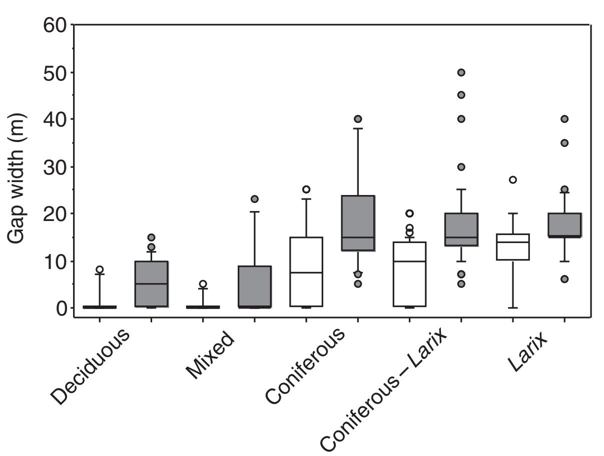

Figure 7 Interactions between gap width, forest type, and occurrence of avalanches starting within the forest. Solid bars indicate range of gap width in observed starting points. Open bars: range of gap width in control plots without avalanche release. Reproduced with permission from Schneebeli M and Meyer-Grass M (1992) Avalanche starting zones below the timberline: structure of forest. In *Proceedings of the International Snow Science Workshop*, 4–8 October 1992, Breckenridge, CO, pp. 176–181.

Stand properties related to avalanche control are permanently changing and may be altered dramatically after natural disturbances (extreme wind, landslides, avalanches, forest fires) or human intervention (mostly logging). The relevance of such disturbances in altering the forest's potential for avalanche control is dependent on: (1) the size and intensity of the disturbance, and therefore the degree of destruction, (2) the ability of remnant trees to maintain sufficient surface roughness, and (3) the time required for the establishment of a new effective forest cover.

Management Implications

In mountainous regions, the protection of human settlements against avalanches is often considered to be the most important forest function. When discussing management implications we therefore have to differentiate between cases where the forest fulfills such a protective function (German: *Schutzwald*), and where management should aim mainly at increasing forest water retention or timber production.

In a *Schutzwald*, the following measures may be applied to improve or support the protective role of forests with respect to the reduction and prevention of snow avalanches:

- silvicultural measures relating to the intensity and method of timber harvesting, and reforestation of open or deforested spaces
- structural measures including all kinds of engineering works like wooden avalanche defense structures (**Figure** 8)
- hazard mapping (as a base for land-use planning) on the basis of slope steepness, aspect, surface roughness, and tree cover
- organizational measures (early warning systems, forecasting of heavy snowfall or sudden increases in temperature, temporary road closure).

The practical importance of these measures is strongly related to population and infrastructural densities. Silvicultural and technical measures to improve avalanche control have a long tradition in steep, densely populated areas such as the European Alps, but such measures become less important in sparsely populated areas or where much damage may be avoided by the proper planning of settlements, roads, and other infrastructural works. In avalanche protection forests on very steep slopes, silvicultural measures generally aim to avoid the (persistent)

Figure 8 Avalanche starting zone in a gap within the forest protected with wooden defense structures in the Taminatal, Switzerland. The design life of such temporary wooden constructions is at least 50 years and allows time for young trees to become well established.

occurrence of large gaps and open forest. However, because natural regeneration in mountain forests often requires openings with sufficient light availability, optimal silvicultural measures for avalanche protection are often difficult to establish and time-consuming to execute. Where natural tree regeneration is too slow to guarantee a protective effect or is impeded by unfavorable microsite conditions, silvicultural treatment may have to be complemented by temporary or permanent technical support structures. Furthermore, as labor and material costs continue to rise, silvicultural and technical measures in remote mountain forests are gradually becoming less cost-effective. It is therefore inevitable to restrict such measures to the most critical areas and combine them with organizational measures wherever possible to achieve maximum effect against minimum expense. Logs lying about and upturned root plates often enhance the protective effect of a forest by increasing the overall roughness of the terrain and by providing favorable microsites for subsequent tree regeneration. Management strategies, both in disturbed and intact avalanche protection forests, should therefore rely more on naturally occurring forest dynamics and stimulate the inclusion of areas without silvicultural intervention in the planning process.

Storage of snow and therefore increased water retention of a forest can be optimized by limiting the size of any clear-cuts to about five times the tree height or by favoring a forest structure with variable heights. While these requirements are always fulfilled in the variously aged stands that are considered optimal for *Schutzwald*, this kind of management is rarely introduced where timber production is considered more important.

Forest Inventory and Monitoring

M Köhl, Dresden University of Technology, Tharandt, Germany

Introduction

Decision-making processes require sound and reliable information. This assertion is well borne out in forest science, indeed in the practice of forestry, where decision-making must rest on many sources of information, all of which ultimately recognize the need to manage forestry resources wisely over long periods of time. Forest inventory and monitoring is an essential means of obtaining this information and is a basic component of the cycle of procuring information, decision-making, and control of operations.

Forest inventories offer a bundle of instruments, which provide decision-makers with a wide range of sound and reliable information concerning the forestry sector. Forest inventories utilize expertise from different fields such as sampling theory, surveying, information technology, remote sensing, geographical information systems, mensuration, or modeling.

In the following article a general introduction to inventory and monitoring forests will be given. This overview covers inventory concepts, attributes assessed, data sources, categories, and work phases of forest inventories.

Inventory Concepts

Sampling Designs

Due to cost and time constraints a full tally of forests must be ruled out and is generally replaced by sampling techniques. The use of statistical sampling techniques can be traced back to a period in the early nineteenth century that also witnessed the formation of statistical societies in Europe and North America. About 150 years ago the Danish forest service conducted a nationwide census of forests, which can be seen as the first national forest survey. About 1850, Brandis introduced strip surveys in Burma at 5% intensity for inventory and management. Linear strip samples were used in Sweden as early as in the 1840s. In the 1920s Swedish forests were assessed at a national level by measuring strips from the coast to the Norwegian border across the country and deriving estimates for the entire nation.

In the eighteenth and the beginning of the nineteenth century methods were developed that were based on the visual assessment of forest stands. In the nineteenth century a shift from fuel-wood to high-quality timber production forced a change in monitoring methods. Visual assessments were replaced by measurements and censuses of the quantity of standing timber. The German forest commissioner Schmidt wrote in 1891:

> *Unfortunately is this assessment method (i.e. the census) especially in dense stands time consuming and expensive, and one replaces it often and with pleasure by the plot assessment method. It is a known fact that hereby a conclusion is made from a part of the stand to the entire stand.*

Schmidt notes that the (rectangular) plots should be placed in those parts of the stand which represent the entire stand. According to Schmidt it is difficult to decide which plot design is suitable in heterogeneous stands to represent the entire stand, and that one can solve this 'embarrassing situation' by selecting several plots in different parts of the stand. He concludes that 'one comes the closer to the truth the more plots are selected.' In spite of a knowledge of statistical theory, Schmidt utilizes two major principles of sample survey: representativeness and replication.

As the tools of statisticians to collect, analyze, and draw inferences from data continued to expand in the twentieth century, forest research moved along to set statistical principles in the framework of forest resource assessments and to use those tools to understand better both the ecology of forests on local, regional, and global scales, as well as the environmental impact of forest management at these scales. In the 1930s sampling of forests started in North America. A lack of forest maps and limited knowledge about extensive forest resources gave rise to inventory techniques that were very different from those used in Europe at that time. Survey sampling in a sound statistical manner was first reported by Hasel in 1942.

A driving factor in developing sample-based inventory systems was the need to provide for cost-efficient methods for forest resource assessments. The general principle of sampling is to select a subset of elements (i.e., a sample) from a population, to measure this subset intensively, and to draw inferences from the sample to the entire population (**Figure 1**). Statistical theory is applied for the selection process by assigning each population element a (known) selection probability. The selection probability is then utilized for the inference process.

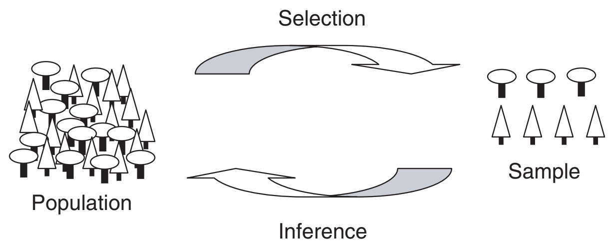

Figure 1 The concept of statistical sampling.

An outstanding number of sampling designs for natural resource assessments has been presented in the literature. They can be divided into two main groups: (1) sampling designs without utilization of auxiliary information, and (2) sampling designs utilizing auxiliary information. In sampling designs without auxiliary information, only observations on the attributes of interest that are obtained from population elements selected by the sample are used for inference. As, apart from the sample, other information about the population is often available or can easily be obtained, e.g., from aerial photography or satellite imagery, designs have been developed in which such information is used in estimation procedures. As a rule, sampling designs with auxiliary information are more efficient than those without. The major types of sampling designs with and without auxiliary information are presented in **Figure 2**.

Sampling Units

Before selecting a sample the population must be divided into parts that are called sampling units. The sampling units applied in forest resource assessments are single trees only in exceptional cases. In order to reduce assessment efforts and costs, groups or clusters of trees are selected. The clusters can be formed by selecting at each sample location a fixed number of trees (so-called nearest-neighbor or *n*-tree methods), or all trees that are located within an area of fixed shape and size, i.e., circular, squared, or rectangular plots (**Figure 3**). These alternatives assign a constant sampling probability to each tree. Typical plot areas are between 100 and 700 m^2. As stand density is related to tree size, large-area plots can result in

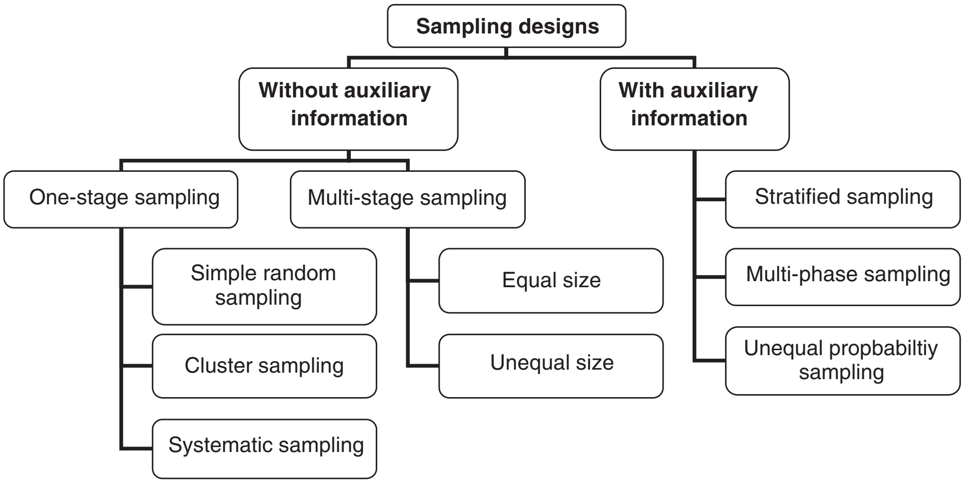

Figure 2 Sampling designs.

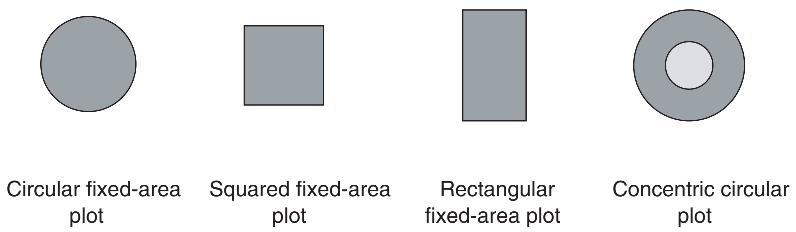

Figure 3 Fixed-area plots.

situations where a large number of trees (e.g., >100 trees) with small dimensions are located on a sample plot. To reduce the number of selected small trees and to increase cost-efficiency, concentric plots can be applied; these are a cascade of plots with different areas. On the smallest plot all trees are selected while for the larger plots only trees with larger thresholds of minimum diameter at breast height (dbh) are considered. For example, the Swiss national forest inventory utilizes two concentric sample plots with sizes of 200 m^2 and 500 m^2. On the smaller plot all trees are selected while on the larger plot only those trees with a dbh above 35 cm are selected.

Where the sampling probability of a tree is proportional to some tree attribute, the selection incorporates unequal probability sampling, e.g., probability proportional to size (PPS) or probability proportional to prediction (PPP). The most widely used unequal probability sampling approach in forest inventories is point sampling (also known as plotless sampling, angle count sampling, or Bitterlich sampling), where trees are selected with a probability proportional to their dbh (**Figure 4**). The selection procedure is realized by viewing all trees visible from a randomly chosen sample point within a forest by a constant angle. Those trees appearing larger than the constant angle are selected as sample trees. As a tree with a large dbh can be further apart from the sample point to be included in the sample (i.e., appears larger than the constant angle) than a tree with a smaller dbh, the procedure assigns a sampling probability proportional to the size of the dbh.

The selection of the optimal sampling design for a specific assessment program is an iterative process that is driven by the required information needs, the available resources, cost-efficiency, and the desired reliability of the information to be provided.

Monitoring Change by Sampling at Successive Occasions

The idea of describing the development of stands through permanent observations and thereby controlling the sustainability of forest management was born in the nineteenth century. In the 1930s, sampling methods, known as continuous forest inventory (CFI), were developed which were based on repeated measurements of a set of sample plots. With the CFI method, all sample plots, which are measured at the initial occasion, are measured again in successive inventories. Changes can be quantified by calculating the difference of estimates on two successive occasions.

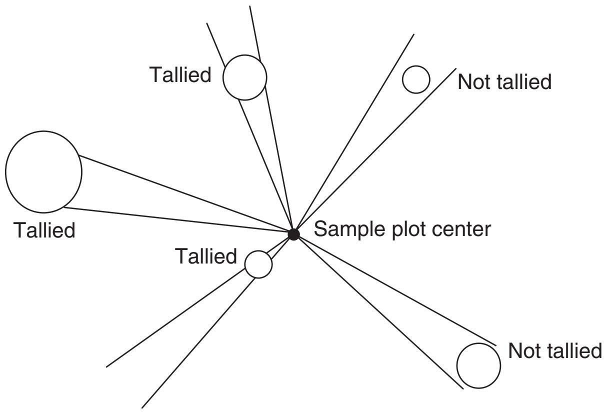

Figure 4 The principle of point sampling.

Remeasured plots are called permanent plots and are established at the first occasion by registering the plot location as well as the position of the trees inside the plots. Permanent plots can be realized by fixed-area plots, point samples (Bitterlich plots), or nearest-neighbor methods. As the location of each sample tree is known, it is straightforward to describe the individual tree history and thus the growth components formed by survivor trees, in-growth, mortality, and cuts.

The application of the CFI method over long periods of time may lead to problems caused by its rigid system of permanent plots. An initial set of plots may lack representativity when plots are lost, e.g., by disturbances or land use changes, or cannot be relocated in the course of time. When inventory objectives are changing over time, it may become necessary to establish additional plots at new locations. However, the statistical estimation procedures used with CFI are straightforward and can be understood intuitively.

A sampling method for field surveys that was introduced into forest inventory in the 1960s is sampling with partial replacement (SPR). With this method, part of the sample plots that are measured at one occasion are replaced by new sample plots at the next occasion (**Figure 5**). For two occasions three types of sample plots are obtained:

1. Sample plots, which are measured at time 1 as well as at time 2 (permanent sample plots, matched plots).
2. Sample plots, which are only measured at time 1 (unmatched plots).
3. Sample plots, which are only measured at time 2 (new plots).

SPR is a flexible design with several advantages. It is possible to replace lost plots and to allocate new plots according to changes of inventory objectives.

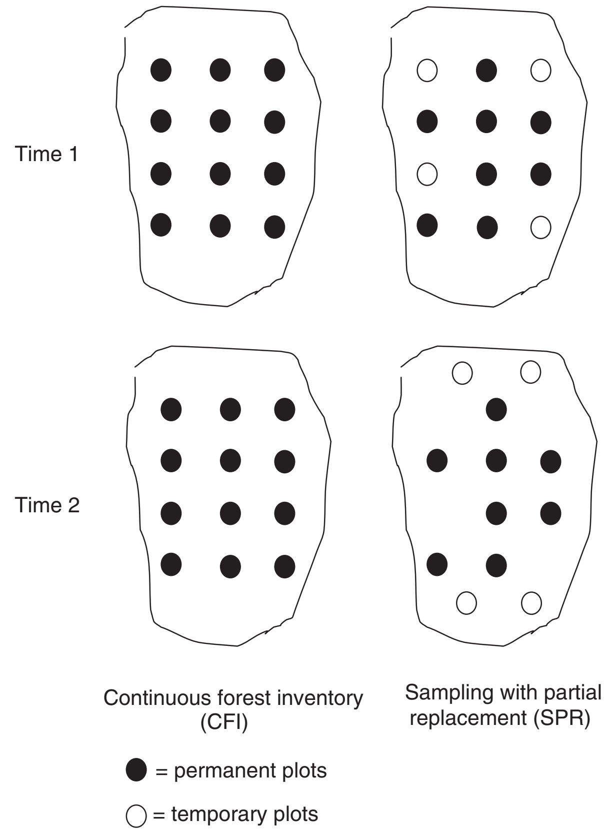

Figure 5 Sampling at successive occasions.

The number of unmatched and new plots does not necessarily have to be the same. By adjusting the proportion of new and matched sample plots it is possible to optimize cost-efficiency according to the focus on current state or changes. If only current state is to be considered, temporary sample plots often prove to be more cost-effective than permanent plots, since the expenditures for marking the sample plot centers and the registration of sample tree coordinates do not exist. However, permanent plots result in precise change estimates. A major disadvantage of SPR is that the estimation procedures become unwieldy and deterrent after more than two occasions.

Besides CFI and SPR, other approaches have been described to assess changes. Those approaches include independent assessment at each occasion, updating observations by modeling, or a combination of a low number of permanent plots and extrapolation of past observations by modeling.

A Typology of the Attributes Assessed

The sampling concepts described above determine the procedure by which the sample is selected from the populations. Once a sample has been selected, attributes are assessed at the individual sampling units. Attributes assessed in forest inventories can be related to individual trees or to areas such as the site or the stand. Only a limited number of attributes can be directly measured, such as tree height, diameters at different stem heights, crown length, bark thickness, bole length, basal area, or thickness of the humus layer. From a statistical perspective those attributes are observed on interval or absolute scales and allow for the computation of a variety of statistical parameters (e.g., mean, variance, standard deviation, coefficient of variation, median, or coefficient of correlation). A large set of attributes is assessed according to definitions, e.g., tree species, crown shape, defects, diseases, tree layer, soil type, development stage, or management activities. As those attributes are nominal or ordinal-scaled, they only allow for a limited number of statistical parameters (e.g., median, mode, range, or proportion). Attributes directly assessed can be used as input variables for models and form the base for a large set of derived attributes. Among those are, for example, stem volume, above-ground tree biomass, assortments, timber value, species mixture proportions, and site class.

Data Sources

The major data sources utilized by forest inventories are *in-situ* assessments. Attributes that cannot be assessed by field visits, such as ownership, past management activities, or investments in infrastructure, render data assessment by questionnaire necessary. Despite the fact that the location where data are assessed may be georeferenced, it is not possible to derive spatially explicit data (i.e., maps) from those data. The visualization of results in mapped format is restricted to the spatial resolution of the units of reference.

Since the beginning of the 1920s the use of aerial photography for forest resource assessments has been studied. The development of operational remote sensing techniques in the 1970s added a new data source to traditional information gathering. Remote sensing imagery provides wall-to-wall maps of land cover and forest types for entire inventory areas and allows for spatial analyses. However, the number of attributes that can be derived from remote sensing data is limited. The combination of remotely sensed and *in-situ* data by statistical approaches offers the potential to utilize both the depth of the thematic information of *in situ* assessments and the spatially explicit information of remote sensing data.

Beside field data, questionnaires, and remote sensing data, other data sources are utilized for forest inventory purposes. Among those auxiliary data are statistics, e.g., on population, timber markets, or economy, and thematic maps displaying topography, geomorphology, administrative boundaries, transport systems, climate, or location of settlements and industries. The availability of geographic information systems and their capability to handle spatially explicit data layers offer powerful tools for spatial analyses and spatial modeling.

Information Needs

Long-term sustainability motivated forest scientists to seek methods to monitor and predict the long-term development of forests. The principles of sustainable forest management were developed in times when public demands concerning forests concentrated on the production of timber. Thus traditional inventory and monitoring methods mainly focused on the balance of timber growth and timber utilization. During the past decades sustainability became a prominent concern in the entire environmental context. In the context of sustainable development forests are no longer seen solely as a timber resource, making sustainable forest management, according to the Intergovernmental Panel on Climate Change, ‘a system of practices for stewardship and use of forest land aimed at fulfilling relevant ecological (including biological diversity), economic and social functions of the forest in a sustainable manner.’

In order to meet today’s information needs the methodological background of forest inventories has been significantly widened in the past decades and allows information to be provided on the multiple wood and nonwood goods and services of forests. Forests are not solely treated as management systems but as a holistic concept subject to multiple ecological, economic, and social relationships. Sustainable forest management requires the observation of forests in successive points in time. Forest inventories thus provide tools to assess current information as well as information on changes. A set of successive forest inventories is often called a forest-monitoring system.

Decision-making in the forestry sector is realized at different levels and thus requires information for different spatial scales. Forest management planning has a high demand of spatially explicit, local information, while decisions at a political level render information aggregated to the regional or national scale necessary. National information can be cumulated on a multinational, continental, or global level and form the information base for multinational programs and initiatives. The vertical aggregation from task-specific to integrative and

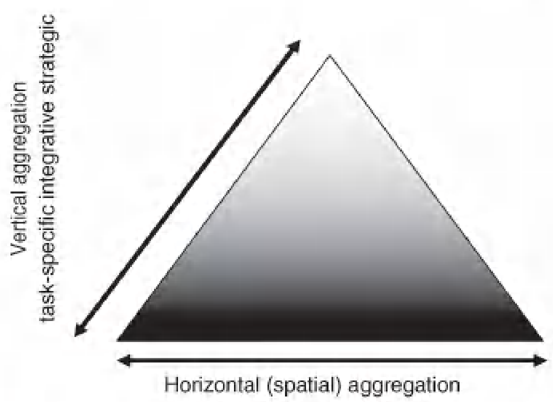

Figure 6 Horizontal and vertical aggregation of information.

strategic planning goes hand in hand with spatial (horizontal) aggregation, resulting in an increasing area of units of reference for which information is provided (**Figure 6**).

In the context of sustainable forest management, forest resource assessments may provide information on the current state and changes over time on the following thematic aspects:

- forest resources, including forest area and growing stock
- carbon balance
- health and vitality of forest ecosystems
- productive functions, including growth and harvested timber
- biological diversity
- protective functions
- socioeconomic functions and conditions.

For specific questions such as scenic beauty, forest ecology, or potential forest habitats, it can be necessary to study forests in a landscape context, rendering spatially explicit information of the location of forested land necessary.

Categories of Forest Inventories

According to the inventory objectives and the size of the area to be surveyed, different categories of forest inventories can be defined. Forest inventories are for the most part realized as multipurpose resource inventories and aim at an ample picture of the multiple functions provided by forests.

Global forest inventories are conducted to determine forest resources at a global level and were compiled by the Food and Agriculture Organization several times since 1946. Global forest resource assessments utilize existing national data to a maximum extent. As national assessments are aiming at specific national or regional information needs, they do follow individually designed inventory concepts and systems of nomenclature. Much discussion and readjustment of the results of national forest inventories is necessary before they can be compiled to give a global picture. Advances in remote sensing techniques allow satellite imagery to be applied to determine the distribution of forest vegetation throughout the world.

National forest inventories are already being conducted in many countries, especially in temperate and boreal regions. In Scandinavia national forest inventories have been running since the 1920s. Timber volume is usually employed as a key parameter, though information on the distribution of forested areas, the condition of the forest, and productivity also has to be collected. The non-wood functions of the forest are receiving increasing attention. Ideally, national inventories are planned as permanent surveys with periodic updates. Information obtained through national inventories is mainly applied in questions of national forest policy and international commitments and initiatives.

Land-use inventories extend the concept of forest resource assessments to other types of land use. Aerial photographs and satellite data are of especial importance here. In the scope of UN Framework Convention on Climate Change (FCCC) land use, land use change and forestry (LULUCF), land use inventories are a major tool in quantifying carbon sinks and sources.

The term 'regional forest inventory' is applied to a variety of inventories. Regional forest inventories register only a subset of the national forested area or an area which is assembled by two or more countries. The size of the area covered by regional forest inventories usually comprises between 50 000 and some hundreds of thousands of hectares. Similarly to national inventories, they are intended to provide a general picture of the situation regarding forestry. In a global framework the term 'regional forest inventories' is used to describe inventory areas that cover entire continents, parts of continents, or forest vegetation zones. Similar to global forest inventories, data available at the national level are utilized to a maximum extent.

Stand level inventories are the most intensive type of forest inventory and aim at detailed information for forest-planning purposes on individual stands and on intensively managed but restricted areas. Usually the data are computed on a stand-by-stand basis for each species. Information on increment, detailed forest maps, and data on the quality of the various sites are just as necessary as details on topography, ownership, and accessibility. As an integrated part of sustainable forest management, stand level inventories are normally realized as permanent inventories.

Reconnaissance inventories provide a rough insight of forest characteristics of a limited area. As well as the location and extent of forested areas, they register accessibility, species composition, tree dimensions, the distribution of various forest types, and initial data on timber quality and forest ecology. As reconnaissance inventories are conducted at minimum cost, the employment of remote sensing data is promoted while field surveys are restricted to the minimum. They frequently serve for the preparation of an intensive forest inventory by providing basic information on the degree of variation of forest attributes.

Exploitation surveys, logging plan surveys, and wood procurement studies are conducted to provide a basis for the planning of timber-harvesting operations. The main focus is on determining the current state of standing crop, classified according to species, dimensions, and assortments. Information on accessibility can be included in nonopened-up areas. Information on increment, sustainability, or ecological conditions is not in the focus of such inventories.

Forest health monitoring became prominent in European countries in the 1980s when forest decline was a public concern. In Europe and North America such surveys are conducted regularly in order to track the course of development of different types of damage. Among the attributes assessed are crown transparency, needle and leaf discoloration, regeneration, and mortality.

The typology of forest inventories described above does not represent a rigid classification scheme. Special surveys may be conducted to satisfy individual information needs. For instance, the assessment of current state and changes of woody biomass can be a major concern for carbon budgeting. The various types of forest inventories may overlap and increasing demands for information on nonwood goods and services and biological diversity may lead to new inventory types.

The Work Phases of Forest Inventories

The planning of forest inventories is a complex task that brings together experts with different technical backgrounds. The time span between the expression of the need for a forest resource assessment and the availability of inventory results may easily cover a decade. In order to plan and organize a forest inventory the proven rules of system analysis and project management are to be followed. Carrying out a forest inventory can be divided into four main work phases:

1. Definition of the inventory objectives and the information desired.
2. Development of the sampling design, the sampling methods, and the concept for data analysis.
3. Data assessment (field surveys, remote sensing data analyses, and collection of information in other data sources).
4. Data analyses and publication of the results.

Large-scale Forest Inventory and Scenario Modeling

T Nuutinen, Finnish Forest Research Institute, Joensuu Research Center, Joensuu, Finland

Scenarios as Tools for Planning for the Future

Forestry is facing trends such as population growth, uncertainties such as climate change or market fluctuations, as well as major drivers of change such as new governmental policies or international agreements, new markets for forest products, or new harvesting technologies. There is increasing need to manage forests effectively to meet multiple requirements (including preservation of biodiversity) and changing conditions, and to show it to the customers and the surrounding society. Scenarios are tools for planning for changes and uncertain future. It is possible to derive expert scenarios without computerized models. In forestry, scenarios are usually based on the complex analysis of ecosystems and human behavior at the national, regional, and global level. In the analysis, large-scale forest inventory data and computerized scenario modeling are needed to explore resources and their alternative futures.

Scenario Approaches

Scenarios integrate information on what might happen based on drivers, the probabilities of future events, and the interests of different actors. There are four different scenario approaches: (1) vision; (2) projection; (3) pathway; and (4) alternative scenarios. The vision scenarios are based on subjective hopes. Projections are based on past trends and they predict how people expect the future to be. The pathway scenarios compare the present and desired future to assist in the design of strategies on how a certain future is achieved. The alternative scenarios map the possible futures based on anticipated changes.

Forestry Scenario Models and Forest Sector Models

Forestry scenario models are sometimes defined as computerized models used to make long-term projections of forest resources over a large geographical region (from a couple of hundred hectares to global level). They may be referred to as timber inventory projection models, timber supply models, timber assessment models, or long-term strategic planning tools.

Forestry scenario models cover natural processes of forests as well as management activities. There are different ways to classify forestry scenario models. A common classification is based on the forest growth prediction method (yield tables, stand models, or individual-tree models). Another classification distinguishes timber assessment and timber supply prediction models. Timber assessment models illustrate the effects of different harvest levels on the forest. Timber supply models predict supply, taking into account the forest structure and growth as well as the expected harvest.

Forestry scenario models are closely related to forest sector models. Forest sector models cover both forestry and the forest industry and they can be classified according to how they deal with spatial markets. There are two region nonspatial models, multiregion nonspatial price equilibrium models, spatial equilibrium models, trade flow and market share models, and transportation models.

Forestry Scenario Systems

Forestry scenario analysis is usually based on quantitative models covering natural processes (trees, other species, soil, etc.), products and services, human activities and their economy, and their interactions. For the analysis these models are integrated into software systems where appropriate data and models are integrated to mimic the real world and interaction of its components and processes.

The common components for most forestry scenario systems are: large-scale (national) forest inventory data as input, a simulation model for projections, and a method for the actual scenario generation corresponding to the defined assumptions. Depending on the method used in the generation of scenario, the models can be divided into optimization or iterative simulation models.

Examples of Forestry Scenario Models

Typically, a large-scale forestry scenario model has been designed for particular conditions and forestry-related problems. In northern Europe, national-level forest scenario models are available, for example, for Finland, Norway, and Sweden. In other parts of Europe, the models have been mainly designed for specific tasks and regions. In the USA, strategic planning software has been used for decades in the land management of public forests. New Zealand has utilized integrated simulation and optimization in the management of plantation forests.

In Finland, the MELA model of the Finnish Forest Research Institute is used for forestry modeling and analysis. MELA was designed in the 1970s for the regional and national analysis of timber production based on national forest inventory (NFI) sample plot data. MELA has two components: (1) a forest stand simulator based on individual-tree distance-independent models to generate automatically a number of feasible (sound and acceptable) management schedules for the stands over time; and (2) optimization software. In MELA, JLP software is used as the solver. In principle, JLP is a general linear programming (LP) package for solving Model I-type forest management planning and conventional LP problems. However, JLP is characterized by its outstanding capacity and speed in solving large-scale multilevel LP problems. This is due to the capability to utilize the specific problem structure where several management schedules are simulated for each stand. The structure of JLP makes it possible to solve both a production program for the whole forestry unit and the management of hundreds of thousands of stands simultaneously based on user-supplied goals. In MELA, hundreds of variables are available as optional decision criteria, combining the state of the forests, physical production, and economy. A typical analysis is based on the maximization of net present value. Three rounds of national analysis based on the NFI sample plot data have been carried out for the preparation of national forest programs since the 1980s.

In Norway, a similar approach to the Finnish MELA, based on integrated simulation and optimization, was adopted. The GAYA-JLP is a forest scenario model based on simulation of treatments for stands and linear programming (JLP) for solving management at forest level. The growth models are standwise. In addition to GAYA-JLP, the Avvirk simulation model is used for national and regional timber production analysis based on NFI sample plot data.

In Sweden, the Hugin simulation model has been used for long-term forecasts of timber yield and possible cut based on NFI sample plot data since the 1980s. Hugin is a deterministic simulation model with some built-in stochastic components. The growth models are based on individual trees.

In Germany, several models exist. For example, the FORCABSIM model is used to study the effects of management practices on the value of forest land and timber stock, as well as the stocks and fluxes of carbon. The FORSKA gap model uses forest inventory plot data to study the impact of projected climate change and alternative forest management strategies. In the Netherlands, the HOPSY model, based on singular stationary Markov processes, is used for wood forecasting.

In the strategic planning of US public forests, SPECTRUM was developed to replace FORPLAN, which has been used for Forest Service land management planning since the 1980s. FORPLAN was originally built for integrated resource planning of national forests. SPECTRUM was designed to incorporate new analytical capabilities to address ecosystem management issues. Both FORPLAN and SPECTRUM are general modeling tools applicable in different conditions.

In Minnesota, the DTRAN model has been used to analyze state-wide timber supply. DTRAN deals with interactions concerning timber supply within a region, taking into account the specific product requirements at specific market locations. In general, DTRAN is an optimization model that minimizes cost while meeting forest-wide production targets over the planning horizon. The advanced feature of DTRAN compared with other forestry scenario models is its ability to take into account transport costs.

In New Zealand, the IFS/FOLPI model has been used in forestry modeling. IFS is an interactive forest simulator used by the New Zealand Forest Service. FOLPI is a system based on LP. The system automatically translates the planning problem into an LP formulation, solves the problem using a standard LP package, and interprets the solution. The basic data for both IFS and FOLPI consist of tables of initial areas by crop type and age class.

In addition to national models, there are models covering larger regions. At the European level two approaches are used: the European Timber Trend Studies (ETTS) regularly carried out by the United Nations Economic Commission for Europe (ECE)/Food and Agriculture Organization are compiled from national estimates and the EFISCEN – developed from the former International Institute for Applied Systems Analysis (IIASA) timber assessment model – is a harmonized model based on NFI data. ETTS includes scenarios for the outlook for supply and demand of roundwood and forest products in Europe. In ETTS V the demand and supply forecasts are the results of econometric models, and the roundwood supply is based on the aggregates of national scenarios considered most likely by national experts.

The predecessor of EFISCEN, the original IIASA model, was developed in the late 1980s. The IIASA model is an area matrix model into which the management regimes are given exogenously. The EFISCEN matrix model uses NFI results, including area, volume, and net annual increment by age classes for more than 2500 forest types. The

EFISCEN has been used, for example, to study the impact of climate change on long-term growth and development of European forests.

Examples of Forest Sector Models

The most famous forest sector models are the Timber Assessment Market Model (TAMM), the Price Endogenous Linear Programming System (PELPS), the Global Trade Model (GTM), and the Timber Supply Model (TSM). Both TAMM and PELPS are mainly used at national level. GTM and TSM are designed for global analysis.

TAMM is a spatial model of the US solid wood and timber inventory. TAMM provides annual volumes and prices in the solid wood products and saw timber stumpage markets and estimates of total timber harvest and inventory by geographic region for periods up to 50 years. TAMM has been used to examine issues ranging from log export policies to the impact of carbon sequestration through tree planting.

PELPS was originally developed for the North American pulp and paper industry but PELPS III can be used for any sector to predict consumption, production, and capacity by technology, and trade within or among several regions or countries.

GTM is a partial market-equilibrium economic model originally developed at IIASA to predict future world trends in forest product consumption and production, timber supply, and global trade. The model finds, at any time period, the market equilibrium solution for all regions and all forest products such that demand and supply are equal for each forest product in each region. National versions of GTM have been used, for example, in Finland (SF-GTM).

The Center for International Trade in Forest Products (CINTRAFOR) has extensively revised the original GTM into CGTM. CGTM has been used to assess the economic impacts of climate change on the global forest sector, impacts of US carbon mitigation strategies on US and global carbon accounts, impacts of timber supply shortage on land-use allocation, and impacts of supply constraints and trade policies on global tropical forests. In addition, the model has been utilized in studies on the development of tropical hardwood markets, effective trade policies on tropical deforestation, and on market distortions and their impacts on the forest sector in Latin America.

TAMM and GTM are static simulation models. A static simulation model utilizes econometrically estimated functions of supply and demand to determine the single period equilibrium price and harvest level. Both models simulate the supply as price changes and growing stock adjusts through growth and harvest of timber. The solutions in many periods are linked together to project market behavior over time. Supply and demand relationships derived from historic data may or may not hold up during the projections.

TSM is an optimal control model that uses dynamic optimization to determine (solve endogenously) the path of price, harvest, and management that maximizes the net present value of consumers' plus producers' surplus over all time periods in the future. In TSM timber supply is a function of price and the amount of harvestable age classes. In forest sector models, the control theory may be more suitable than static simulation for long-term analysis because it provides the theory for predicting harvest behavior in the future when econometric relationships may not be valid.

TSM has been used, for example, to analyze the economic impact of climate change on global timber markets. In addition, TSM has been used to forecast the likely response of industrial wood producers to increased or decreased demand for fiber over the long term, and to analyze the effects of further set-aside or the adoption of more costly forest management or harvesting systems on timber supply.

In the USA, two different model sets have been used to analyze US private timber resources: the TAMM/NAPAP/ATLAS/AREACHANGE (TNAA) system and the Forest and Agriculture Sector Optimization Model (FASOM). The TNAA system consists of four linked models: TAMM, The North American Pulp and Paper (NAPAP) model, the Aggregate Timber Land Assessment System (ATLAS), and the AREACHANGE model. The AREACHANGE model projects the shifting of timberland between forest and nonforest uses and among forest cover types. NAPAP is a static, price-endogenous, spatial equilibrium model – like TAMM. NAPAP projects consumption, production, prices, and trade in pulp, paper, paperboard, and fiber markets. TAMM deals with solid wood and provides an interface with the timber resource model ATLAS. The TNAA system has been used for more than 20 years, especially in US Resource Planning Act (RPA) timber assessments and updates. The RPA assessment is the evaluation of the supply and demand situation for timber in the USA mandated by Congress and carried out by the US Department of Agriculture (USDA) Forest Service. The purpose of RPA is to analyze the timber resource situation to understand the implications for future cost and availability of timber products. The basic set of models has also been used in regional studies, for example in the south.

FASOM is a spatial, intertemporal optimization model which links the US forest and agriculture sector. FASOM was originally developed to examine forest and agricultural carbon sequestration policies. The Office of Economy and Environment in the Environmental Protection Agency (EPA) initiated the development of a dynamic model of the joined forest and agriculture sectors to be able to model the competition for the land. In FASOM the management investments and land use options are endogenous. The model employs a joint objective function, maximizing the present value of producers' and consumers' surpluses in the markets of the two sectors, subject to restrictions on the disposition of the land base that is suitable for use in either sector.

Forestry Scenario Analysis

A typical forestry scenario analysis includes several steps. First, the scenario assumptions are outlined. Second, the appropriate data and model or models are selected and preprocessed to be compatible with each other and the assumptions, if necessary.

Scenarios are usually based on the existing forest inventory data. Sometimes problems arise due to incompatibility of the inventory (designed perhaps to serve other purposes) and the selected model. It is possible to select the model according to the data available (bottom–up) or synchronize data with the selected model (top–down) using other models. The complex chain of models may cause additional errors to the scenarios. Therefore a careful validation of the model integration should be included in the selection process.

The choice of model type should depend on the problem in question. In the analysis, any number of input assumptions and structural relationships are manipulated. Most models are different in the model theory, model scope, and exogenous assumptions applied and therefore their ability for analysis varies. The utilization of forest sector models in the analysis of timber supply is often limited because the simple and aggregated forestry submodel does not allow modeling options for forest management regimes. Forestry scenario models usually provide more detailed analysis of forest management. However, forestry scenario models fail to solve the optimal management of forests under market economy because they cannot model the balance between supply and demand through prices. A popular solution is to use iteratively a forest sector and timber assessment model. By linking different models it is also possible to cover a larger range of social, environmental, and economic measures from the local to the global level. The outputs from one model are used as (exogenous) input assumptions in the other model.

Third, the assumptions are transformed into scenario parameters relevant for the data and model or models selected. Fourth, actual scenario runs are carried out and the results interpreted. Sometimes it is necessary to iterate between steps 1 and 4 several times – either for the actual study or for sensitivity analysis.

Future Challenges of Large-Scale Forest Inventory and Scenario Modeling

Forestry scenario modeling is needed, for example, to solve ecologically, economically, and socially sustainable use of forest resources for national forest programs. In economic and environmental policy analysis, scenarios may be conditional predictions on what will be the carbon sequestration of forests if the amount of harvested wood is decreased or increased, or studies on how forestry should adapt to and mitigate the effects of climate change.

Due to globalization it is important to incorporate a global scope and trade into the analysis to understand how, for example, plantation establishment or aging in the emerging region, environmental pressure to reduce harvesting in certain regions, and technological change affect global, national, or regional timber markets. In these trade-off studies, the model should be able to describe simultaneously the quality differences and resulting price differences among wood producers and between wood and nonwood, the price adjustment when matching demand and supply, as well as how wood producers change their investment, management, and harvest decisions in response to changes in relative prices. The models should cover all the relevant phenomena. For example, when solving forest management endogenously, models for nontimber products and services, damages, biomass, carbon, and different ecological/landscape considerations may be needed.

In scenario analysis, the magnitude of relative differences between different scenarios is important. Sometimes the uncertainty due to the models used is greater than the difference between scenarios. Because errors and uncertainty are rarely incorporated into the models, the interpretation of results is often difficult.

In the future, research and development should pay more attention to the optimal choice and integration of data and models, as well as modeling stochastic phenomena and errors explicitly.

Multipurpose Resource Inventories

H G Lund, Forest Information Services, Gainesville, VA, USA

Introduction

Resource inventories are often functionally oriented and confined to areas where resource management opportunities are the highest (e.g., timber inventories were only conducted as commercial forest land). However, many lands are now managed for a variety of benefits, including water, forage, wildlife habitat, wood, recreation, wilderness, and minerals. International agreements and recent legislation often require that we take an integrated approach in our decision-making, resource planning, and inventories. In order to address increasing concerns about the environment and sustainable development and to reduce costs, we are finding we need more information than we normally collect in traditional timber inventories. Faced with new information requirements and decreasing budgets, many resource inventories in the future will have to change from the traditional functional inventories we conduct now. They will have to meet more needs with less funding. Future inventories will need to concentrate on measuring basic resource attributes in a manner that will permit multiple use interpretations. The inventories must be comparable across forests, states, and regions. They must also promote a continuity of information and direction between major decision levels. Lastly, future inventories must link to the past, provide a basis for monitoring plan implementation, and provide information on changes and trends.

Multipurpose resource inventories (MRIs) help meet our needs. MRIs are data collection efforts designed to meet two or more needs. Integrated, coordinated, and multiple resource inventories are forms of multipurpose inventories. Such inventories help meet the new information requirements. Fundamental to the successful development and implementation of MRIs are information needs assessments, cooperation and coordination, standardization, objectivity, and control.

Background

In one regard MRIs are new, yet in another they have been around since humans evolved. The data-gathering techniques were reconnaissance-type, multipurpose inventories conducted by the scouts of the tribes and reported verbally. The primary use of these exploratory inventories was to determine if the lands should be settled. When the capability of the lands to produce food and shelter became exhausted, humans simply moved on.

As land became scarce and human populations grew, settlement took place. With settlement came more specialized information needs and data collection techniques to fill them. Timber inventories, soil surveys, agricultural censuses, mineral surveys, and wildlife censuses, emerged. **Table 1** lists some of the specialized or focused inventories that were conducted by the US Department of Agriculture (USDA) Forest Service on its national forests in 1987.

Most inventories were conducted for specific functional uses and generally confined to areas where those functional management objectives were to be emphasized. Some inventories, even at the national level, were redundant and resulted in conflicting information. There was little attempt to tie inventories between resource functions, administrative units, and planning levels. In addition, many inventories were designed for very short-term problems. Little consideration was given to long-term integrated development now required in our planning processes.

There are common data requirements for several of the inventories listed in **Table 1**. For example, all of the timber, range, and wildlife surveys require information on vegetation. In addition, recent laws required that the USDA Forest Service look at its resources in an integrated manner – that is to say, understanding the management of one resource would affect the sustainability of another. The agency could realize cost savings and meet its legal obligations by developing multipurpose or multiple resource inventories where attributes are measured once but used by many (**Figure 1**).

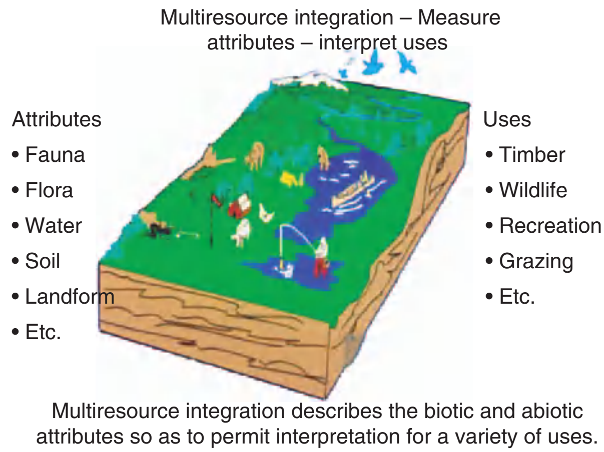

Figure 1 Measuring attributes and interpreting uses.

Table 1 Resource inventories conducted by the US Department of Agriculture Forest Service

Responsible staff	*Inventory subject*	*Major uses*
Forest research	State-wide forest survey	State survey reports, national and international assessments
Timber management	Forest-wide surveys	Forest planning
	Silvicultural examinations	Forest and project planning
	Timber cruises	Project planning
	Regeneration surveys	Project planning
Range management	Range analysis	National assessments, forest and project planning
	Noxious weed survey	National assessments, forest and project planning
Watershed and air management	Water-quality survey	National assessments, forest and project planning
	Air-quality survey	National assessments, forest and project planning
	Soil survey	National assessments, forest and project planning
Wildlife and fisheries management	Threatened and endangered species	National assessments, forest and project planning
	Wildlife and fish habitat survey	National assessments, forest and project planning
Recreation management	Cultural resource survey	National assessments, forest and project planning
	Recreation opportunity spectrum	National assessments, forest and project planning
	Visual management	National assessments, forest and project planning
Minerals and geology management	Common-variety minerals	National assessments, forest and project planning
Fire and aviation management	Fuels inventory	Forest and project planning
Forest pest management	Forest pest condition	Forest and project planning
Lands staff	Land status and utility corridors	National assessments, forest and project planning

Multipurpose Inventories

New concepts in resource management planning require periodic inventories that are free of political judgments and not conceived to support foregone conclusions about which lands will be used for what purpose.

Given today's funding, we cannot get the necessary information by each resource collecting data separately. We need to start collecting data so it can be used by other resource sectors. Multiresource inventory integration is a must.

If we are to avoid contradictory data and keep costs down, the same inventories we use at the local level should be used for national and global assessments. Multilevel inventory integration is needed as much as multiresource integration is needed.

As inventories are aggregated for national assessment, they must be compatible across states and provinces. This requires multilocation integration. Lastly, the success of our plans and programs needs to be monitored and evaluated. Temporal inventory integration has to be involved. Thus, multipurpose inventories may take on up to four forms of integration (**Figure 2**).

MRI Requirements

Successful multipurpose inventories depend upon the fundamentals of cooperation and coordination, standardization of terminology and techniques, objectivity in design, and control and responsibility. Without these, integration is not possible.

Cooperation and Coordination

The most important elements for successful inventory integration are cooperation and coordination – cooperation between data collectors and decision-makers so that inventories meet an organization's objectives and coordination among data collectors so that the required information is gathered most effectively. This may include cooperation between functional specialists, line officers, and research units.

Cooperation is needed to: (1) establish minimum requirements for meeting information needs irrespective of agency or organization; (2) establish inventory standards providing uniformity between data collectors; (3) provide minimum quality requirements against which inventories can be evaluated; (4) eliminate unnecessary duplication of data collection; and (5) increase utility of resulting information.

Coordination improves cost-effectiveness by eliminating redundant data collection and reporting and by incorporating alternative measuring and sampling techniques. Involving all interested parties clearly identifying intended uses, defining areas of responsibilities (particularly when inventories may be conducted by two or more individuals and agencies) and designing inventories that are multipurpose all improve efficiency.

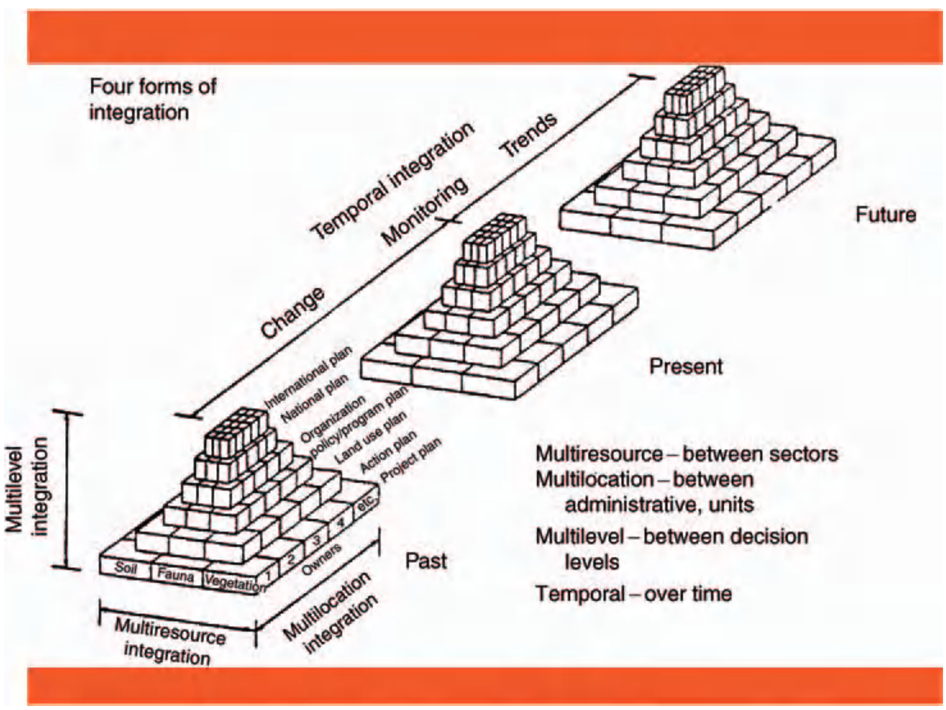

Figure 2 Four forms of integrated or multipurpose inventories: multiresource, multilocation, multilevel, and temporal.

Standardization

Standardization adds to the value of information, for information that becomes useful to more people and data can be compared and combined. Definitions, classifications, and measurement require standardization, but to encourage innovativeness, flexibility in how those standards are met should be allowed.

Objectivity

Objectivity in inventory designs is needed so that data from different sources can be scientifically compared and aggregated. Objectivity is maintained through the use of sound sampling strategies. The proper choice of sampling strategies involves minimizing bias, constructing a sample frame, and selecting a sampling technique.

- Implied in objectivity is that all locations or survey units be mutually exclusive (i.e., boundaries do not overlap) and data from all locations must be complete (i.e., all locations are accounted for).
- The inventory of each location must be based on complete enumeration or on a scientifically valid sample.
- Common definitions and standards must have been used or data collected in such a manner that they can be converted to common definitions and standards.
- The information produced from each inventory includes estimates of the mean (or total), the standard error of the mean (or total), and the probability level at which the standard error is calculated.

Control and Responsibility

Quality control provides the mechanisms for ensuring inventories are carried out according to specifications. Control includes assignments of responsibilities, choice of area bases, time frames, and data collection, compilation, and summary processes. Control should be established in an inventory plan and begun before the first field plot is established.

Responsibility Assignment of responsibility indicates who will do what, when, and how. Responsibility also includes assignment of authority to resolve any conflicts or questions that may arise in the course of the inventory. This authority should monitor the inventory work, make changes in inventory methodology, and ensure that users understand the processes and correctly apply the results.

Area control Decision-makers usually require area statistics as well as volume and production information. All those concerned with integrated inventories must utilize the same area control base from which to compute areas. Without an agreed-upon base, there would be no means of determining if areas are omitted or duplicated. The sum of the mapped and/or survey areas must equal the total area of interest.

Time frame In addition to utilizing a standard land base, inventories should also be within compatible time frames. If compatible time frames cannot be used, it is often necessary to update or 'grow' the inventory through simulation models, to make the data compatible. The models used, as well as the coefficients, may also become a form of control.

Data collection, compilation, and summary Measurements and observations should be made as objectively as possible. Detailed instructions should be provided for each step of the inventory from measurements to ensure uniformity. Checks should be made throughout the inventory to ensure procedures are being followed. The central authority should be available in case procedural questions arise. The more authority provided, the more compatible the multipurpose inventories become.

Advantages/Disadvantages of MRIs

The advantages of developing MRIs are that they:

- reduce overall costs of gathering data (US Forest Service table)
- provide more useable information for easier analysis of interactions
- get people talking and acting together
- eliminate confusion and duplication.

The disadvantages are that MRIs:

- are more costly than a single-purpose inventory as one is gathering more data
- require working with other people with different goals, agendas, and backgrounds
- require partnerships to share responsibilities, results, and credit
- require more time to determine information needs and to develop methods to collect the necessary data.

Information Needs Assessment (INA)

Decisions are often based in part on inventory summaries. To determine the kinds of summaries needed, we have to examine the kinds of decisions a large organization has to make. Then we need to look at the techniques and fundamentals available for designing inventories that can link these decisions together.

In planning for the management of its resources, a large federal agency can be involved at several decision levels, including international, national, agency, regional, forest, district, and compartment, and stand. Each level of decision has its own information needs, uses, and, requirements. Typical characteristics of various decision levels are given in **Table 1**.

You will note from **Table 1** that data collected at the local level are also needed at the national and international levels. **Table 2** shows the kinds of information needs at various levels of decisions.

The information required at a given decision level is usually more general and broadly based than the information required at lower levels. Users of the information also differ. Users of national-level information are usually more numerous and diverse than users of project-level information. At the same time, information needs change as an organization matures. When first created, an agency may have need for (and access to) only broad descriptive information about its resources. As management intensifies, more detailed information is needed and more information becomes available.

Integration between decision levels or multilevel integration is usually required to provide a continuous flow of information and management direction between the highest levels in the organization and the

Table 2 Typical decision level characteristics

Level	*Characteristics*
International	Goal: To develop international assistance programs or action plans to reverse the depletion of resources and degradation of the environment; foreign trade agreements to shift surplus to meet demands; or cooperative agreements to control pests and diseases or to address other catastrophic occurrences. Information sought includes the present state of the resources and the rate and pattern of change. An international group usually assembles data
National	Goal: To develop long-range federal policies and programs for public and private land-administrating organizations within a given country. National assessments often provide basic and relevant data on renewable resources held by all types of owners within a nation, appraising changes in supplies of resources and demands for them, the outlooks for the future, and possible alterations in these outlooks by changes in national program end policies. National assessments include descriptions of the present situation and estimated changes due to management, cultural influences, and natural or secondary factors. The data are usually assembled and compiled by a federal agency or an association dealing with a specific resource product. The primary users of the information are the executive branch, Congress, and regulatory agencies. Private industries also use long-range estimates of production and trends to develop their own strategies
Agency	Goal: To develop an overall strategy for the management of resources within the agency's jurisdiction; to define a policy; to express that policy as a set of regulations; and to carry out and execute the policy through the agency's program. The information required usually reflects current values and rates of change. Inventories conducted at this level may be considered as a prelude to the development of the resource. Inventories focus on the resource stock and the land's capability to produce on a sustained yield basis. The inventory units used in planning are usually based upon political or administrative boundaries. Broad management goals and objectives and financial plans for the organization are the eventual products
Region, forest, district	Goal: To develop long-term direction for each management or administrative unit (e.g., region, forest, district) within an organization. The resources and their condition and potential are described only in sufficient detail to direct the manager's attention to specific portions of the management unit for more intensive planning. Area, volume, and production estimates are usually tied to each unit. For timber planning, information sought includes areas by land class, soil-vegetation types, estimates of growing stock within the classes, and accessibility. The product is a management plan
Compartment and stand	Goal: To determine what, where, and when specific treatments are to take place. Decisions regarding timber sale locations and prescriptions for specific stands are examples. Inventories to assist the decision-maker often include maps of vegetation conditions by compartments and stands, description of vegetation and terrain within the units, and accessibility and relevant classification of the units with respect to the alternatives selected under the land use planning process. Data observed include vegetation factors, potential productivity, accessibility, and economic factors in order to determine specific management actions to take place within the treatment unit. The district usually conducts the inventories. The output is a functional action plan showing the treatment areas and indicating what is to be done when, where, and how. The plan is used for the day-to-day operations of the lowest-level field office

lowest levels. This ensures that the lowest units are carrying out the policies of the agency and that policies can consider the most recent data available. The differences in users, needs, and timing between decisions present special problems when trying to develop inventories to support multiple decisions.

Approaches for determining information needs There are two approaches generally used in determining information needs – a bottom–up and a top–down approach.

In the bottom–up approach, the information requirements are defined at the local level and accumulated upwards. The disadvantage is that the information identified may not include the information required at the top level of the organization.

With the top–down approach, information needs are defined at the highest echelons. At each subsequent decision level, more information is added to meet more local issues. A problem with this approach is that the people collecting the data at the project level feel burdened collecting information for which they do not feel a use.

If we assume that information needed at the top decision levels in an organization is needed at subsequently lower levels, the top–down approach is preferred.

To develop a workable information flow, decision-makers at all levels of the agency must be involved. Information needs and reporting formats must be identified at each planning level, starting at the highest or broadest level. This procedure establishes a minimum core of information and priorities required at all decision levels and ensures that the policies, regulations, and information needs of the organization are developed and fulfilled. The commitment to provide information from the lower levels will only be as strong as the field perceives the need for the information. Consequently, field units will be more cooperative in supplying information when they have been involved, and clearly understand why the information is needed and how it will be used to serve their needs.

Inventory design options There are two design options for meeting multipurpose information needs. The first option is to design a system in which the mapping and sampling is intense enough to meet the most demanding needs (i.e., at the compartment and stand decision levels). The second option is to conduct two or more inventories on the same piece of terrain but at times corresponding to different stages of development.

The first option has the advantage that one inventory would provide compatible information for all decision levels. However, because all lands may not be managed at the same intensity, this option can be costly if the production potential and management intensity of the lands are low.

Under the second option, a broad decision level is chosen as a base where the same detail of information is required across all lands. As with the first option, these inventories would be aggregated to provide more generalized information to the upper levels in the hierarchy and would provide defined survey areas for the lower echelons. Additional inventories for the more detailed planning levels would be conducted within those survey areas only when and where they are necessary, resulting in overall cost savings. Information from the broader inventory would be used to enhance, expand, and supplement the more intensive surveys.

Minimum data As a minimum and regardless of information source (imagery or ground observations) where possible measure, record and make available the following information:

- geographic coordinates of observation
- date of observation dominant
- vegetation type (life form as a minimum)
- height of dominant vegetation
- percent of canopy cover of dominant vegetation
- area classification surrounding point of observation to which observations apply.

This is the very minimum set of data that should be recorded for each plot or polygon in national vegetation inventory and mapping efforts. By using this information, one can resort the data to fit almost any international vegetation classification schemes, especially when used in a geographic information system with soils, climate, and topography data. In addition, these attributes can be used for developing classes, validation of classes, and for accuracy assessment.

Research Needs

Regardless of design used, data collection is still costly. The identification of indicators and development of models can reduce inventory costs.

Research on new products, uses, and cultivation of native vegetation is needed. As new products and uses are identified, new measuring and sampling techniques will need to be developed.

Production coefficients, linked to soil and climatic factors, need to be developed for existing and emerging uses. Without this information, we cannot develop resource management programs.

Statistical strategies for combining existing information also need to be strengthened. There is a wealth of data available, but how can we combine it, compare it, and disaggregate the information?

Finally, we need more research on integrated analyses to determine how changes in one resource will affect other sectors. For example, forest land is increasing in many parts of the developed world as agricultural lands are abandoned. Does this reduction of agricultural lands in the north increase deforestation in the developing world as lands are converted to agriculture?

Summary

Agencies such as the USDA Forest Service are taking an integrated approach to developing inventories. Inventories concentrate on measuring basic resource attributes in a manner that will permit multipurpose interpretations.

Cooperation and coordination, standardization, objectivity, and control and responsibility are fundamental in designing these inventories to ensure that the inventories can be summarized and used by decision-makers for a variety of purposes.

Stand Inventories

O Eckmüllner, Institute for Forest Growth and Yield Research, Vienna, Austria

Introduction

Stand inventories are the classical way to build a management plan. The first step is the delineation of stands: useful for this are forest survey, aerial photography, or remote sensing technologies (*see* **Resource Assessment**: GIS and Remote Sensing). The second step is to collect information on each stand. This can be done by using inventory techniques (sampling techniques) or by using aerial photographs or remote sensing. In the future, a new approach could bring better results: airborne laser-scanning combined with high resolution satellite data, for example.

This article covers special stand inventory techniques based on considerations of precision and accuracy and tries to demonstrate the differences between stand inventories and forest inventories.

Historical Overview

The classical method to obtain data for a management plan is to use stand inventories. After the stands have been delineated, some information on each of them is collected. See **Table 1** for an actual example from the nineteenth century.

Table 1 An example from the nineteenth century of classical stand inventory, transformed, simplified, and translated from the method of Judeich

Stand number	*Area (ha)*	*Tree species*	*Age (years)*	*Volume ($m^3 ha^{-1}$)*		*Site class*	*Crown closure*
				Coniferous	*Deciduous*		
20a	3.03	8 spruce, 2 fir	79	400	–	3	0.8
20b	2.25	4 spruce, 3 fir, 3 beech	65	180	70	1	0.8
20c	5.06	10 spruce	5	–	–	1	–
20d	4.50	8 beech, 2 spruce	125	50	500	4	0.7

The stand borders were measured with a tape and a compass. The stand area was taken from maps using planimetric techniques. The stand age was derived from older information or by counting tree rings or whorls in younger stands. Tree species composition and crown closure were ocular estimations. The volume per hectare was estimated ocularly or measured by complete enumeration. Finally, the site class (relative yield class) was determined from yield tables using the age and the volume per hectare. These tables were only used to estimate the volume increment and the 'normal' volume (mean volume of a full stocked stand over a complete rotation).

In those days all information such as allowable cut and rotation length were derived from these data. Today stand inventories are more sophisticated, using a wide range of different estimation methods. Forest inventory covers the need for strategic information, and involves surveying the whole forest enterprise area with designed sampling and measuring techniques. Stand inventories are used to obtain area (stand) related data. This data collection is problem oriented and these data should form the database for decision support systems.

Stand Inventory Techniques

Ocular Estimation of Volume

This method is very crude, because the quality of obtained data is dependent only on the experience of the person doing the estimating. Precision (confidence interval at 5% level) has been reported from ±31% to ±38% and bias from 4% to 20%. This method is quick and cheap but neither the precision nor the accuracy are reliable.

Yield table estimation using dominant height, age, and ocular-estimated crown closure to determine the stocking degree An investigation of 1221 sample points showed a standard error of estimation of ±27% (calculating a regression between stocking degree and crown closure) but no bias. The results of this method will not be better than the results of ocular estimation alone.

Sampling techniques to measure the basal area In this case the basal area will be estimated using simple point sampling (counting only the trees) without control of borderline trees. The omission of these trees could introduce a bias (in one example we found a bias of 18% and a confidence interval at 5% level of ±16%). On the other hand the trade-off is that you need an appropriate yield table to estimate the volume – this is not true – only the form factor and the relation between dominant height and mean height will be used from the yield table.

Complete Enumeration Methods

Measuring all diameters This technique consists in measuring the diameter at breast height (dbh) of all trees in a stand and to record this in dbh classes (this can be also done by using special callipers with scales divided into 4-cm or 5-cm classes). As height measurement is time consuming, the height will only be measured on a subsample of trees (not smaller than 20 trees per stand).

Theoretically, this method should be error-free for the number of trees and the basal area. The error of the volume estimate will be inflated by height measurement error. During field camps students have applied this technique on 28 different stands with an area of ~1 hectare. A week later other students have measured the same stands. From these data the confidence interval at 5% level was calculated giving ±4% for the number of trees, ±5% for the basal area and ±11% for the volume. The confidence interval is strongly dependent on the sighting visibility condition in the stand: in pure stands without shrubs and regeneration the confidence interval is significantly smaller than in mixed stands with more layers, shrubs and regeneration. The minimum confidence interval found was ±2% and the maximum confidence interval found was ±9% for the number of trees.

Another reason for error could be the use of a minimum diameter – excluding the smallest dbh class from the above-mentioned data reduced the confidence interval to ±3% for the number of trees.

The higher confidence interval for the basal area can be explained by a diameter measurement error of

0.8–1.0 cm, which is approximately double the reported errors in the forest inventory. In complete enumeration the measurement instruction for dbh: ('on the hillside, 1.3 m above ground, direction downhill') cannot be carried out because it is too time consuming.

Complete enumeration with dbh measurement gives precise and accurate stand data and information on texture and structure. The stand area is not needed for the estimation, but this can be sometimes helpful. This technique is time consuming, with the investigation time being strongly correlated with the number of trees. This method can only be recommended for older stands of special interest.

Using ocular estimates of tree volume This method is an application of '3P' sampling techniques (sampling with probability proportional to prediction). The preliminary steps are:

1. Define either an average volume per tree in the stand (this is similar to the choice of the basal area factor (BAF) using point samples) or define a certain number of trees to be measured. In this case we need also an estimate of the stand total volume (ocular estimation or from an older management plan). The average volume per tree in the stand is obtained by dividing the stand total volume by the number of trees.
2. Create a list of equal distributed random numbers between zero and the average volume per tree in the stand.

Field operation For each tree of the stand the volume will be ocularly estimated. These values must be summed and compared with a random number from the list (every random number is to be used consecutively only one time for one comparison). If the estimated volume is greater than the random number then the volume of the tree must be measured. This can be done by measuring the dbh, the height, and occasionally also an upper diameter. These data should be recorded as well as the tree species and the estimated volume.

The stand volume is finally calculated by multiplying the sum of ocular estimations with the average ratios between measured tree volume and ocular estimated tree volume. The confidence interval of the stand volume is equal to the one calculated from the ratios. The principle of 3P sampling assumes that these ratios between measured and estimated volumes are constant over the range of trees sampled. In a similar way to the number of trees in complete enumeration the sum of ocular estimates is affected by a certain confidence interval from $\pm 2\%$ to $\pm 3\%$.

Complete enumeration using ocular volume estimation of each tree gives accurate results for the total stand volume and for the number of trees by counting the used random numbers; the precision depends on the quality of the ocular estimates and on the number of trees with measured volume. This technique gives only fair information on texture (derived from measured trees) and no information on structure. This technique is faster than complete enumeration but the time taken also depends on the number of the trees in the stand. Considerable experience and knowledge of the stands being sampled is needed.

Sampling Techniques

The following sampling techniques are applied in stand inventories:

- point sampling
- rectangular, quadratic, or circular plots
- *n* tree sampling (point-to-tree distance method)
- tree-to-tree distance method.

Common Problems of All Sampling Techniques Used in Stand Inventories

Correction of finiteness A stand has a defined area. To calculate the correct standard error from a sample a correction of finiteness is necessary. This finite population correction multiplier is generally the square root of 1 minus the quotient of investigation (sampling fraction). This quotient can be calculated as cruised area divided by the stand area (recommended for rectangular, quadratic, or circular plots, *n* tree sampling (point-to-tree distance method), tree-to-tree distance method); or as measured number of trees divided by total number of trees in the stand (recommended for rectangular, quadratic, or circular plots, *n* tree sampling (point-to-tree distance method); or as measured cross-sectional area divided by the stand basal area (recommended for point sampling).

The sample size formula for sampling without replacement from finite populations will differ from the formula for infinite populations

$$n = \left(\frac{t\mathrm{CV}}{A}\right)^2$$

for infinite population

$$n = \frac{1}{\left(\frac{A}{t\mathrm{CV}}\right)^2 + \frac{1}{N}}$$

for finite population where CV is the coefficient of variation in percent, A is the allowable error expressed as a percent of the mean, Student's-t (2-tailed) has $n-1$ degrees of freedom, N is the number of sampling units in the population (e.g., number of trees in the stand), and n is the number of required samples in the stand.

Edge effect bias or boundary overlap In stand inventories sample plots or points can lie near or at the stand boundary. These samples will not be wholly in the stand. This problem, commonly referred as edge-effect bias or boundary overlap, can introduce a bias. In forest inventory with temporary plots this boundary-overlap problem is often solved by moving the plot until the entire plot lies within a stand. This method is not suitable for forest inventory with permanent plots (new boundaries can arise) and for stand inventories because the trees near the edge can be different to the trees in the remainder of the stand, and the trees in the edge zone may be undersampled.

One method of dealing with the edge-effect bias problem is to apply the mirage technique in the field. Another possibility is a computational correction. When the plot center falls near a stand boundary the surveyor measures the distance from plot center to the boundary. If the computational correction is to be applied then this distance is tallied. Otherwise a correction-plot center is established by going this distance beyond the boundary. All trees in the overlap between the two plots are recorded twice. This simple method can be used for circular plots and for point samples (**Figure 1**).

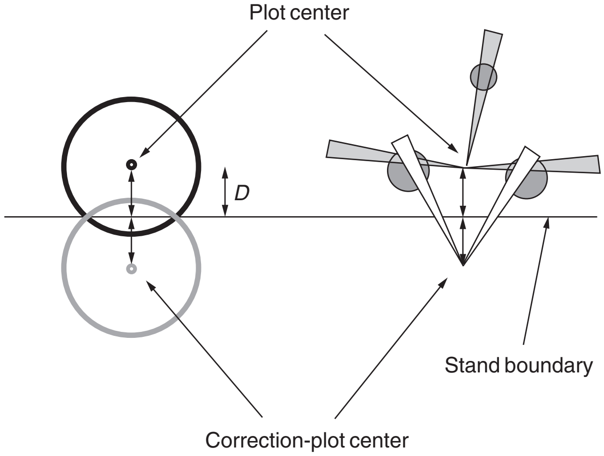

Figure 1 The mirage method for correction of boundary overlap bias when circular plots (right side) or point samples (left side) are used. Trees falling in the control plot are tallied twice.

Computational correction If we define $x = \frac{D}{R}$ with D the distance between the plot center and the stand boundary, and R the radius of the circular plot respectively

$$R = \frac{\text{dbh} \times 50}{\sqrt{\text{BAF}}}$$

in point samples where BAF is the basal area factor and dbh the diameter at breast height in meters. The correction factor can be calculated for the whole plot respectively for each single tree in point samples (but only for trees with R greater than D) with one of the following formulas (arccos gives results in radians, $\cos^{-1}$ gives results in degrees):

$$bf = \frac{1}{\left(1 - \frac{\arccos(x)}{\pi} + \frac{x}{\pi}\sqrt{1-x^2}\right)}$$

$$bf = \frac{1}{\left(1 - \frac{\cos^{-1}(x)}{180} + \frac{x}{\pi}\sqrt{1-x^2}\right)}$$

If a plot falls near to two edges then move the plot along the nearest boundary until the problem is reduced to a one edge effect (**Figure 2**). In very small stands or fractal stand boundaries a complete enumeration is recommended.

Sampling size versus plot size Small sample plots usually exhibit more variability; the coefficient of variation is greater than in large plots. In the literature often the formula suggested by Freese is cited:

$$\text{CV}_2 = \text{CV}_1\left(\frac{P_1}{P_2}\right)^{\frac{1}{4}}$$

where CV_2 is the estimated coefficient of variation for the new plot size, CV_1 is the known coefficient of variation for plots of previous size, P_1 is the previous plot size and P_2 is the new plot size.

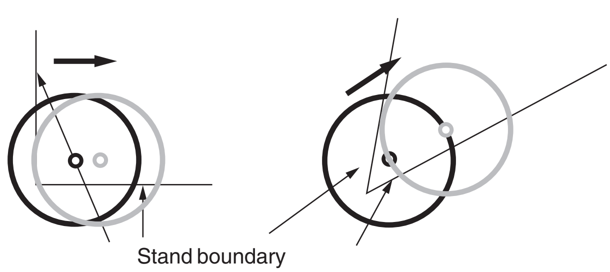

Figure 2 Multiple boundaries overlap: moving the plots along the nearest stand boundary to reduce the problem to a one-boundary overlap.

This formula is a very fair approximation in forest inventories and wrong in stand inventories. In a stand this relation depends on the stand structure. The theoretical correct formula for stands with spatially random distributed trees is:

$$\mathrm{CV}_2 = \mathrm{CV}_1 \left(\frac{P_1}{P_2}\right)^{\frac{1}{2}}$$

The simulation of artificial stands with structure ranging from a quadratic distribution (Clark and Evans index = 2), random distribution (Clark and Evans index = 1), and clumped distribution (Clark and Evans index = 0.5), with different densities (from 400 to 2500 trees per hectare in steps of 300 trees per hectare), and different plot sizes ranging from $12.5\,\mathrm{m}^2$ to $800\,\mathrm{m}^2$ (doubling space) gave the following results:

In uniform stands the calculated exponent is 0.8 with a range from 0.78 to 0.85; in the stands with a random distribution of the trees the exponent is 0.5 with a range from 0.48 to 0.52; and in the stands with a clumped tree distribution the exponent is 0.52 with a range from 0.50 to 0.54. In stands with a clumped tree distribution the effect of enlarging the plot size is slightly more efficient than increasing the sample size. In so-called 'Poisson' forests (random distribution of the trees) there is no difference in the efficiency. But changing the plot size in uniform stands (e.g., plantations) can be very efficient. In uniform populations the coefficient of variation is very small, therefore the influence of different plot sizes in forest inventory is very small, but in a given stand this effect is very high. In one reported study the exponent was calculated to be 0.43 using nine out of 10 stands. Only for one stand was the exponent 0.22 (close to 1/4). This stand was described as including gaps larger than the maximal plot size.

A 'loss of effectiveness' also occurs if spatial correlation exists in the stand , or if the stand can be stratified. In these cases the approximation of Freese is also wrong but can be useful.

Temporary versus permanent plots In stand inventories permanent plots are only useful for investigating special problems or for accurate growth information. Usually temporary plots are sufficient to obtain the required data and results. The major argument against permanent plots in stand inventories is the change in stand boundaries over time, and due to stand dynamics the change of variables of interest (e.g., in a regeneration period browsing is of interest, or several years later precommercial thinning could be important; the variables to investigate will not be the same).

Slope compensation This problem is common to all sampling techniques on steep terrain. Special care must be exercised. There are three possibilities to avoid bias:

1. Compensation by the surveyors. For distance measurement this could be provided by holding the tape more or less horizontal (the maximum remaining slope must be less than 6° or 10%). For point sampling using a stick gauge or a wedge prism, one of the surveyors measures the dbh with a calliper and moves this calliper into the horizontal. The limiting factors are the slope and the plot size. The maximum compensation difference is dependent on the height of the surveyors, somewhere between 2 and 3 meters (taking into account the 6° or 10% mentioned above).
2. Compensation by the measurement instrument used: slope compensation is automatically provided by the Spiegel (mirror) relascope in point sampling. Distance measuring instruments based on laser or ultrasonic technologies can often also measure the slope angle and calculate the horizontal distance.
3. Computational correction of the slope: this can be done either in the field or a posteriori in the analysis. For the latter, the slope angle must be measured and recorded in the field. For field correction a new radius (circular plots) must be calculated:

$$R_{\mathrm{new}} = \frac{R}{\sqrt{\cos(\alpha)}}$$

where R is the intended radius of the circular plot (valid only in flat terrain), and α is the slope angle. The plot will be established holding the tape parallel to the ground. Respectively the new BAF (basal area factor) in point sampling must be calculated as

$$\mathrm{BAF}_{\mathrm{new}} = \frac{\mathrm{BAF}}{\cos(\alpha)}$$

and as field correction this must be applied on the stick length with multiplying the length with $\frac{1}{\sqrt{\cos(\alpha)}}$. For computational compensation the plot size must be calculated as $R^2.\pi.\cos(\alpha)$ and the BAF must be corrected according to the above-mentioned formula. Note that if these computational compensations are used, the means and standard deviations must be weighted to obtain statistically sound results.

Special problems with some sampling techniques

***n* tree sampling (point-to-tree distance method)** This technique is known as *n* tree sampling. One of the advantages of this method consists in the fixed number of trees to be measured per plot, and therefore a more or less clearly defined amount of time taken on each plot. The efficiency of this method decreases when the number of measured trees increases. The surveyed area to find the tree number *n* follows a quadratic function.

Using this technique all means must be calculated by weighting with the area, and the standard deviation can only be approximated by the error propagation law (first term of the Taylor-algorithm – without correlation).

Tree-to-tree distance method In recent years, caused by an emphasis on continuous-cover forests, a very old technique suggested in the nineteenth century has unfortunately had a second revival (the first was in 1940–1960). This sampling method is known as tree-distance technique. The density (number of trees) is estimated from the distances to the nearest neighbor tree. Different proposals deal with the distance to the next, the second or the mean distance between the second and the third nearest neighbor tree. In all these cases a correction factor is reported (e.g., using the distance to the second nearest neighbor tree this correction factor is 0.78 to 0.85 according to different authors).

For the simplest possibility, distance to the next neighbor tree, the correction factor is as follows. Transforming the formula of Clark and Evans (describing the spatial distribution of the trees in a stand),

$$\mathrm{CE} = \frac{2.\bar{e}}{\sqrt{\frac{10000}{N}}}$$

where $\bar{e}$ is the average distance from a tree to its nearest neighbor tree, and N is the number of trees per hectare, will result in the following formula:

$$N = \frac{10000}{\bar{e}^2}\left(\frac{\mathrm{CE}}{2}\right)^2$$

The distance between neighbor trees is dependent on the spatial distribution of the trees in the stand (stand structure); therefore without information on the stand structure the number of trees per hectare (density) can never be derived from tree-to-tree distance information.

Looking Forward

In the future a new technology, airborne laser scanning, could bring a revolution in stand inventories. The first investigations and reports indicate a high performance in the development of digital elevation models but also of digital canopy elevation models. The precision of derived tree or stand height is higher than in terrestrial measurements. Stand and single-tree delineation approaches promise good results under certain (simple) conditions.

Modeling

T M Barrett and J S Fried, USDA Forest Service PNW Research Station, Forest Inventory and Analysis, Portland, OR, USA

Published by Elsevier Ltd., 2004

Description and Terminology

Modeling is used extensively in forest inventory applications. Models, which are described as deliberate 'abstractions of a system,' are used to calculate forest attributes that cannot be easily measured, to understand how forest ecosystems function, to extrapolate forest attributes over space, and to project how forests change over time.

Until the early twentieth century, models used in forest inventory consisted of hand-drawn graphs and tables. Over the course of the past century, models were increasingly expressed in mathematical terms and modelers used statistical methods in model development and evaluation. The rapid development of computers in the past few decades has facilitated increasing sophistication of modeling techniques and broadened the scope of model application.

Modeling terminology in forestry follows that of other fields where modeling is applied. Models can be deterministic, where a single outcome is predicted, or stochastic, where random elements are incorporated. Statistical models are created with a development data set, but evaluated with an independent validation data set. Modelers sometimes distinguish between validation, a formal test against the independent data set, and verification, or the internal consistency of the model. Models are often tested with sensitivity analysis, the evaluation of model performance when input parameters are varied. Models are adjusted to local conditions through the use of calibration. Model complexity is influenced by model scope, the area of interest, and model resolution, the amount of detail in the model.

Modelers in forestry have liberally borrowed ideas and terminology from other fields, with the result of occasionally inconsistent use of terminology. For example, scale in geography represents the ratio of map units to real-world units, with the unfortunate result that small-scale is used to refer to spatial models (maps) of large land areas. In other fields, such as ecology, it is common to use small-scale to refer to things that are small in scope or area. In forestry literature, examples of both uses of the term may be found, and the meaning must be inferred from the context.

Some modeling terminology in forestry has developed coincident with particular classes of models that are specific to the field. Growth and yield models are one such example. Growth and yield models, developed within the field of forestry, are sometimes contrasted with process models, developed within the field of ecology. Both may model tree or stand growth, but are characterized by some general differences. Growth and yield models tend to be empirically based, use statistical techniques to relate variables that may not have a direct causal relationship, and are intended to aid prediction. Process models tend to be conceptually based, often use a large number of variables that represent the ecological components of a system, and are intended to increase understanding. In practice, most models have a mix of these characteristics, and the classes are imperfectly distinguished.

Growth models are often combined with forest planning models to project how inventory will change over time. Such models can have very substantial impacts on forest policy, even though they have at times proved inaccurate (**Figure 1**). Inventory projections such as those shown in **Figure 1** have been used in debates about how much forestland should be maintained in reserves, to influence policies of taxation and trade, and to support various types of forest regulation. It is likely that projections of forest inventory will play a role in international debate about carbon storage and global climate change.

Models, in short, play a variety of roles in forest inventory, from the relatively simple function of replacing or augmenting field measurements, to sophisticated policy models with far-reaching implications. The following sections illustrate the great variety of methods and applications.

Modeling Tree and Forest Attributes

For Efficiency in Forest Inventory

In some cases, field measurements of a tree or forest attribute are replaced by modeled values to increase efficiency of the inventory. Individual tree height, the length from the base of the tree trunk to the tip of the apical meristem (tree top), is an example of this type of model use. Tree heights can be measured in the field with a variety of techniques, including height poles, clinometers, and laser instruments. Tree height measurements are important values for calculating timber volume, biomass, or forest structural characteristics. However, tree height measurements take more time than measurements of many other individual tree attributes, such as tree diameter or

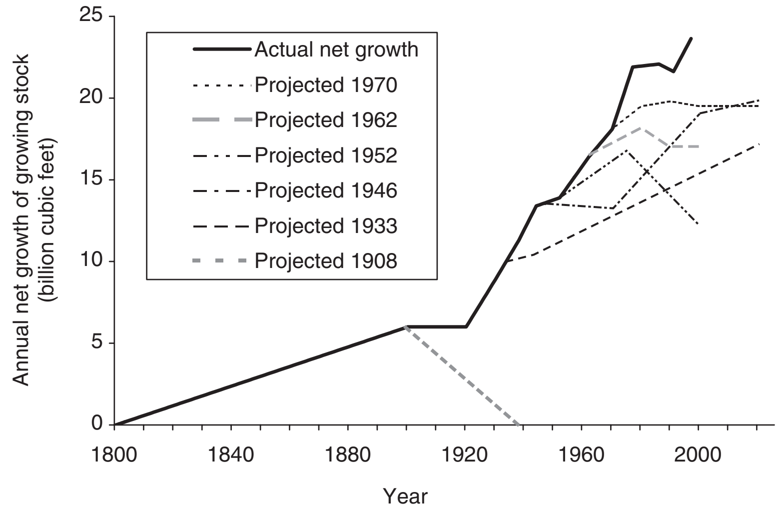

Figure 1 Annual net growth of timber in the USA, 1800–2000, and projections of future growth made in 1908, 1933, 1946, 1952, 1962, and 1970. Reproduced with permission from Clawson M (1979) Forests in the long sweep of American history. *Science* 204: 1168–1174, fig. 4. Copyright 1979 American Association for the Advancement of Science.

species. For this reason, some types of forest inventories measure heights for a subsample of trees and model heights for the rest.

Early height models for a geographic region used equations that expressed individual tree height as a simple polynomial function of tree trunk diameter; model forms have changed over time, but it is still common to use regression techniques to relate height to diameter (**Figure 2**). Although additional variables may be used, such as density or site quality attributes, the purpose of the model is prediction rather than an understanding of why different trees have different heights.

Site quality measurements are also sometimes based on models of tree heights. ‘Site’ is the local environment where a tree grows; ‘site quality’ refers to the potential productivity of this area. Site quality is most frequently measured with site indices, which are models of dominant tree height in relation to tree age. Other methods of measuring site quality include use of indicator plants, recent height growth, or physical attributes such as slope, aspect, and soil properties.

Crown cover is another inventory attribute that is commonly modeled. Crown cover is the percentage of the ground that is covered by the vertical projection of tree crowns or leaves. In recent decades, measurements of crown cover have been used in assessments of wildlife habitat and fire hazard. Similarly to height measurements, a variety of specialized methods have been developed to measure crown cover, including instruments such as densiometers or canopy cameras, and techniques such as interpretation of aerial photographs. A strong allometric relationship exists between tree crowns and tree trunk diameters; in the early days of aerial photography, this relationship was used to model tree diameters from crown widths, so that estimates of timber volume could be made. As interest in crown cover itself became important; the same allometric relationship was used to model crown widths from tree diameters. For continuous coverage of large land areas, crown cover information is often developed from models using a combination of remote sensing data and field inventories.

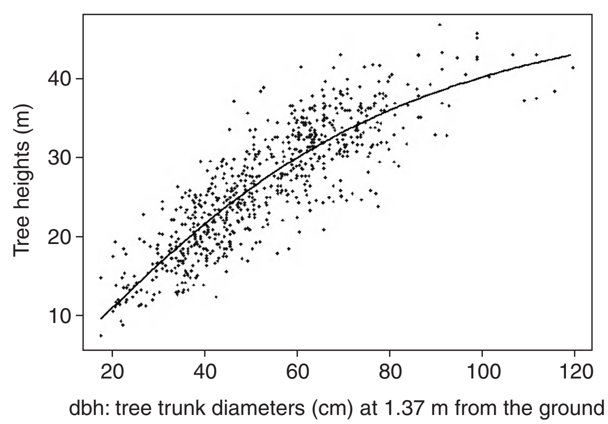

Figure 2 Nonlinear model (black line) of tree height as a function of diameter for *Pinus ponderosa*. Model is Richard’s form: height = 1.37 + 47.11 (1 − exp (− 0.021 diameter))^1.50. Data are from Forest Inventory Analysis program, west coast of USA.

When modeled values are used to replace inventory measurements, as may occur with tree heights or crown cover, both bias and imprecision can contribute to errors. Although modeled values may be less accurate than measured values, the decreased costs of data collection make the technique useful for some types of inventory where efficiency is particularly important. Knowledge of the accuracy of the models is critical to correct use. For example, the imprecision of the height model shown in **Figure 2** would make it unsuitable for many applications.

Computed Inventory Attributes

Even when an inventory contains an extended list of field-measured attributes (e.g., the US Forest Inventory and Analysis Program includes up to 50 tree attributes in its core measurement protocol), the attributes of greatest interest to inventory users almost always require modeling. Timber volume has long been the most commonly modeled tree attribute. Now, a recent focus centers on estimating biomass and carbon, not only for standing live trees but also for standing and down dead wood, such as snags and logs. At the plot level, all manner of management-relevant attributes are routinely estimated, such as biodiversity, wildlife habitat potential, fire hazard, and susceptibility to insect attack.

Whole-tree volume equations are widely available for most tree species utilized as timber and can be found in articles, published compendiums, and documentation of inventories. For the most common species, it is not uncommon to find several equations to choose from, for example, equations designed primarily for a particular region, for various merchantability and processing standards, in various units of measure, or for old versus second growth stands. Most such equations take field measured diameter at breast height (dbh), height, and sometimes site index as inputs, and produce estimates of either total bole volume or bole volume within locally prevailing merchantability limits (e.g., above a specified stump height up to a minimum top diameter). For species not commonly utilized, the selection of equations is often quite limited, and inventory compilers must choose between using equations developed for other species believed to be similar or resort to using basic geometric formulas, an approach that fails to account for variation of tree form or taper. Such formulas are also useful for estimating the volumes of down wood pieces (dead woody material on the ground, such as logs or branches), with the choice of formulae constrained by which diameters are measured (e.g., large end, small end, or at the point of transect intersection).

Some inventories involve field estimation of the numbers of logs in each tree, and, sometimes, the diameter at the breakpoints between logs (e.g., via reloskop). This opens the possibility for modeling volume for each log using volume formulas or tables designed around log size, or modeling tree volume based on dbh and the number of logs in the tree. This extra effort is sometimes justified when more precise merchantable wood volume estimates are needed.

Tree biomass is frequently estimated to assess biological productivity and ecological dynamics, to characterize fuel loadings for fire hazard assessment, and to serve as a basis for modeling carbon stores and dynamics. Bole biomass can be estimated as a scalar multiple of cubic volume, where scale factors reflect wood density and are estimated separately for each species or species group. Branch and leaf/needle biomass attributes are usually estimated via allometric relationships with dbh, and sometimes site index and/or height, which are developed via destructive sampling – harvesting, clipping, drying, and weighing of these plant parts from a representative sample of trees for each species of interest. Biomass of shrubs and herbs is also of great interest, and can be estimated from cover and height measurements taken in the field; however, there can be considerable variation among species, and cover-based biomass equations have been devised for very few shrub and herb species, making the use of equations from 'comparable' species a common fallback.

Amounts of elemental carbon can be derived as a scalar multiple of biomass, with different scale factors used for woody and herbaceous plant parts. Carbon and biomass amounts in down wood must be adjusted for the degree of decay/decomposition that has already occurred in the down-wood piece. Adjustment factors are generally specified when a down-wood decay class system is established for field classification of decay degree.

Wildlife habitat is another increasingly important forest attribute that can be modeled from forest inventory data. Habitat for individual species may be described by forest attributes such as average tree size or canopy cover. For example, a 2002 analysis of habitat for northern spotted owls (*Strix occidentalis*) in Washington, USA, found that averaged roosting habitat variables were tree dbh of 37 cm, canopy cover of 84%, 51 snags ha^{-1}, and 120 tonnes ha^{-1} of down wood. Such information can be paired with forest inventory data to build models estimating how much habitat might exist for this species. Such a model would be an example of calculating habitat attributes specific to an individual species.

Another common approach uses a standardized forest classification system that is then given species-specific rating values. For instance, one class in the California Wildlife Habitat Relationships system is tree species of red fir with average tree diameter greater than 61 cm and canopy cover $>60\%$; for feeding habitat, this class is rated as 'high' for the spotted owl, 'medium' for the big brown bat (*Eptesicus fuscus*) and 'low' for the mountain lion (*Puma concolor*). Additional habitat elements, such as presence of water or decaying logs, can contribute to these ratings of habitat suitability. Both species-specific and generalized classification systems are most often nonspatial, but an active area of research is spatially based models that factor in attributes such as patch size, proximity to water, distance between patches, and extent and type of edges.

The most common accuracy assessment method is to correlate model predictions with the presence or absence of wildlife species. Habitat alone is not enough to understand wildlife population distributions, because of impacts such as hunting, predation, intra- and interspecies competition, and migration. None the less, habitat classification is a useful method for understanding how impacts that change forest species, age, or structure may affect wildlife species.

The increasing frequency of large, wildland fires and broad agreement that, in many areas, fire exclusion has led to changes in forest structure that make today's forests more vulnerable to stand-replacement fire, has generated substantial interest in predicting fire and fuel attributes from inventory data. Such models can be ad hoc, for example, indices of stand density or standing biomass thought to be related to potential fire impacts. Others, which involve processing inventory data through formal simulation models, predict attributes related to fuel laddering and crown fire, such as torching and crowning indices, which depend on height to crown base and crown bulk density (itself a modeled attribute). When such models are coupled with stand-projection models, attributes like crown fire potential can be evaluated at many points in the trajectory of a stand, and under a variety of silvicultural management and fuel treatment regimes.

Other fire-modeling approaches utilize whatever field-measured inventory data attributes are available. They impute additional attributes by relating measured attributes to those in a database of reference plots, and ultimately predict levels of a multitude of surface fuel, surface fire behavior, crown fire potential, and fuel consumption attributes. Enthusiasm for all of these fire-modeling approaches is tempered by the scarce validation evidence associated with these models, and the substantial challenges to obtaining such evidence in adequate quantities.

Inventory data are also used to model surface fuel characteristics via classification (e.g., into stylized, surface fuel 'models') based on forest type. When a multipurpose inventory includes down-wood measurements (most commonly collected via line-intersect sampling transects), along with litter depth and mass and understory height and cover, surface fuel loadings by fuel size class can be directly estimated, potentially enhancing the specificity and accuracy of fire behavior and outcome predictions.

Spatial Modeling of Forest Inventory

Paper maps were the earliest form of spatial models used in forestry and they continue to enjoy wide use. Primitive, computer-based mapping systems were developed in the late 1960s, and these ultimately evolved into the modern geographic information systems (GIS) now used routinely in forest inventory applications.

Field measurements of forest inventory rely on sampling, or the selection of units from a larger population. The desirability of spatially continuous models as a basis for many applications has motivated the development of numerous techniques for extrapolating plot measurements to larger landscapes. Aerial photographs have long been used to map a forest through delineating stands (contiguous groups of trees that are similar in age, species, or structure). Forest attributes may be assigned directly by the air photo interpreter. For attributes that are difficult to estimate, an alternative is to delineate stand boundaries through photo interpretation, but assign attributes calculated from inventory plots or transects that were measured within the stand boundaries.

Since the 1970s, remote sensing imagery has been used to provide continuous spatial models of forest attributes (*see* **Resource Assessment**: GIS and Remote Sensing). Remote sensors do not directly measure the attributes of interest. With the most commonly used sensors, the digital data represent electromagnetic radiation intensity in different spectral bands or wavelengths. A number of standardized ratios of intensity in one band relative to another, and texture measures (typically based on variance in reflectance within a moving window) have also proved helpful. With the aid of additional sources of information such as geo-referenced plot information or stand maps, mathematical models are then used to relate this digital data to the forest attributes of interest. Although Thematic Mapper data collected by LANDSAT satellites have been most widely used, other remote sensing information such as AVHRR, SPOT, SLAR, and aerial infrared video have proved useful for specific applications. As part of the earth-observing system (EOS), a variety of new sensors began to be launched in 1999, and may prove useful for large-area ecological modeling of forests. There is also great interest in using the hyperspatial (~1 m resolution) and hyperspectral data recently available from space-based platforms to provide species-level and even tree-level representations of the forest, and many believe that light detection and ranging (LIDAR) imagery shows great promise for remote sensing of canopy structure and subcanopy vegetation layers.

The mathematical models used to create spatial models of forest attributes have evolved over time. Automated or semiautomated classification has been the standard method for mapping forests from satellite imagery for over two decades, including supervised and unsupervised approaches. Classification relies on statistical procedures, usually based on maximum likelihood estimation, to assign each pixel in the landscape to a forest-type class. Density and size classes are also sometimes assigned from image data. Classification accuracy is typically assessed via a confusion matrix – essentially a cross-tabulation of predicted and observed values, where the latter are derived from a set of ground control points that are either visited in the field or manually interpreted from aerial photographs. It is generally the case that the larger the number of classes (e.g., forest type by size by density) attempted in the classification, the lower the overall accuracy of the classification. Despite experimentation with various fuzzy classification approaches that assign partial credit for near-misses, overall accuracy rarely exceeds 85%.

Disillusionment with classification accuracy and the comparatively greater flexibility (e.g., in modeling derived attributes) that comes with continuous modeling of inventory attributes has led to the increasing popularity of imputation approaches to spatial interpolation of inventory plot data, including most similar neighbor (MSN), gradient nearest neighbor (GNN), and *k* nearest neighbor (*k*NN) variants. The first two impute all of a single inventory plot's attributes to all unsampled pixels in the landscape judged most similar on the basis of a similarity- or gradient-based weight matrix (**Figure 3**), and the third combines the *k* plots nearest in attribute space to an unsampled pixel to assign attributes to that pixel. Neural nets have also been used to merge inventory data and remote sensing data to provide spatial models of vegetation. Developers report that the technique can be used to develop maps of acceptable accuracy rapidly, but the models function as 'black boxes' that provide little insight into how a map was produced. The accuracy of any of these imputed maps can be assessed via cross-validation with samples not used in the development of an imputation model. As with other types of models, the appropriate use of spatial, GIS, and remote sensing models requires understanding the accuracy of the model for the specific application being tested.

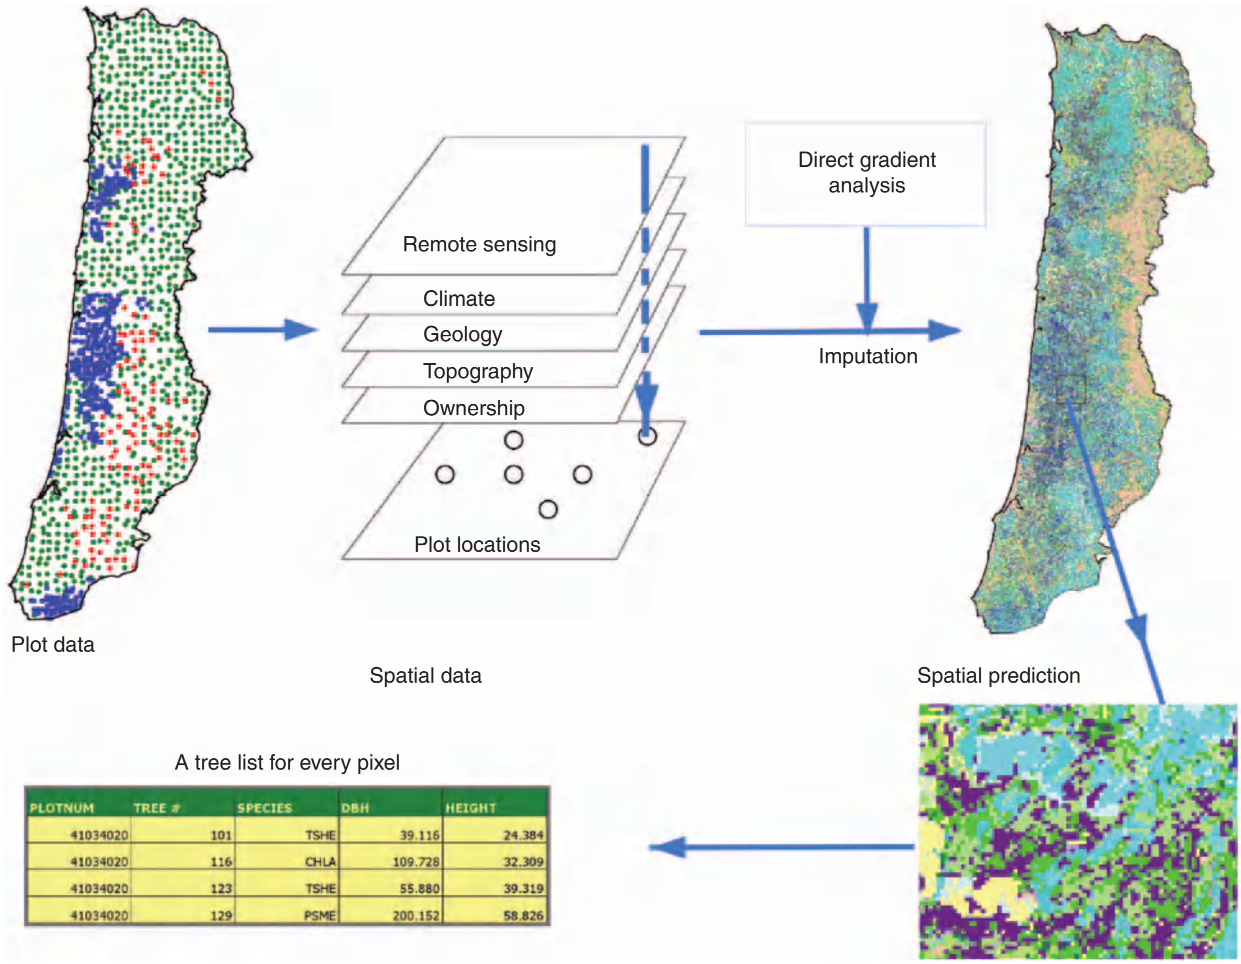
One application that combines spatial and temporal modeling is inventory updating. Continuous forest inventory (CFI) systems often measure a portion of plots each year. This approach results in having a portion of inventory data always current, but it also means that most data are from previous years. The national inventory of the USA uses such a system, and a variety of methods have been proposed to update inventory to the current year. Some methods involve imputation, or the substitution of information from similar trees or plots. Other methods use modeling procedures to update the plots, with or without the use of ancillary remote sensing data.

Temporal Modeling of Forest Inventory

Temporal modeling helps us understand how forests have changed in the past and predict how they will change in the future. Temporal modeling that accounts for management alternatives often serves as a basis for planning, and can help ensure the sustainability of forest resources.

Yield tables, which display timber volumes for forests of different ages, were one of the earliest and simplest temporal models. Simulation models that dynamically project forest attributes over time now serve as the basis for most temporal modeling (*see* **Mensuration**: Yield Tables, Forecasting, Modeling and Simulation). Growth models of various types are typically embedded within forest planning models, and use initial conditions and a set of assumptions to project forest characteristics over time. The planning model is used to vary the assumptions, establish a basis for choosing among management alternatives, and to synthesize and display forest-wide outputs. For example, a nonspatial individual tree growth model that predicts height and diameter growth for every tree may be used to project forest inventory for a set of silvicultural alternatives. The planning model might combine the output from the growth model with cost and revenue information, include an optimization algorithm to allow decision-makers to test different management strategies, and link to a GIS or visualization program to display what the forest would look like in the future.

Different purposes require approaches that vary in scope (spatial and temporal scale) and resolution. Planning models may cover very short time frames for small land areas, or they may cover long time frames and large land areas. Foresters divide



PLOTNUM	TREE #	SPECIES	DBH	HEIGHT
41034020	101	TSHE	39.116	24.384
41034020	116	CHLA	109.728	32.309
41034020	123	TSHE	55.880	39.319
41034020	129	PSME	200.152	58.826

Figure 3 Inventory plot data can be imputed via the method of gradient nearest neighbors using multivariate techniques like canonical correspondence analysis. This approach creates a full suite of internally consistent plot attributes for every pixel in a forested landscape based on the similarity of remote sensing and ancillary geographic information systems (GIS) layers at plot and unsampled locations.

planning models into hierarchical levels to reflect this range. Strategic models may be used to project forest inventory attributes over a 50–200-year time horizon, typically use time steps of 10 or 20 years, are used for forests of 20 000 to 200 000 ha, and generalize vegetation into fairly broad classes. Tactical models may be used to project forest inventory over a 10–100-year time frame, are used for forests of 1000–20 000 ha, may use smaller time steps, and may allow spatially explicit projections of vegetation over time. Operational models may be used to project forest attributes over short time horizons of 10–20 years, often use single-year time steps, are applied to forests of less than 1000 ha, recognize stands as unique entities, and are focused on short-term decisions such as what harvesting system to use, which roads to build, and which roads to close. As computing power has grown exponentially over the past two decades, these hierarchical distinctions have become blurred and it has become common to include greater detail and spatial resolution for large land areas and long time horizons.

Strategic, tactical, and operational planning models use a variety of mathematical techniques to aid in selecting silvicultural and management alternatives. Until the 1990s, linear and goal programming were the most common solution methods. Spatial restrictions between neighboring stands, whether imposed by regulation or necessitated by management goals, required different techniques. Integer programming and a number of heuristic methods, including simulated annealing, genetic algorithms, and tabu search, have been applied to spatially restricted planning problems.

Extremely large land areas are addressed with forest sector models, which are used to project forest inventory on a national or international scale. Forest sector models differ from planning models by relying

Figure 4 Visualization model of hemlock-fir inventory plot as measured in 2000 (left), and after 100 years using models of growth, mortality, and snag decay (right). Plot data are from Forest Inventory and Analysis program, growth model used is Forest Vegetation Simulator program, and visualization program is the Stand Visualization System.

on supply and demand functions rather than treating prices as fixed. Forest sector models also differ in that they are not explicitly linked to management decisions, although they may project future inventory levels for a variety of possible scenarios. Forest sector models provide useful insight into how forest inventory levels change in response to trade restrictions, technology development, or general demand trends.

Along with growth models, forest planning models, and forest sector models, many other kinds of models aid in projecting inventory attributes over time. Snag models may be used to understand how dead trees are recruited, decay, and fall down. Forest fire simulation models are used to predict how forest stands or landscapes would burn under different assumptions of weather, initial conditions, and suppression strategies. Ecological process models have been used to understand how net primary productivity and biomass would change under different climate and atmospheric carbon dioxide levels. Visualization models are used to generate graphic displays of how trees, stands, and landscapes would look in the future under alternative management scenarios. Models are frequently combined in any particular application (for example, see **Figure 4**). Relatively little research has been devoted to the effect on error and accuracy of predictions when models of different spatial and temporal scales are combined.

Modeling has become a regular component of day-to-day forest management. Improvements in validation may follow as the specific fields of application mature. The vast change in the past century, from simple hand-drawn graphical models of basic allometric relationship, to elaborate computer models intended to simulate global ecosystem processes, indicates that modeling in forestry will continue to be an active area of research.

LANDSCAPE AND PLANNING

Contents

Perceptions of Forest Landscapes

M J Meitner, University of British Columbia, Vancouver, BC, Canada

Context and Limitations

For many centuries people have been concerned with perceptions of the natural world. Philosophers have written about it, psychologists have studied it, and, more recently, foresters have become concerned with it. However, when we speak of 'perceptions of forest landscapes' in relationship to forest science, we are typically referring to a variety of assessments and their associated methodologies applied to the quantification of some visual aspect of forested lands rather than the larger context of what it means to perceive the world around us. Because of this, perceptions of forest landscapes can be seen as a restricted subset of a larger body of generalized perception research that will not be dealt with in much detail in this article. First, the discussion will be limited to forested landscapes and will not deal with perceptions of urban or built environments, for which there is a great deal of research. Additionally, this article will focus on topics related primarily to visual perception. This is an obvious simplification/reduction of the larger construct of perception but has certainly received far more attention over the years than all of the other senses combined. Lastly, of all of the measurable dimensions arising from these visual perceptions of forested landscapes, scenic beauty will receive more attention than a host of alternative dimensions (such as general preference, acceptability, visual impact) since it has historically been quite important to forest managers and the decisions that must be made regarding the balance of competing forest values.

Both the preponderance of research and this article concentrate on scenic beauty as a central issue of forest management. Going back at least as far as the ancient Greeks, aesthetics has been of fundamental concern to thinkers of the day. Most simply, aesthetics relates to appreciating, perceiving, or describing the beautiful. It then follows that forest aesthetics must relate to appreciating, perceiving, or describing what is beautiful about a given forest.

Object and Observer

We are often told that 'beauty is in the eye of the beholder' but, in the absence of an external world to behold, this would have little meaning. Conversely, consider this famous quote by William James (the father of American psychology):

> Imagine an absolutely material world, containing only physical and chemical facts, …without even an interested spectator: would there be any sense in saying of that world that one of its states is better than another.

(James, W (1891) The rural philosopher and the rural life. An address to the Yale Philosophical Club, published in the International Journal of Ethics April 1891)

Taken together these ideas lead to the supposition that beauty is transactional, where forest aesthetics is a perceptual state brought about by the interactions of the visible biophysical features of a forested landscape and the perceptual processes of an individual observer. Since the beauty of an object depends on the properties of that object as well as on an observer who can experience the beauty, any property in virtue of which an object is found to be beautiful or aesthetic is a relational property – it is a property of the object, but one which depends on something in addition to the object. In this case, the object must be related to a person who can experience the property in virtue of which the object is said to be beautiful. Simply stated, the experience of natural scenic beauty depends on properties of an individual and properties of an object where:

- properties of the observer include sense perception, thought, and feeling
- properties of the object are its perceived properties – sense data such as color and shape
- properties of both the observer and the object interact creating the foundation on which the experience of natural scenic beauty is laid.

Object

Let us then first turn our attention to the object. Traditionally aesthetics has been intimately tied to the study of art, but more specifically it is concerned with objects that give rise to aesthetic experiences. In the context of forest aesthetics this is rarely a constructed 'art' object. The more typical unit of analysis is often the view afforded by a certain location in the natural world. The term 'landscape' has also been used quite a bit in this field and for the most part it is synonymous with photographs or paintings of the visible portion of the topography and vegetation/landcover of a given place or region. This, however, is not without its controversy and, at times, 'landscape' will be used to denote regions akin to ecosystems or other logical subdivisions of an environment. In this case, the unit of analysis would be a bounded region of forest and the aesthetic qualities of that region would need to be assessed using multiple views sampled from within its borders. While this aggregation of views raises a number of problems of its own, the fundamental issue still revolves around how one might go about the business of evaluating a given view of a forest along an aesthetic dimension and so we must revert to the more restrictive definition of landscape as a view before we think about issues of aggregation. However, it is not the study of the views themselves but the perceptions of those views that form the basis for the study of natural scenic beauty in the broader context of forest aesthetics.

Observer

Perceptions require an observer and few people would argue with the statement that people (observers) are complex. We are driven by an often conflicting array of needs, wants, and desires to which each of us reacts/responds in a variety of ways. Our attitudes and motivations are influenced by our upbringing, our culture, our self-image, our need for recognition, etc. We possess the capacity for both rational and irrational thought, at times motivated by emotion, while other times we act in a cold and calculating manner. All of this variation in the human condition makes the study of environmental perception a challenging one. Current psychological research has shed some light on this complexity and indications are that perception follows a certain time course as percepts travel through various regions of the brain.

For example, imagine you are out walking and a grizzly bear (*Ursus arctos horribilis*) suddenly crosses your path. Initially, light from the bear strikes your retina. Shortly thereafter, your body reacts by activating your sympathetic nervous system (the so-called 'fight or flight' response). As you begin to move, you become aware that you are frightened as evaluations of the percept in conjunction with internal indicators of body state become available to the emotional centers of your brain. Now you are aware that you are scared and moving but have yet to fully appreciate why. You begin to access the higher centers of cognitive brain activity and are able to retrieve linguistic representations of the object in question (the bear). It would not be until that point that you would be able to formulate the utterance 'That's a scary-looking bear. I'm getting out of here.'

While it might be said that there is a somewhat innate aesthetic response given the affective (emotional) components of the aesthetic experience mentioned above, it cannot be expressed, nor even consciously experienced, without some form of cognitive apparatus and as a result cannot wholly be considered innate. This leads us to conclude that the fundamental aspects of an aesthetic response, which some have argued are evolutionarily driven, must be affected by our learned understanding of what it means to 'be' beautiful. More simply put, both 'nature' and 'nurture' are necessarily implicated in the assessment of forest aesthetics. One possible explanation for how our evolutionary history might be relevant in the assessment of forest aesthetics can be found in the savannah hypothesis. This postulation states that humans lived for nearly 2 million years on the savannahs of East Africa where certain features of the landscape offered greater chances for both individual and group survival. Therefore evolution should have predisposed us to prefer these landscape features that are beneficial to our survival. Experimentally there is some evidence to support this including a tendency for children to prefer savannah-like environments over all other biomes, our collective tendency to create gardens with savannah-like characteristics and cross-cultural studies that have shown amazing similarities in our landscape preferences.

Common definitions of environmental perception include cognitive, affective, interpretive, and evaluative components, all operating at the same time across several sensory modalities. However, these components of environmental perception have historically been approached from a great diversity of intellectual viewpoints. The expert approach to environmental perception has attempted to develop formal rules for the quantification of forest aesthetics while the psychophysical and cognitive paradigms have traditionally focused on studying perceptual processes to gain insights into how our evaluations of forest aesthetics are derived. In simple terms, the psychophysical and cognitive paradigms have mainly differed in subtleties of this debate with the former ascribing more weight to the mostly passive sensing of our external world and the later focusing more on how information is given meaning by our mental processes. Lastly the experiential model sees humans as integral parts of the world around them deriving their understanding of forest aesthetics by a set of transactional experiences. Certainly each of these perspectives has something unique to offer, but despite these differences the field of environmental perception remains focused on understanding how we move through time, from state to state, influenced by what came before and our visions of what is to come, attempting to make sense of our internal condition (thoughts and feelings) in light of our evaluations of the external world. It is in these evaluations of the external world that we are concerned in the study of forest aesthetics but we must always keep in mind that these seemingly overt valuations are responses to complex conditions of perception.

Assessment and Evaluation

Most perplexing to those who devote their careers to studying the aesthetic experience in a natural setting is the difficulty of arriving at adequate methods for assessing the relative merits of one forested landscape configuration versus another. This is related to the fact that the aesthetic experience is a complex one. This can be explained intuitively if you think about your own personal reactions to the world around you. For example, at any given time a researcher might ask you to verbally characterize or explain your current aesthetic experience. After being given some reasonably detailed explanation of what this means (similar to the one you have just read) you would then need to come up with a story of how you perceive, make sense of, and then report on your reactions to the world around you, even though you are now somewhat removed from that experience by a new one (namely the researcher asking you the question in the first place). You then need to remember your experience and relate it back to the question being asked of you. Surprisingly enough, people are actually quite good at tasks such as this and measures of reliability point to a degree of consistency in these evaluations not intuitively expected.

Common Methods

Common quantitative methods for measuring these subjective evaluations include forced choice (choose which one of these is more beautiful), Q-sort (placing relevant images in categories), rank order (highest to lowest on some dimension), or some form of scaled response (rate the images on a scale from 1 to 10 representing low to high scenic beauty). This is generally done using photographs (or more recently computer images) as surrogates for onsite experiences of forest aesthetics, though field assessments can also be conducted. A variety of qualitative methods have also been employed, such as open-ended survey type questions, naturalistic observation, and a multitude of ethnographic methods including the camera method (e.g., give out disposable cameras and have recipients take photographs of what they think are the most beautiful views in the area). When combined these methods allow forest aestheticians a great diversity of tools with which to approach a multitude of research questions.

Temporal Integration

In order for us to respond to a researcher's questions we must typically access our memory. This opens the door to possible misattribution of the cumulative effects of past experience (both cognitive and affective). For example, in the case of a slide presentation where we are rating images on a 10-point scale (relative to one another), we must remember the context of the slides that have come before and assign a rating based on our perceptions of where the current image falls on that scale. Even more problematic in this regard are survey methods, which may ask us to recall a walk down a forest trail or a recent camping trip, causing us to need to integrate information over longer periods of time. Recent research by Daniel Kahneman and others has uncovered some interesting effects that may begin to explain how accessing memory representation could affect our perceptions and ultimately our expressed assessment/evaluation of a given forest scene. This research can be summarized by briefly explaining the peak–end rule. This rule states that the affective value (preference rating) of a given moment is a simple average of the most extreme affect in a set (peak) and the affective state that is present near the end of an experience (end). While this research has focused mainly on our perceptions (and evaluations) of pain, it may likely extend to the visual assessment of forest aesthetic dimensions.

Experts versus the Public

Additionally, aesthetic experiences of forests are not limited to formal visual rules but are also colored by our scientific understanding of the underlying systems. In other words, visual beauty is but one component of a fully fleshed out aesthetic experience, which may also be affected by differing frames of perception based on dissimilar experiences in one's life. For example, a forester may find a particular ecosystem quite beautiful due to its rarity, while the average observer may be unaware of this and may judge the ecosystem on its visual characteristics alone. There is no a priori reason why the aesthetic value of a forest could not be intellectual in addition to being perceptual, or even intellectual rather than perceptual as some ecologists advocating a move to an 'ecological aesthetic' would suggest. However, this raises a number of normative issues and to date no method has been suggested to evaluate who among us is sufficiently qualified to determine what that new aesthetic might be. This premise of 'unique perceptions' has led to the formulation of the idea that 'experts' should be employed in the evaluation of forest aesthetics. To that end, the US Department of Agriculture Forest Service, having become the largest US employer of landscape architects in the early 1970s, tasked these 'forest aesthetics experts' with categorizing the scenic resources of the National Forests based on formal aesthetic features of the landscape (e.g., form, color, texture, etc.) (*see* **Landscape and Planning**: Visual Analysis of Forest Landscapes).

This expert-based method can be contrasted with a competing perception-based approach of forest aesthetics assessment where groups of ordinary citizens are enlisted to evaluate landscapes rather than individual expert assessors. Intuitively, the perception based approach is less susceptible to individual variation because evaluations of landscape aesthetics are based on numerous individual evaluations. This leads to greater confidence in our estimates but comes with some cost as well due to the increased burden of deriving multiple measures for every landscape assessed. For this reason the expert-based approach has historically been applied more to the practice of public land management while the perception-based approach has been employed predominately in landscape assessment and environmental perception research.

While both of these paradigms are alive and well in forest aesthetics research, the remainder of this article will deal exclusively with the perception-based approaches. The tradition of landscape architecture approaches is described in detail elsewhere (*see* **Landscape and Planning**: Visual Analysis of Forest Landscapes).

Results and Applications of Research

Much as artworks presuppose artists who produce them, and audiences who can be aware of them, forestry presupposes foresters who produce altered landscapes, in light of public opinion which serves to critique these management actions. Therefore, foresters must be conscious of the intent to do something, thereby creating a new object for evaluation, which ultimately becomes the public's primary means to understand and interpret the underlying properties of that landscape that the forester hopes to maximize. In the case of forestry, these underlying properties are typically multidimensional and are often in conflict; attempts to resolve conflicts involving aesthetics need to be grounded in the results from perceptual research.

Rules of Thumb

Over the years, a great deal of research has been done (particularly in the Western world) to aid foresters in understanding the linkages between manageable landscape characteristics and predictions of perceived scenic beauty. While this research area is still an active one, with many unanswered questions, a number of rules of thumb can now be derived from this body of knowledge. Overwhelmingly, people prefer natural to urban scenes. In addition, this principle has been extended to more natural scenes though indices of naturalness, such as 'evidence of humans,' common in current recreation management frameworks (*see* **Recreation**: Inventory, Monitoring and Management; User Needs and Preferences). Visible evidence of facility development and site modifications (denoting human use) are typically seen as negative contributors to scenic beauty.

Another of these rules of thumb can be derived from perceptual studies that have investigated the configural aspects of landscape. This line of research has been quite productive. People of diverse cultures, languages, or experiences, tend to prefer open areas with fairly low groundcover punctuated by clumps of trees and shrubs, as demonstrated for example in Western public parks and green spaces. This is not to say that there are not significant individual or group differences, but that they have typically been small in magnitude when compared to the degree of concurrence. A similar convergence is found in our clear preference for water in a forested landscape. This can be evidenced through direct means such as a lake or stream but can also be realized indirectly through indications of the presence of water such as abundant greenery and flowering plants.

More generally, mature trees are preferred to saplings; this is especially true in even-aged stands but there remains a great deal of variation in preferences when considering highly complex multi-aged stands. Dead and downed wood has also been shown to negatively impact preference where live plants are always preferred with a minimum of visible debris. However, caution should be used in interpreting this finding since downed wood that is sufficiently decomposed to support other plant life will appear as live plant material in a purely visual assessment. This is also related to the finding that the presence of low groundcover (grass and forbs) is often implicated in positive forest evaluations.

Research into the preference for the form of individual trees may also be of value in understanding this topic. Researchers have consistently found that deliquescent tree form is preferred to excurrent tree form. Furthermore, deliquescent trees that bifurcate closer to the ground, like the acacia tree, also seem to be preferred. These findings can be thought of in terms of preferred biomes, where some researchers have suggested that savanna-like environments are most preferred, followed by deciduous forests, coniferous forests, tropical rainforests, and deserts. These findings have also been shown to be mediated by experience, where the trends in preference are most clear for younger participants, whereas adults tend to elevate biomes with which they are more familiar when compared to the average. However, it should be noted that, while experience seems to have some effect on landscape preference, resulting differences are rather small in comparison to the larger similarities as evidenced by the bulk of empirical studies in this area.

The Promise of Visualization

Fundamentally aesthetics can be seen as related to quality of life or a more generalized sense of well-being so far as a life lived in the absence of beauty would certainly leave much to be desired. So far, we have seen how perceptual assessments of current forest conditions may offer advice to foresters in incorporating visual aesthetic components of the landscape into a multi dimensional management framework common in today's era. However, if we are to truly manage forest aesthetics, we must be able to project the likely aesthetic outcomes of our proposed management alternatives so that perceptual evaluations might be employed as input to the planning process rather than simply reacting to past management and attempting to uncover rules of thumb to guide future management. One exciting technology that offers promise in this regard is data-driven environmental visualization (*see* **Landscape and Planning**: The Role of Visualization in Forest Planning). Currently we are able to create near photorealistic images based solely on data descriptions of possible management alternatives. This may allow for the development of an entirely new method for incorporating public evaluations of forest aesthetics in the near future beyond its use in research.

Beauty necessitates and fundamentally relates to experience. This can be seen as the gold standard for the application of research findings in the area of perceptions, and as a result we must always strive to understand how this body of research relates to the larger issue of the human condition. The appropriate management of our forested environments obviously has a large part to play in that concern. Forest aesthetics has a long tradition of importance in this context and research into the interactions of human perception and forested landscapes will hopefully lead us to a better understanding of the fundamental principles related to its management. A great deal of advancement has been made in this area and technological advances offer new opportunities for exploration of these issues. The challenge now is to continue to develop research questions that adequately address the complexities of our experiences of forest aesthetics, while attempting to maintain a link from theory to practice.

Visual Analysis of Forest Landscapes

S R J Sheppard, University of British Columbia, Vancouver, BC, Canada

Introduction

This article examines the broad concepts and methods underpinning the management of visual resources in forestry, and describes some of the key scientific methods of addressing the often difficult issue of aesthetics and public perceptions of forested landscapes. It draws on accumulated research knowledge on public perception (*see* **Landscape and Planning**: Perceptions of Forest Landscapes) and provides general concepts and methods employed in more specific procedures for managing landscape values under visual resource management (VRM) (*see* **Landscape and Planning**: Visual Resource Management Approaches) and other multiple-value forestry programs. The topic of visual analysis focuses on the main human perceptual sense of vision, rather than appreciation of other aesthetic values such as sound and smell, which can also be very important in their own right though typically less critical than visual values in forestry.

What is the purpose of visual analysis? There are a number of reasons to conduct visual analysis or to be aware of its methods and underlying theories:

1. It can provide support for rational VRM and broader forest management decision-making, supplying credible scientific data on human perceptions, scenic quality, and visual design that can be used on an equal basis with ecological, economic, or other social data.
2. It provides systematic support for project planning and design where aesthetic values are important
3. It can be used to monitor visual qualities and VRM performance (at the regional to project level), as part of social sustainability assessments and forest certification efforts.
4. It can provide an indicator or predictor of public perceptions about some forest management issues, which can be useful as background for developing effective public involvement strategies.
5. It can provide visual documentary evidence for monitoring visible conditions over time (e.g., vegetation growth, human uses, etc.) that are important to various sustainability values or management issues other than aesthetics.

The history of visual analysis as applied today in forestry can be traced back most clearly to the practice of landscape architecture in Great Britain, where deliberate design of larger-scale somewhat naturalistic landscapes for aesthetics began in the eighteenth century. Certain principles of landscape design and analysis were first systematically applied to forestry by Sylvia Crowe, an English landscape architect working for the Forestry Commission in the 1960s. Since then there has been a tradition of landscape architects developing visual analysis and management approaches in forestry, incorporating both design principles and a growing body of research on aesthetic responses to forest landscapes. Researchers, most notably R.B. Litton Jr., and other landscape architects in the USA, developed the field of visual analysis in the 1960s and 1970s. The introduction of the National Environmental Protection Act (NEPA) in 1969, which recognized the need to protect the rights of Americans to aesthetic enjoyment, and the 'clear-cut crisis' in the US National Forests, led to the implementation of a major program of VRM in the US Forest Service, adapting Litton's work. This in turn has led to development of visual analysis procedures and VRM programs in other regions and jurisdictions, such as British Columbia in Canada. Other systems of landscape assessment and visual analysis have developed somewhat independently in various parts of the world, though mostly in the more developed and affluent nations.

Visual Landscape Description and Inventory

This section reviews some basic principles of visual perception and landscape characteristics, which govern how observers see landscapes. It represents the first stage of visual analysis, which permits quantifiable, objective analysis that does not require much interpretation or argument. It is based on a review of documented observation and research, as well as landscape design principles.

Fundamental Visual Characteristics of Landscapes

The process of vision exerts various influences on visual perception of landscapes. Key aspects of the physiology of vision include: visual acuity and contrast, which enables detection, and recognition of landscape elements; the field-of-view (horizontal and vertical extent); and the nature of eye movement, which automatically records visual information from certain points within the field-of-view. Vision is affected by variables of light transmission within the visible spectrum.

Litton in his seminal work *Forest Landscape Description and Inventories* was the first to develop comprehensive principles for analyzing and inventorying the visual characteristics of larger-scale natural landscapes. This work has been supplemented since by many others, such as the US Forest Service series on National Forest Landscape Management. Such methods are based on definitions of certain visual elements, which can be used to describe objectively the perceptual characteristics of landscapes (**Figure 1**). These elements include:

- color, including hue, value (lightness–darkness), and chroma (saturation or brilliance)
- texture
- scale (in absolute terms, relative to landscape scale, or relative to human scale)
- form (comprising three-dimensional (3D) forms and two-dimensional (2D) shape)
- line/edges
- position in the landscape
- movement in the landscape.

These elements can be used to describe the visual characteristics of the landscape and its principal components: landform, vegetation, water bodies, human land uses and structures, and atmosphere. The combination of these components and visual elements forms the landscape patterns and spatial (3D) structure that we see. The elements can be measured through approaches such as color charts or specifications, photographic image analysis, and pixel counts applied to representative images of the landscape.

Litton also described various perceptual relationships which affect how we see the landscape. These relationships include: diurnal/seasonal aspects of temporal variation (such as lighting direction, shade/shadow, weather); viewing distance and scale effects; observer position (superior, normal, or inferior with respect to the landscape being viewed); and observer motion (determining the effective field-of-view and viewing sequence).

In any natural landscape situation, various landscape compositional types can be identified, as follows:

1. Fundamental/large-scale compositions or spatial configurations.
   - panoramic: offering wide, unobstructed views over a large area
   - feature: views dominated by a major landscape feature such as a mountain peak or waterfall (**Figure 2**)
   - enclosed: views confined by enclosing elements such as forest edge or hills
   - focal: views focused in a particular direction by the alignment of topographic or other landscape components, e.g., a view down a narrow valley or road corridor.
2. Supportive/small scale compositions.
   - canopied: views within a forest stand, with overhead closure

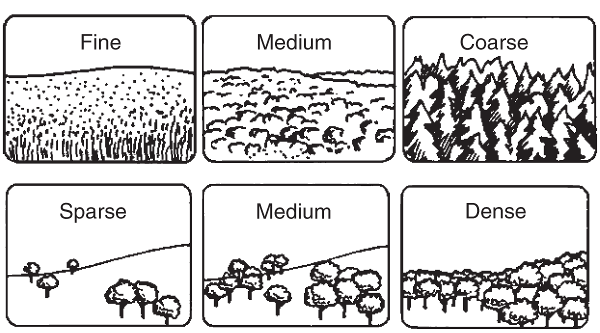

Figure 1 Example of a visual element texture that can be objectively described in the landscape. Graphic by Richard Alcina, reproduced with permission from Sheppard SRJ (1989) *Visual Simulation: A User's Guide for Architects, Engineers & Planners*. New York: Van Nostrand Reinhold).

Figure 2 Feature landscape with view dominated by a mountain peak.

- detailed: close-up views of small-scale landscape features, e.g., wild flowers.

Temporal landscape patterns can also affect landscape perceptions, sometimes dramatically. Ephemeral landscapes include views of short-lived or rapidly changing landscape features, such as fall color on trees or reflections in lakes. Change of landscapes over time are usually evaluated in terms of visual impact prediction for specific projects such as forest harvesting activities (see 'Visual Impact Assessment' below); here, there is a tendency to assess 'before and after' conditions, rather than the landscape dynamics of natural disturbance regimes, succession, or forest rotation cycles over time. The rise of landscape ecology has focused more attention on some visual descriptors of the results of natural disturbance events, in the form of a classification of landscape mosaics into patches, corridors, networks, matrix, etc. These can be quantified, but common landscape ecology metrics do not appear to be closely related to aesthetics.

Landscape Inventory Concepts

This section describes conventional approaches used to document and classify the existing ('baseline') landscape conditions.

Visual units Various organizational frameworks for mapping and classifying visual landscapes have been suggested, on a hierarchy of scales that can be related to physiographic regions, biogeoclimatic zones, forest types, the 'landscape' or watershed level, and stand level. However, these other landscape description systems cannot be expected to correspond closely with visual mapping, due to the integrative nature of the essentially visual experience: a visual landscape is defined by the totality of what is seen within the viewshed, not necessarily what it consists of in any one place.

Each of these landscape scales can be described in terms of geographic extent, boundaries/edges, landform, vegetation, water forms, and focal attractions/local features. This combination of landscape components defines what the US Forest Service calls the 'Characteristic landscape' and what in Europe is referred to as landscape character.

The visual unit level most closely approximates the scale of the forester's meaning of the word 'landscape,' although visual units can range from small valleys to very large basins. A visual unit represents a distinct area of recognizable unified character, often defined by spatial enclosure such as basins, valleys, watersheds, etc. Visual units have been mapped as the basic spatial units for visual assessment in many studies. Descriptors of visual characteristics of individual units, commonly used in many larger scale inventories, include:

- scale (extent)
- boundary definition
- spatial configuration/proportions
- landscape patterns
- unifying/detailed features
- other sense-of-place indicators that contribute to the unique character of each place.

Some visual landscape inventory systems also recognize landscape subdivisions at a subunit level, such as a particular hillside or other landform component (**Figure 3**).

Landscape visibility Beyond the broad organization of spatial and temporal landscape patterns,

Figure 3 Identification of landscape subunits (termed visual sensitivity units) using the British Columbia Ministry of Forests method. Image by Ken Fairhurst; courtesy of Greater Vancouver Regional District.

visual inventories often attempt to measure the visibility of specific areas, points, or objects in the landscape, as seen from certain viewing locations. This is often termed viewshed mapping or ‘seen area’ analysis. Clearly, visibility factors are critical in determining whether or not there can be a direct visual impact from forest operations or natural disturbances.

Visibility of landscapes depends upon the viewer location. Viewpoints are usually identified as certain use areas (e.g., recreational sites, residential areas, or other community gathering points) and travel routes. These can be specific points, often termed key observer points (KOPs), or linear travel sequences. Selection of appropriate viewpoints for analysis is often conducted with knowledge of relative observer concerns (see below). Observer position (elevation) makes a considerable difference in terms of what can be seen of a particular forest landscape.

Visibility is limited by topography, vegetative screening, man-made structures, atmospheric conditions, and, over long distances, by the curvature of the earth. Visibility can be described in terms of viewing distance, viewing angle (horizontal and vertical), and visual penetration (the extent to which observers can see through screens or filters of intervening objects, such as tree belts).

Techniques used to map visibility include linear map notation, cross-section analysis, manual mapping of visible areas from on-the-ground viewpoints, and computer viewshed analysis using 3D geographical information system (GIS) datasets. Whether these techniques take into account tree height in calculating and mapping visibility can make a difference in terms of accuracy in lowland landscapes or detailed, site-specific studies.

Visual Landscape Assessment

Visual landscape assessment goes beyond the relatively objective inventory of conditions, to evaluate and interpret forest landscapes for certain characteristics or qualities important to forest planning and management. These can involve prioritizing areas of the landscapes that are suitable for certain management regimes or actions, or identifying particular constraints, risks, or opportunities that are important to bear in mind in forest planning and design. Various methodologies for landscape assessment have been applied to large-scale landscapes. These are important as a possible framework for VRM decisions to predict aesthetic values and for modelling of future management outcomes.

In the interpretation process, there is the need to consider both the landscape characteristics described above (typically evaluated by trained experts), and the characteristics and concerns of observers. Both can be mapped and to some extent quantified. Both landscape and observer characteristics can be assessed by expert methods, public perception testing, or a mix of these methods.

In general, methods of visual analysis usually address one or more of the following major aspects of visual landscapes (although they may not be defined in these terms and often overlap within the assessment methodology):

- visual absorption capability
- viewer sensitivity
- visual quality
- landscape meanings.

Visual Absorption Capability

Visual absorption capability (VAC) is defined as a measure of the landscape’s ability to absorb alteration and maintain its visual character. It expresses the likelihood that a landscape change will be noticeable, and serves as a general predictor of visual impact (**Figure 4**). It describes how well a landscape

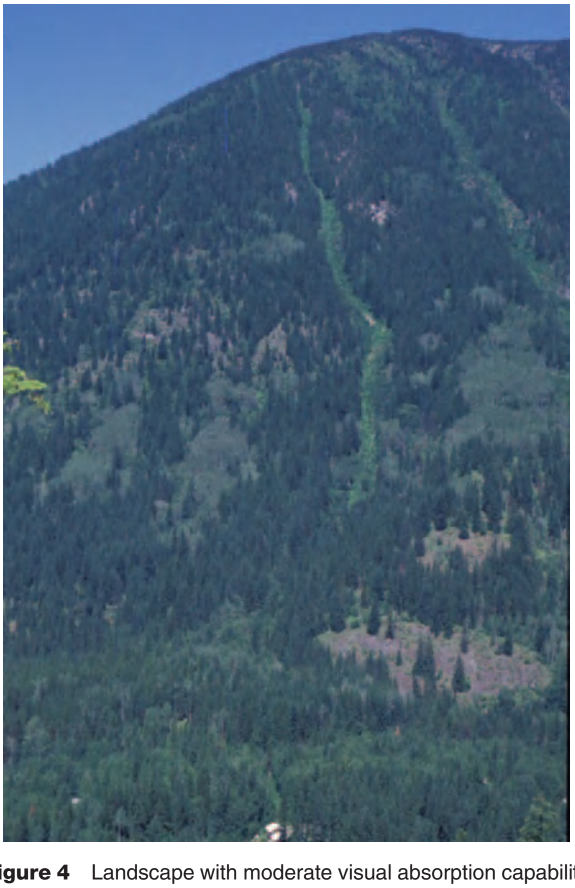

Figure 4 Landscape with moderate visual absorption capability due to strong vegetative patterns but steep terrain.

disturbance might fit in to the landscape. Typical indicators of VAC may include:

- slope (angle and screening)
- vegetation pattern (color, texture, orientation, uniformity)
- soil erosion potential
- soil color
- landform screening/surface variations
- vegetation screening
- aspect
- man-made features/urban clutter.

Typically, the steeper the slope and the more uniform the surface patterns, the harder it is to design a forest intervention that will be unnoticeable or acceptable to the public. VAC evaluation is usually conducted by visual resource experts, and is intended to help locate and/or design forestry activities to fit the landscape character.

Viewer Sensitivity

Classically, viewer sensitivity levels have been defined as a measure of people's concern for the scenic quality of the landscape. While this can be obtained directly from or verified by community representatives, in most cases viewer sensitivity is assessed based on a set of assumptions about what viewers are likely to care about. It embraces the concepts of landscape visibility (how the landscape is viewed) and viewer concern (how much viewers care about the visual characteristics of the landscape). The key indicators usually used include a few quantifiable and mappable factors:

- type of viewer: recreation users, sightseers/visitors, and residents are commonly considered to be the most concerned
- number of viewers (use volumes)
- visibility and viewing distance from key observer points: foreground and middleground views are most sensitive
- viewing duration and frequency
- other viewing conditions, e.g., roadside screening, direction of view, view angle, etc.
- land designation/policy indicators, e.g., parks, wilderness area, scenic area, scenic highway corridor, designated urban viewshed.

Mapping procedures for viewer sensitivity include composite viewshed mapping from viewing areas and division of visible areas into distance zones (foreground, middleground, and background).

In essence, this part of the assessment weights those areas that are seen most closely and most often by people with a high expected concern for aesthetics in that area. Landscapes that are more seldom seen, or seen mainly by workers, for example, are typically considered to be less sensitive to human disturbance (on visual grounds). While this tends to work in practice, this often-adopted policy has been criticized as representing an 'out of sight, out of mind' approach, and may also raise issues of social justice. It is generally understood that it is best to verify expert assumptions on viewer sensitivity with real perception data from a sample of the affected public.

Visual Quality

Visual quality has been defined in various ways by different researchers and practitioners, but it is often used in forest management as the overall dimension for aesthetics. It is sometimes referred to as scenic beauty, aesthetic value, or a measure of visual preference, factors that approach the landscape as a source of aesthetic enjoyment. It is sometimes directly addressed by forest policies and management practices, though often in a vague manner.

Classically, VRM approaches recognize that landscapes with the greatest visual variety or diversity have the greatest potential for high scenic value (**Figure 5**), using indicators such as slope, rock form, vegetation pattern, and water forms (*see* **Landscape and Planning**: Perceptions of Forest Landscapes). Research and practice have found that such features can create visual interest and draw people's attention. The landscape can therefore be mapped by experts in terms of its level of distinctiveness within a regional landscape character type. This usually assumes a typical observer in a first-encounter viewing situation. Some systems have developed methodologies that recognize a broader range of indicators of visual quality, such as vividness, variety, intactness (freedom from obvious human-made changes), and overall visual unity or harmony of the parts.

Figure 5 Landscape with high visual variety and distinctiveness.

Relatively few studies have attempted to assess the effects of natural disturbance on visual quality. Some scientists believe that cultural forces in Western nations have led to forest landscape preferences (and assessment approaches) that favor a static, visual mode of landscape experience, and an aversion to the death of trees and the 'messiness' which results from rapid landscape change.

In North America and some other countries, human influences on the forested landscape have until recently been viewed as positive features only where they represent limited, traditional (usually pastoral or historic) features of largely rural cultures. Most human interventions in landscape assessment approaches are treated as negative 'visual intrusions' by default. The largely expert-based US Forest Service Visual Management System in 1974, for example, equated departure from natural-appearing conditions with reduced visual quality, on the assumption that the public visiting the US National Forests held an expectation of a naturally appearing landscape character. Western research on human perception of timber harvesting does provide support for these assumptions: visual preferences generally decrease as the perceived degree of disruption (i.e., sudden change, perceived destruction, and 'messiness') increases, and people tend to prefer smaller-scale clear felling or plantations, for example, over larger changes. Expert evaluations of existing visual condition (EVC) attempt to map and quantify the apparent naturalness of or level of human disturbance in the landscape, as a contribution to overall visual quality at a given time.

In more obviously developed and culturally modified regions, there is no baseline of a natural landscape that can readily be used in visual analysis, and a richer set of issues and influences on aesthetic values needs to be considered. In some countries with long cultural histories of landscape manipulation, for example in Europe and China, formal views of aesthetic quality have arisen from art appreciation, landscape design, and other cultural or religious movements, which recognize human modifications or transformations of natural landscapes as closer to the ideal (**Figure 6**). These beliefs can lead both to an expert view of appropriate or higher-quality scenery, and popular appreciation of certain landscape characteristics. These values can be applied to forests by means of landscape assessments or appraisals by experts, which identify the important aspects of both natural features and landscape heritage to be protected.

Other approaches to assessing visual quality have relied exclusively or partly on soliciting people's opinions on different landscapes or landscape conditions. This can take various forms, from direct judgments about levels of scenic beauty to general questions on preference (like/dislike). Public perceptions can also be gathered on one or many of the factors described in the expert assessments, such as viewer sensitivity. Such methods can be used to verify the criteria and results of experts, though this practice is still rare. Methods have not generally been well documented, and range from very loose public participation exercises to rigorously controlled psychological experiments. One of the few methods of measuring and predicting public perceptions that has been formalized and documented is the Scenic Beauty Estimation method developed by Terry Daniel of University of Arizona, which associates people's stated scenic beauty judgments with physical features of forested landscapes, such as stand density or openness of views. A variety of methods are available to collect public perception information: workshops, stand-alone surveys with images to be rated (e.g., photo-questionnaires), public meetings where surveys are administered, user-selected field photography exercises, etc.; certain methods may not be equally suitable for all cultural contexts.

Figure 6 Wychwood Forest, Oxfordshire, UK: an example of a pastoral landscape with relic woodlands which hold substantial cultural meaning to local residents.

Landscape Meanings

While it is generally believed that visual quality of forested landscapes can be associated closely with human preference, it is also understood that many other factors beyond a concern with aesthetics or beauty are invoked by the look of the forest. These other meanings that the forest landscape may have for people may be confirmed, suggested, or exaggerated by certain visual characteristics. With indigenous cultural groups in North America and elsewhere, visual quality can be difficult to separate from other cultural, spiritual, and use values of the land and forests.

Assessment of public observer factors needs to take into account the particular sociocultural context, drawing on cultural traditions, use areas, documented public preferences in the area, past project experience, etc. There are many possible influences on human perceptions of landscape and their appreciation of it (*see* **Landscape and Planning**: Perceptions of Forest Landscapes). Both instinctive and cultural factors may exert an influence. Factors that may need to be taken into account in evaluating landscape meanings for forested areas include: familiarity and level of knowledge of observers with local conditions; the ability of the landscape to offer further information for viewers, e.g., through following a path or attaining a prospect over the surrounding landscape; and the relationship of the viewer to forestry activities (e.g., logger versus environmentalist). Theories such as information processing of landscape scenes and prospect-refuge theory underpin some of these kinds of analysis. Simply because a given forest landscape is not particularly scenic or unusual does not preclude strongly held local values for that landscape and how it appears to be managed. There is considerable literature documenting the values in the ordinary local landscape.

Methods of evaluating landscape meanings from observers include the range of public perception gathering techniques discussed above plus anthropological and sociological methods such as oral history documentation and cognitive mapping of community areas.

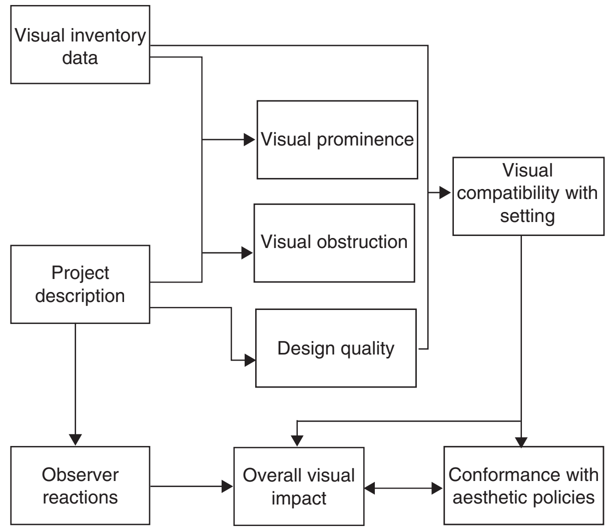

Figure 7 Example of criteria used in the process of visual impact assessment for proposed management activities. Reproduced with permission from Sheppard SRJ (1989) *Visual Simulation: A User's Guide for Architects, Engineers & Planners*. New York: Van Nostrand Reinhold.

Visual Impact Assessment

Visual impact assessment has the purpose of supporting project level decisions and design activities, for consideration alongside assessments of other ecological and social impacts. Expert impact assessments normally determine whether and to what extent the proposed activity would be visible (using techniques such as viewshed mapping), and then describing and evaluating the expected landscape changes (**Figure 7**). Often, visual simulations (or landscape visualizations) are used to assist the process by depicting the expected visual condition of the landscape (*see* **Landscape and Planning**: The Role of Visualization in Forest Planning). Many of the same issues addressed in the overall landscape assessment described in the preceding section also apply to the more particular assessment of project visual impacts.

Visual impact assessment is based on the same general principles and procedures as other resource impact assessments, derived from international and regional environmental impact assessment guidelines codified for example in the National Environmental Protection Act in the USA and World Bank policies. Typically, visual impact assessments contain a baseline assessment, description of visual aspects of the project, assessment of expected visual effects (magnitude and significance), review of compliance with visual quality objectives (VQOs) and policies, mitigations required or desired, and assessment of any residual visual impact. Visual impact can be considered positive or negative/adverse, with impacts described in terms of type, severity, significance or otherwise. Mitigation methods identify visual characteristics that can be modified through the redesign process to achieve a lower or more compatible level of visual impact.

A variety of criteria have been used for assessing the visual impact of forest management activities. Most commonly these address the prominence or visual dominance of the activity relative to the surrounding landscape (**Figures 8** and **9**), and comparison with the desired objectives established through a visual analysis (VRM) process. Thus, a proposed timber harvesting operation might be assessed in terms of the expected visual condition relative to the VQO established for the area. Less visibly contrasting management actions, such as dispersed partial cutting, are more likely to meet a given objective or maximum dominance level than a more contrasting technique such as clear-cutting (**Figure 10**). However, other criteria may be important, such as view blockage, design quality, or other indicators of visual compatibility with the local landscape. Some agencies have developed structured and comprehensive

Figure 8 Harvesting approaches using a geometric pattern of removal tend to be visually dominant. Photograph by P Picard, Collaborative for Advanced Landscape Planning (CALP).

methods of assessing visual impacts, such as rating visible landscape modifications in terms of strong to weak visual contrasts in form, line, color, and texture of the landscape. Some visual impact assessment systems also evaluate harvesting plans on criteria of design (e.g., 'Does it exhibit elements of good visual design?'), and scale (e.g., 'What portion of the visual landscape do existing alterations and proposed operations represent in perspective view?') These criteria can sometimes be quantified through image measurements or professional scoring. However, some research suggests the more numeric systems may suffer in terms of reliability between raters.

Again, public perception information can be used in assessing visual impacts of forestry. People can be asked to judge the visual impact level or acceptability directly, or they can be asked to indicate the criteria important to them for evaluating visual impact, which can avoid bias due to direct 'voting' for an alternative preferred for a variety of aesthetic and other reasons. Public perception data are useful for verifying effects on local or public values, but consistent data should not be expected for all individuals. The view of a cut block or plantation may be a symbol or trigger for many other emotional or cognitive responses, which originate in other sources of information beyond the landscape itself, e.g., cultural background, recent news events, etc. In recent years, a movement headed by Gobster has advocated the improved understanding of ecological processes as a basis for a more informed landscape preference: the 'ecological aesthetic.' The experience of community forests and pre-industrial-scale forestry traditions in many countries suggests that increased activity by local forest managers working inside the community, demonstrating care for the local landscape (sometimes termed 'visible stewardship'), may lead to higher community acceptance of timber harvesting than would reduced or concealed forest management activity. This suggests that visual impact assessments should consider the informational process by which landscape changes are planned, presented, and implemented.

Nonetheless, in Western countries, public reaction to change in the forest setting often demonstrates a negative association with large-scale or rapid landscape disturbance. It is possible to predict the severity of visual impact by examining the proposed project approach to particular practices likely to trigger public concerns, such as perceived waste of resources when slash and snags remain on site (**Figure 11**) or where there are ineffective and wind-prone buffer strips between the viewer and the activity.

Visual impact assessment needs to consider the time elapsed since the activity took place. In general, the longer the time from the disturbance, the lower the visual impact. Vegetation succession tends to reduce visual contrasts, and at some point people may no longer recognize the area as disturbed by humans. Active management areas, once regenerated, may have higher scenic value to people. Perception studies conducted in British Columbia, for example, found a significant threshold, termed Visually Effective Green-up, with tree heights of 3 to 8 meters in clear-cuts.

The foregoing discussion has been couched in terms of predicting visual impacts from future forestry activity. However, visual impact assessment is also necessary for monitoring and assessing visual conditions after the management activity (e.g., post-harvesting assessments) and on a regular basis as part of certification or adaptive management programs.

Conclusions and New Directions

Visual analysis has evolved over the last few decades into a suite of approaches that can be used to describe objectively and even quantify many aspects of the appearance of forest landscapes. The analysis and prediction of public responses to landscape conditions is much more complicated and uncertain, although in certain cultures (notably younger Western nations with a strong image of the natural landscape), research and forestry practice have revealed strong patterns of preference for certain levels and types of forest management practice. In these conditions, prescribed forms of visual analysis leading to VRM programs have proved fairly robust

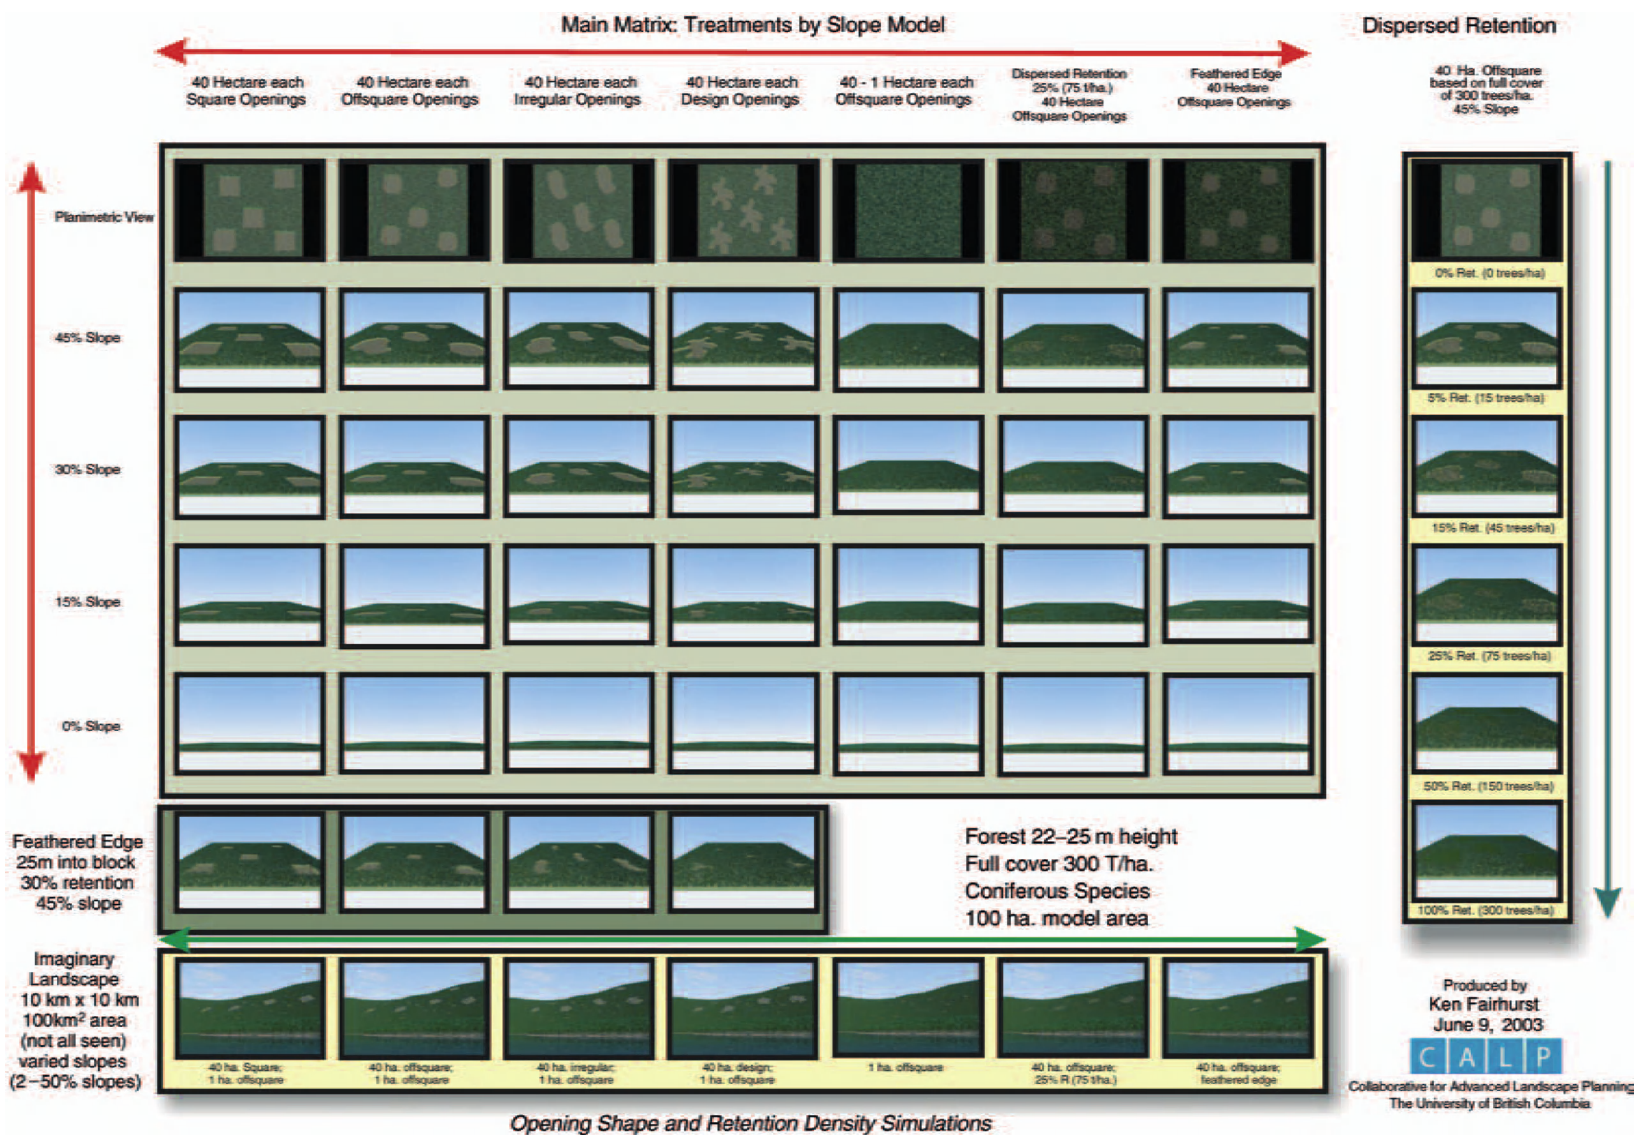

Figure 9 Controlled landscape visualizations of hypothetical forest harvesting treatments, showing differing levels of visual dominance with different design approaches. (Figure by Ken Fairhurst, CALP, reproduced with permission from British Columbia Ministry of Forests.)

Figure 11 Foreground view of landscape showing 'messy' waste material from a logging operation.

(*see* **Landscape and Planning:** Visual Resource Management Approaches). Here, visual analysis can provide a credible basis for policy objectives and design.

The applicability of such methods in other cultures has yet to be comprehensively established. There are as yet no accepted universal standards for aesthetic enjoyment of forest landscapes, and much more work needs to be done on the analysis of landscape meanings and sense of place, as part of defining social sustainability. In the meantime, there seems to be small risk in a careful, detailed attempt by experts to survey and describe landscape conditions, so long as the spiritual, cultural, and historic aspects of the landscape are given full weight, and expert evaluations are compared to and integrated with the knowledge and priorities of local people and other concerned users. The evolving role of other factors such as information, education, and economic necessity in determining public preferences must also be acknowledged. Expert-driven visual analysis should always begin with objective inventory and description before attempting more judgmental evaluations and interpretations, which should be grounded in the local landscape conditions and cultural context.

There do appear to be many places in the world where forestry is conducted without a sensitivity to visual concerns, and many would draw parallels between this experiential deficiency and the long-term unsustainability of the associated forest practices. The interactions between ecological values and aesthetic values require much more study. Time will tell whether emerging concepts in Western countries, such as an ecological aesthetic and visible stewardship, are able to transform how the public views forest management activities; it is interesting to speculate whether such movements will take Western nations back towards the more holistic views of landscape and human use observed in many indigenous cultures. Certainly, more research is needed on the effects of information of various kinds on people's preferences for forest landscapes.

We can expect increased use of visual monitoring methods to track data on both general forest conditions and aesthetic qualities: inexpensive systems of key observer points or 'landscape control points' need to be set up to provide long-term, systematic measurement and documentation of landscape change in perspective view through standard photography, to augment remote sensing data. Such systems, and visual analysis in general, should not be seen as relevant to just 'front-country' situations, in places most visible from current human-use areas: even remote landscapes are being increasingly used for recreation and tourism, and the internet provides the mechanism to broadcast imagery from anywhere in the world to a concerned public that is likely to judge forestry by its appearance.

Visual Resource Management Approaches

S Bell, Edinburgh College of Art, Edinburgh, UK

Background and History

The issue of visual resource management in forestry largely came to prominence after World War II, as the increasing network of highways and mass car ownership enabled large numbers of people to explore the countryside or natural landscapes of North America, Europe, and other developed countries. This period also coincided with greatly increased forestry activity such as afforestation programs in Britain, Ireland, and New Zealand and with increasing levels of timber harvest in the USA, Canada, and Scandinavia, especially on public lands. By the mid-1960s public concerns over the appearance of both newly planted forests and logging operations had increased, prompting agencies such as the British Forestry Commission and the US Forest Service to look for ways in which to safeguard the landscape. The models developed in Britain and the USA followed different routes, partly due to the scale of the forests and forest operations but also reflecting the type of forestry.

The US Model

In the USA logging took place (and still mainly takes place, at least in the National Forest System) in extensive natural forests, where the visual impact of sudden changes to the scenery, occurring over a large-scale landscape, can be very great. While the impact of an individual cutblock could have a negative visual effect, the cumulative impact over large areas was often considered to be greater still. This prompted the development of an approach to suit the scale of the landscape, the extent of the forest, and the need to try to control the rate of landscape change and its degree of impact, an approach that is generally referred to as 'visual resource management' or VRM. This approach aimed to manage the level of impact of logging on the natural scenery, especially as seen from key viewpoints, and this led to a highly developed visual management system intended to prioritize areas within large tracts for different levels of scenic protection (described below in more detail).

The UK Model

In Britain, the program of afforestation led to significant landscape change but each new planting project was relatively self-contained and there was some degree of flexibility over the layout of such forests. Owing to the fact that conserving an existing landscape was not an option, and considering the freedom to create new landscapes offered to the foresters of the time, a design-led model was developed following the appointment of a landscape architect, Sylvia Crowe, to be a consultant to the Forestry Commission, which aimed to use creative landscape design to produce new forest landscapes of good visual quality to fit into the landscape, especially as seen from significant public viewpoints. This is referred to as the 'proactive design approach.'

The Picturesque and the Natural

Although these approaches are generally quite different, they do have some similarities. Both models emphasized the value of the scenic, external mode of landscape experience. Viewers observe the scene from a distance and the aesthetic quality is associated with the notion of the picturesque, the landscape aesthetic model that emerged in the late eighteenth century and which for the first time celebrated the wild beauty and sublime qualities of untouched nature. Viewers expect to see 'natural' scenery and the presence of unnatural elements disturbs the quality (although in many countries, especially Britain, there is no actual natural scenery left). Design aspects were included in the American system, though not so highly developed and not so rigorously applied, while in Britain a degree of management based on relative sensitivity or landscape importance (based on visibility and numbers of likely observers) meant that some areas were designed more carefully than others.

Both Britain and the USA have hills and mountains that are highly visible from roads, settlements, hiking routes, and mountain summits, which partly explains the importance given to the scenic external mode of viewing and appreciation. Forest policy-makers and managers in other heavily forested countries with less dramatic topography, such as Sweden or Finland, where views of the landscape are confined more to forest interiors, did not feel a need to develop VRM programs to the same degree until much more recently. Nor did countries with forested mountains and high scenic qualities, such as Alpine countries, where the forests are managed by continuous cover or selection types of silviculture system. In these areas, although the landscape is highly visible and valued for its scenic, picturesque qualities, dramatic changes to the landscape tend not to take place because there is no clear-cutting, so that the perception of a never-changing natural landscape can be maintained.

The Former Soviet Union

In the countries of the Soviet bloc a much simpler approach was taken which remains in force in many of the former Soviet countries and in Russia itself. Here the forest was divided into three groups. Forests in Group One, accounting for some 25% of the forest area, include many forest reserves, protected for a variety of reasons, landscape and scenic value being one. In such reserves clear-cutting or any form of final felling is not permitted. Therefore, the landscape tends not to suffer dramatic changes, once more preserving the illusion of the never-changing character of the natural forest. Special landscape zones, where such landscape protection is applied, are frequently along roadsides, around cities and towns, and in other places where people can be expected to want the landscape to be protected. It was a highly centralized, regulation-based model, with no support from public preference studies or other evidence. Group Three forests are those where commercial exploitation is permitted (about 70% of the area) and Group Two forests represent an intermediate category. Such a system is effective at controlling the rate of landscape change in visually sensitive areas as long as the land is owned by the state and the central control is strong. Countries of the former Soviet Union, such as Latvia, which became independent and where much of the land was given back to its former owners, were forced to abandon such methods and look elsewhere (see below).

Following the development of the VRM systems in the USA and Britain, the other countries where these methods were adopted also tended to be where either large-scale clear-cut logging or significant afforestation took place in dramatic, highly visual landscapes and where the population expressed concern for the landscape (or where tourism in such areas was important). Thus, places like British Columbia in Canada, New Zealand, parts of Australia, and Ireland tended to be interested in developing similar systems. In the case of New Zealand, an early landscape design-based system was developed independently, whereas in most of the other cases it was adapted from either the USA or Britain, or included elements from both countries.

The Visual Management Approach

The US Forest Service developed a comprehensive system, starting in the 1960s and continuing through the 1970s. The first stage of development was to hire a researcher, R. Burton Litton Jr, to look at forest landscapes and to develop a visual resource inventory and evaluation program. Following this a basic description, analysis, and classification system was developed and implemented. The system was presented in a series of booklets, the first of which explained how to consider a landscape, how to describe and analyze its various characteristics and it introduced some basic design principles, such as line, form, color, and texture and considered the effect of scale, light, time, viewpoint, etc. on how landscapes are perceived in order to introduce some rigor and rationale into the subject (**Figure 1**).

The second booklet presented a method of landscape inventory and analysis so that a forest area could be divided into landscape units, emerging from an overlay analysis, each with its own combination of visual character, visibility, and level of sensitivity. This enabled planners to ascribe a series of visual quality objectives (VQOs) to each landscape unit. For example, in a highly sensitive landscape – one that was very visible to a lot of people, with a high visual quality (often meaning an undisturbed canopy of climax mature forest) and no visible logging – the foreground area might be given the VQO of 'preservation' where no logging was allowed, and the middle ground area, a little further from the viewer, given a VQO of 'partial retention,' where some logging was permitted as long as it did not disrupt the character of the area and any visible logging was subordinate to the rest of the landscape. The base level of VQO for the least sensitive areas was always 'maximum modification,' which meant that logging could proceed free of visual constraints (in some ways the implementation of the system was very similar to the Soviet model, though with some democratic input at the forest plan approval stage). Subsequent books in the series dealt with more detailed aspects such as the design and layout of logging, roads, utilities, and range issues to minimize visual impact.

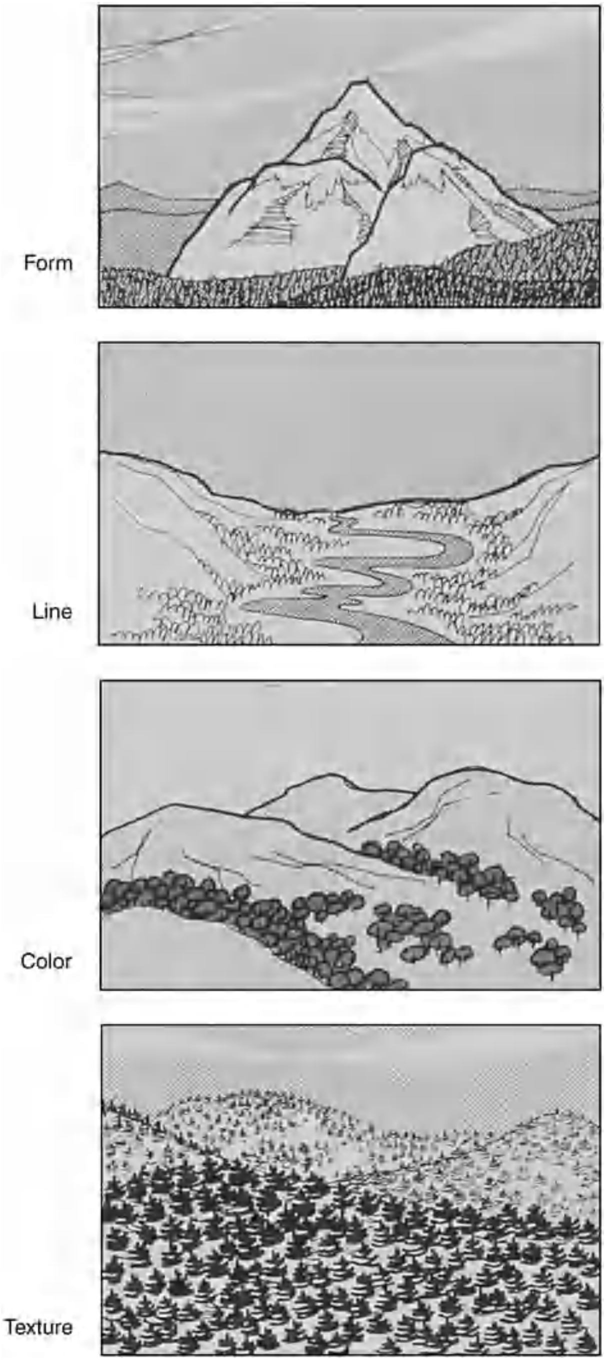

Figure 1 An example from the early US Forest Service visual landscape management system, presenting basic design principles for use in forestry. From US Department of Agriculture Forest Service.

Implementation

The implementation of this system was often prioritized for the visual portion of the landscape as seen from roads and key viewpoints (given that maximum modification was the baseline VQO supposed to be applied everywhere). Viewshed analysis identified what was and was not visible from a set number of viewpoints and the landscape was divided into units, analyzed, and given visual quality objectives. VQOs, set by experts, therefore represented the desired requirements for the visual resource, to be incorporated into the wider forest planning process which included many other resources, such as timber, water, wildlife, recreation, range, and so on. All these competing requirements had to be balanced and this led, in some circumstances, to the visual resource being overridden by other values.

As forest management came under increasing pressure from campaigners for biodiversity and the protection of endangered species (during the late

1980s and 1990s) ecological factors and ecosystem management began in many cases to supersede the significance of the visual and other resources. Logging in some forests of the Pacific Northwest was reduced in scale or ceased altogether for a time, so that changes to the visible landscape became less significant.

Scenery Management System

During the 1990s the system, then some 25 or more years old, was in need of an overhaul and the result was the Scenery Management System. This incorporated much of what was good about the original system but placed more emphasis on landscape character, which recognized the uniqueness of every area and the contribution made to it of cultural as well as natural features.

The current system starts with an Ecological Unit Description, sometimes called a mapping unit description, which represents the common starting point for both the Scenery Management System and for Ecosystem Planning. This was introduced in order to integrate scenery and ecosystem management to some degree and to overcome perceptions that the two aspects could be in conflict with one another. From the Ecological Unit Description an objective (i.e., factual) description of biological and physical elements is extracted, and combined with attributes for landscape character to produce a landscape character description. The idea is to be able to group the combination of scenic attributes that make each landscape distinct, identifiable and unique. This description provides the baseline or reference for the next stages, of defining scenic attractiveness classes and degrees of scenic integrity.

Scenic attractiveness classes are used to determine degrees of relative scenic value of different areas within a particular landscape character zone. There are three possible classes: A – Distinctive, B – Typical, and C – Indistinctive. The method of calculating relative scenic value is to describe the landscape elements that make up each character zone in terms of line, form, color, texture, and composition. Scenic integrity indicates the degree of visual disruption of landscape character. If a landscape has very low disruption it has a very high degree of scenic integrity and vice versa. There are six classes of scenic integrity, from Very High to Unacceptably Low.

The next stage examines the visibility of the landscape and takes into account two factors: (1) the relative importance to the public of various parts of the landscape and (2) the relative sensitivity of the scene based on its distance from observers. Relative importance to the public may come from a variety of sources, including special perception and preference studies. Constituent analysis (a technique for evaluating the views of different people) is used to gauge a level of public concern about aesthetic qualities, assessed as high, medium, or low. Distance zones of foreground, middle ground, or background are used to classify relative sensitivity.

The scenic attractiveness classes and landscape visibility data are combined to create Scenic Classes, ranging from 1 to 7, which indicate the relative importance or value of discrete landscape areas. These scenic classes are used during forest planning (**Figure 2**).

Landscape Value Maps

It is also possible to prepare a landscape value map using overlays in a geographic information system (GIS), in order to present the information spatially for use in various planning procedures. During the development of a plan for a forest area, the descriptive aspects of landscape character are used to develop landscape character options that are deemed to be realistic within the overall multi-objective forest plan. Once the forest plan has been adopted, the landscape character description becomes a management goal and the scenic integrity levels become scenic integrity objectives. These are very similar in nature to the previous visual quality objectives. The idea is that a given level of scenic integrity should not be reduced by forest activities, although it is also recognized that the degree of scenic integrity can change over time through natural landscape processes. In order to meet a specific integrity level and to carry out logging or road construction some design is needed. This is where the system is weakest: it provides very little guidance and few examples of how to achieve a satisfactory result.

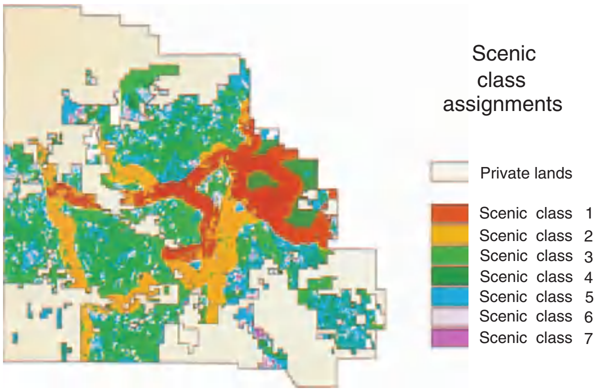

Figure 2 An example of a map showing Scenic Classes derived using the Scenic Management System. From US Department of Agriculture Forest Service.

There have been a number of spin-offs from the US Forest Service systems. The US Bureau of Land Management adopted the VRM system and also incorporated a systematic visual impact assessment process into it. This system was widely implemented during the 1980s and 1990s.

The British Columbia System

The VRM approach was also adopted by the Ministry of Forests of British Columbia, Canada. British Columbia is mountainous and densely forested, and also relies heavily on the timber industry for its economic well-being. In the early 1970s managers recognized that as more and more logging became visible on prominent mountainsides and from significant tourist routes, whether roads or shipping lanes, some kind of visual resource management was necessary. A landscape forester was charged, in 1979, with developing this based on the US Forest Service system, with many adaptations.

The system as originally developed and applied consisted of three steps. Step 1 is landscape inventory, where three elements are identified. The first is the identification of the extent of the landscape visible from established viewpoints such as roads, settlements, and recreation areas. The second element is the suite of landscape features present, both natural and human-made. The third element is landscape sensitivity, calculated from physical factors and viewer-related factors such as numbers of viewers, viewing distance, viewing duration, and perception.

Step 2 is landscape analysis, consisting of detailed mapping, the recommendation of VQOs, and the final establishment of VQOs by the forest manager, taking into account the other resource factors that have to be balanced against aesthetics. Step 3 is design and layout of roads and cutblocks, Step 4 is logging and silvicultural practices, and Step 5 is follow-up (**Figure 3**).

In 1997 a revised method was approved, moving to a more quantitative, numeric and prescriptive

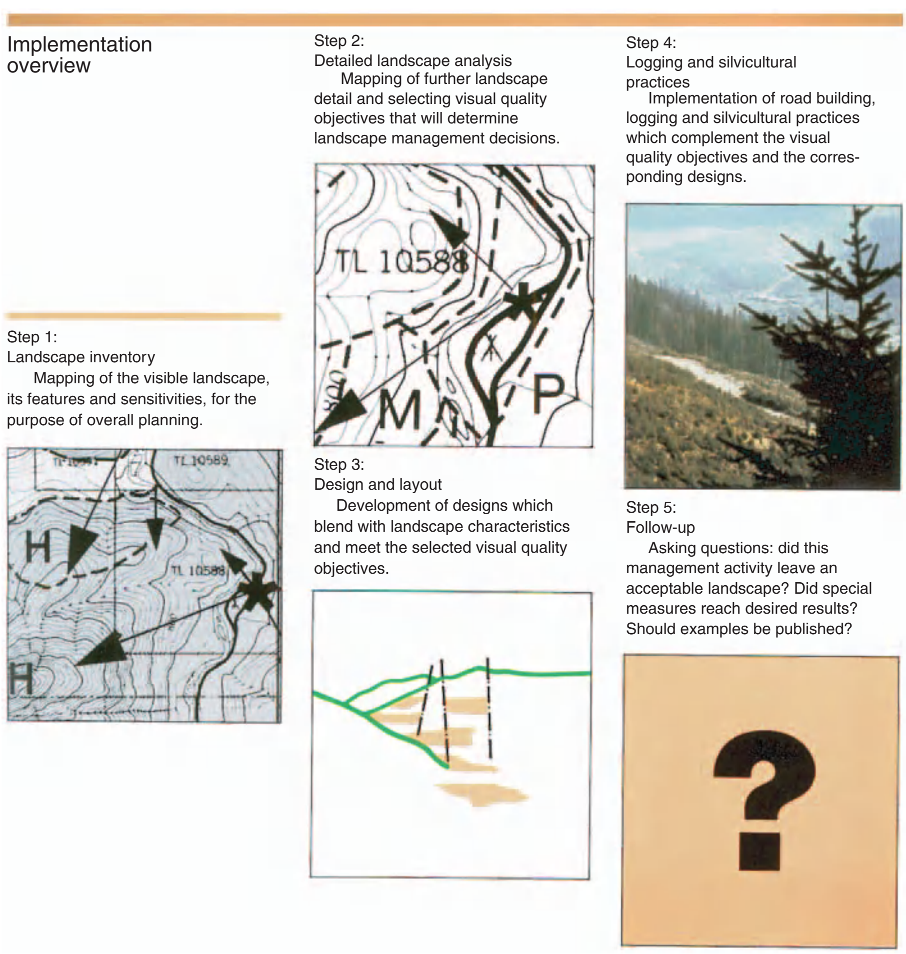

Figure 3 A section from the British Columbia Forest Landscape Handbook demonstrating the five steps of the original version. From British Columbia Ministry of Forests.

system of Visual Sensitivity Classes (similar to VQOs) within preidentified Visual Sensitivity Units.

The information is incorporated into the forest database on the GIS at each forest district and used to inform planners working for both the Ministry of Forests and forest licensee companies. By the early 1990s managers realized that the concept of visual management only achieved a limited level of landscape quality: it could direct how much harvest was possible in a given landscape unit but was not very successful at achieving good design. Thus a form of the proactive design approach was introduced to supplement the visual management system (see below).

Visual impact assessment is the logical development of the visual landscape management system in British Columbia. Where a timber harvest is being planned in a known scenic area with established VQOs, a visual impact assessment is required, in order to prove that the VQOs will be met. It is considered to be an integral part of Step 3 of the process described above. For this it is necessary to prepare a design for the proposed activity and to illustrate how it will look from established viewpoints using various simulation tools, and then to justify how it will meet the VQOs. This includes a qualitative assessment based on the adherence to design principles and also a quantitative assessment based on a concept of 'percent alteration,' where the proportion of the visual scene that will be altered by the proposal is calculated (in perspective, not plan). A table is used to assign allowable percentages in relation to different VQOs.

Australia

The US Forest Service system was also introduced into Australia. The states of Victoria and Tasmania adopted it and, especially in the case of Tasmania, developed their own variations. In Tasmania, the whole island has been divided into broad regional landscape character types. This was an integral part of the Visual Management System following US methodology, giving priority for visual management and generalized visual objectives to be achieved. It did not include design-based principles as in the UK but rather specified generic guidelines for various viewing situations and forestry related operations (**Figure 4**). The system is controlled by staff in the Forestry Practices Board, who regulate the environmental quality of logging proposals.

The most recent version of the Tasmanian Visual Management System incorporates a new tool for rating the importance of any area of the landscape and setting visual objectives to guide management, especially of the location and management of plantation forests. This is called the Rural Landscape Priority rating and has accompanying Plantation Landscape Objectives, which relate to three scales of the landscape and viewing. The new visual objectives are 'Integrated effect,' 'Codominant effect,' and 'Dominant effect,' based on the acceptable degree of influence of the plantation forest in the landscape.

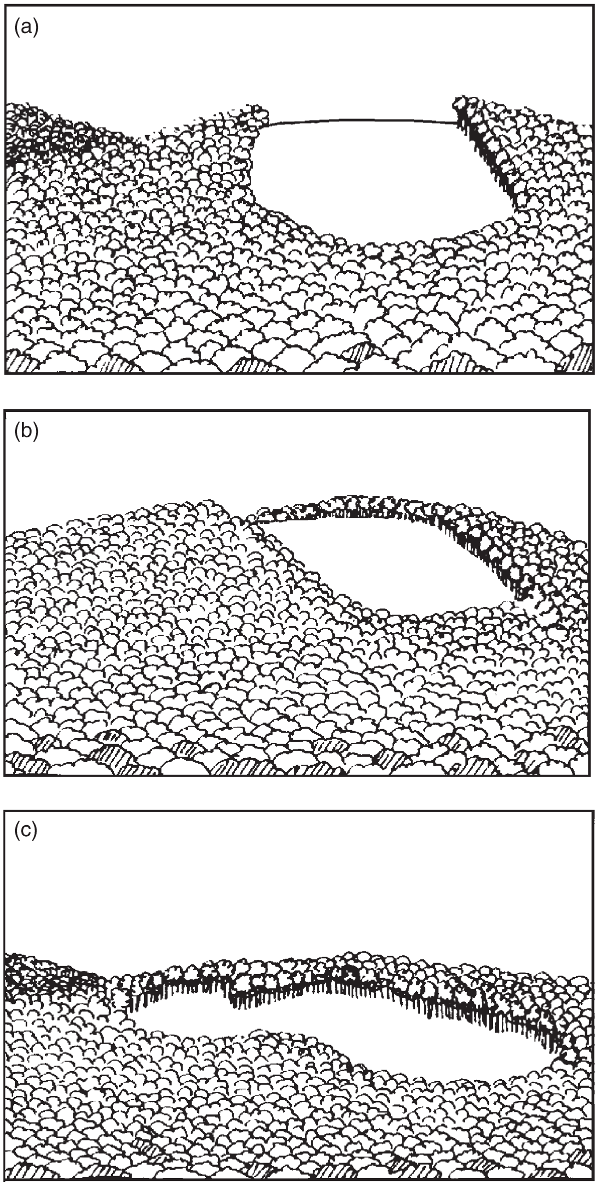

Figure 4 A sample of applied design from the Tasmanian handbook, demonstrating design in relation to a skyline. Skyline notches can have a strong visual impact even when seen in the distant background. (a) Skylines should not be cut directly across in the direction of the principal viewpoint, as the coupe edges will remain clearly visible for many years. (b) If skyline cutting is necessary, arrange the harvest at an angle to the main viewpoint. (c) The impact is lessened if the harvest is along, instead of across, the skyline. From Tasmanian Forestry Practices Board.

In the most sensitive landscapes the assumption is that the integrated effect would be appropriate using strongest adherence to positive design. However all three objectives require the application of principles taken from the proactive design approach (see below).

As an adjunct to the new visual objectives, local visual units are identified and corresponding landscape character attributes defined as a guide to forestry (**Figure 5**). The aim is generally to retain (and in some cases improve) the character diversity between different visual units by achieving specific designs for harvesting and establishment within each visual unit. This is being applied progressively to operations but could be most useful for strategic planning. Thus the management system evolved into a series of local design guidelines as well as incorporating the concept of visual quality objectives based on a viewing rating.

Computer Visualizations

The systems employed in the USA, Canada, or Australia also used early versions of computer visualization software to test the extent to which proposals for logging would meet the established VQOs (*see* **Landscape and Planning**: The Role of Visualization in Forest Planning). In this way a degree of quality control could be exerted in the design and approval process. More sophisticated visualization systems are now available to present much more realistic simulations, especially useful for public participation processes, public consultation, and visual impact assessment.

As well as the visual resource management methods described above for large-scale landscapes, some jurisdictions have developed guidance aimed at the smaller scale of individual logging operations. These concentrate on the leaving of screening belts along roadsides, reducing the impact of slash, ruts caused by harvesting machinery, and road construction. Attention to this kind of detail is important, especially when most views are from within the forest. US states such as New Hampshire and Minnesota have produced booklets describing such practices.

The Proactive Design Approach

In Britain, with its program of large-scale afforestation and, more recently, felling and replanting of its plantation forests, an approach has been developed based on designing forests to fit into the landscape. This originated in the 1960s, aimed mainly at new plantations of nonnative conifers that were being planted on bare, deforested hills and mountains. The original layouts were often highly regular, with

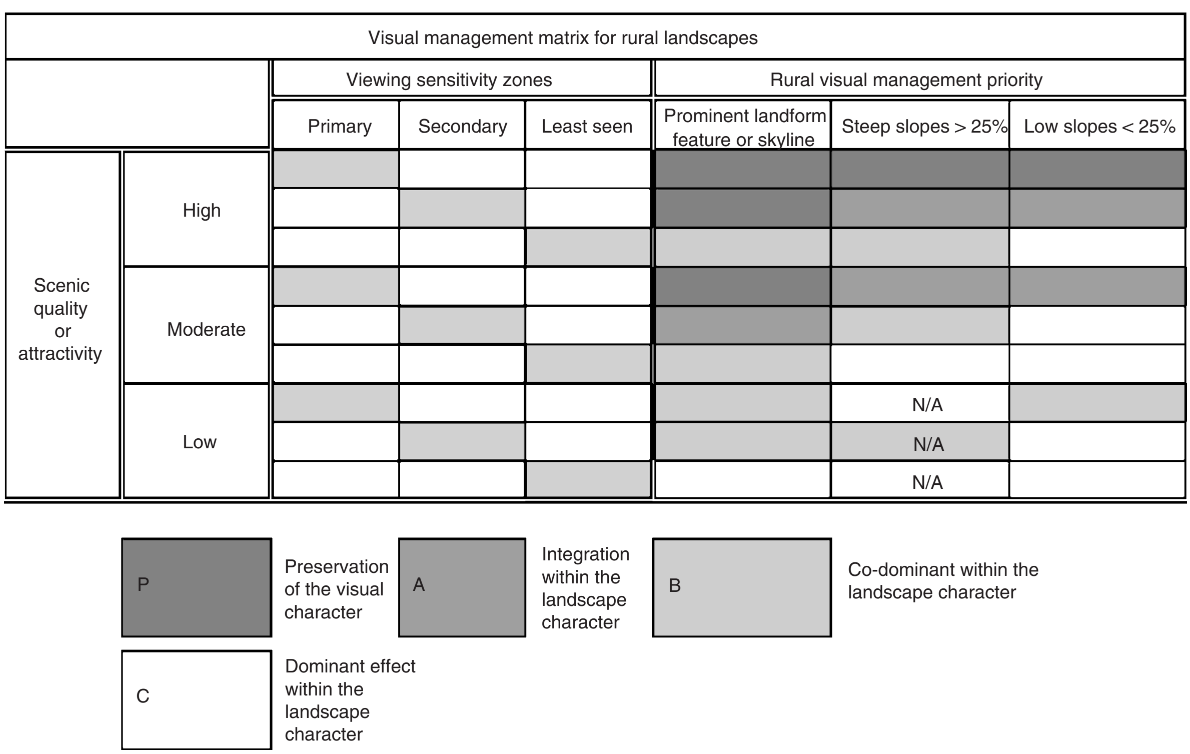

Figure 5 The new visual management matrix for rural landscapes, part of the Tasmanian system. From Tasmanian Forestry Practices Board.

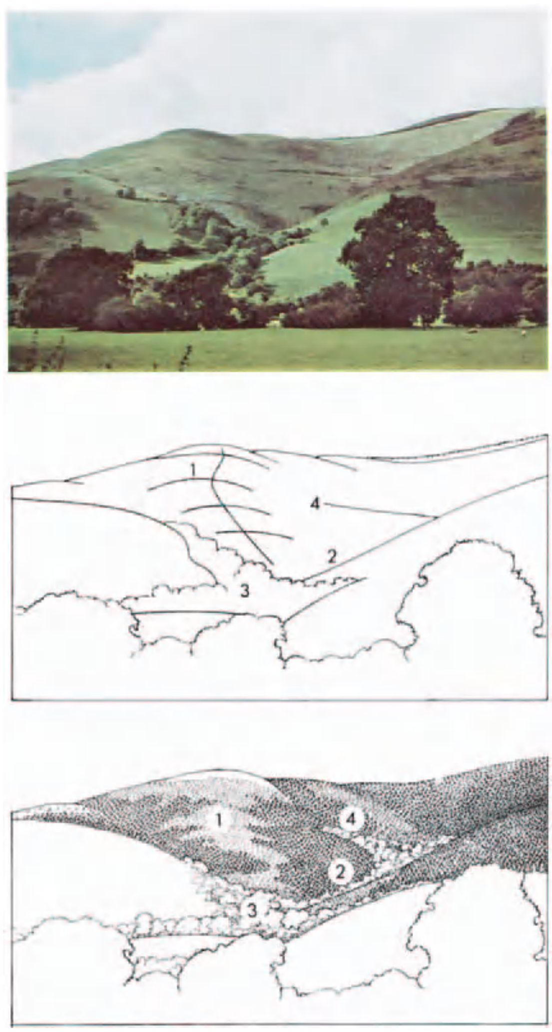
rectangular compartments, vertical fence lines and horizontal upper margins where the trees were planted up to a contour line.

To overcome the artificial appearance of these forests a number of design principles were adopted from landscape architectural practice, for example considering the shape of the forest, its scale and proportion, the degree of diversity of different species, the unity of the forest with its surroundings, how it related to landform, and so on. These principles were developed from the initial work of Sylvia Crowe (**Figure 6**) by Duncan Campbell, Oliver Lucas, Simon Bell, and later generations of landscape architects working for the Forestry Commission.

By the 1980s many of the early forests were ready for harvest and the rate of new planting declined, so the focus shifted to designing the patterns of felling, and the opportunity was taken to use the process of gradually harvesting these forests to completely redesign them, especially if they had not had much design input at planting. At this point a series of detailed guidelines on forest landscape design were published, aimed not only at the state forest sector but also at private forest owners. These guidelines describe what standards are expected and how to achieve them (**Figure 7**). They set out the way the design principles should be applied to aspects of the forest layout but as they need to be interpreted to fit each unique landscape area, they avoid being too prescriptive.

Forest Design Plans

This forest design approach was adopted in the early 1990s as the primary forest-level planning method to be used in Britain. Today, sophisticated 'forest design plans' are the main tool for planning and managing the forests, and they contain a significant element of



The great beauty of this landscape lies in the subtlety of the land-formation.

Analysis
The strongly modelled shoulder (1) flanks the amphitheatre-shaped valley (2). The drift of broadleaves (3) accentuates the composition whilst the forest road (4) cuts across it.

Solution
The modelling of the shoulder could be accentuated by larch (1). Broadleaves would accentuate the valleys (2), linking them to the existing trees (3). The encouragement of native growth at the sides of the forest road (4) curving down to join the valley broadleaves could permanently heal the road scar.

redesign to change the original monoculture, even-aged plantations into something more diverse and attractive.

The forest design planning system follows the well-established design process drawn from landscape architecture. Step 1 is to set objectives. These are not solely for visual quality but also for all the other resource values (this emphasizes the integrated character of this approach compared with the single focus on scenic aesthetics of many others). Step 2 is landscape survey (or inventory) where all the information needed for forest planning is collected. Step 3 is analysis. One key type of analysis is that of landscape character, using perspectives as well as plans (*see* **Landscape and Planning**: Visual Analysis of Forest Landscapes). This analysis is carried out by applying design principles as descriptors, especially focusing on the main components of the landscape and on the visual problems associated with the existing forest. Step 4 is to develop a design concept, which describes the overall strategy for redesign and the desired future character of the forest. Step 5 is more detailed design, where options for dividing the entire forest into coupes/cut blocks and for replanting it over time are developed and evaluated. The final design is presented using computer-based graphic simulation and submitted for approval in Step 6 (**Figure 8**). Steps 7, 8, and 9 are implementation, revision, and monitoring.

The idea of proactive design has also been tested and developed in British Columbia into a complementary method by which to ensure that the VQOs are being met. A program of training was undertaken to support this and a manual published to demonstrate the process. The design approach also expanded the scale from the single cutblock to the entire forest, looking into the future, so that anticipated changes over time and any unforeseen problems caused by cumulative effects could be tested (**Figure 9**). This developed into a much more integrated design method similar to that used in Britain, with the added element of a more comprehensive ecological analysis, based on work developed in the US Forest Service by Nancy Diaz and Dean Apostol, where the proactive design approach was also tried out (see below).

A similar program to that of British Columbia was developed in the Maritime and Atlantic provinces of Canada (Labrador, New Brunswick, Newfoundland, Nova Scotia, and Prince Edward Island) and Ireland. The integrated model was also applied, looking at the whole landscape over time.

Elsewhere, similar design approaches have been developed over the years. In the 1970s and 1980s a method was established in New Zealand and some regional guidance booklets were produced by Clive Anstey and Steve Thompson. In France researchers at CENAGREF, a government forest research agency, also looked at the British model and developed similar guidance for French foresters. Expansion of forestry in Denmark led to guidelines being produced on forest location and design, while researchers in Sweden have also produced a book which seeks to integrate ecology and aesthetics. In Latvia the design approach was also developed, based on the use of a simpler landscape character system and aimed largely at new afforestation, partly in response to the need to replace the Soviet system and also to reflect the change in land ownership and the abandonment of farmland to natural forest regeneration.

Privately Owned Forests

In countries where the forest area comprises the holdings of many small landowners, the kind of broad-scale assessment and design models described above are less easily applied. In Finland, guidance for forest owners considers three key objectives: paying attention to the regional characteristics of the Finnish forest landscape, harmonizing forest management measures with the long-range panoramic views of the landscape, and preserving the pleasant impression of the close range, or feature view. The design of felling coupes is also considered.

Assessing the Success of Visual Resource Management

There has been little recent scientific evaluation of the success of the approaches described above. Casual observation of the US national forests suggests that the VRM approach was successful at directing where logging took place but was unable to exert much influence on the design of individual cutblocks, let alone their cumulative impact. In British Columbia the introduction of design was largely in response to the perceived weakness of the VRM system in this area. Studies have taken place to test whether the expert-led system is supported by the public, for example in the degree of tree growth and stocking densities needed to deliver visually effective ‘green-up’ following logging.

In Britain two routes have been used to validate and test the design-led approach. Several studies have been carried out from the 1980s through to the present to validate the design principles used in the various guidelines and these broadly show public support for the proactive design approach. Secondly,

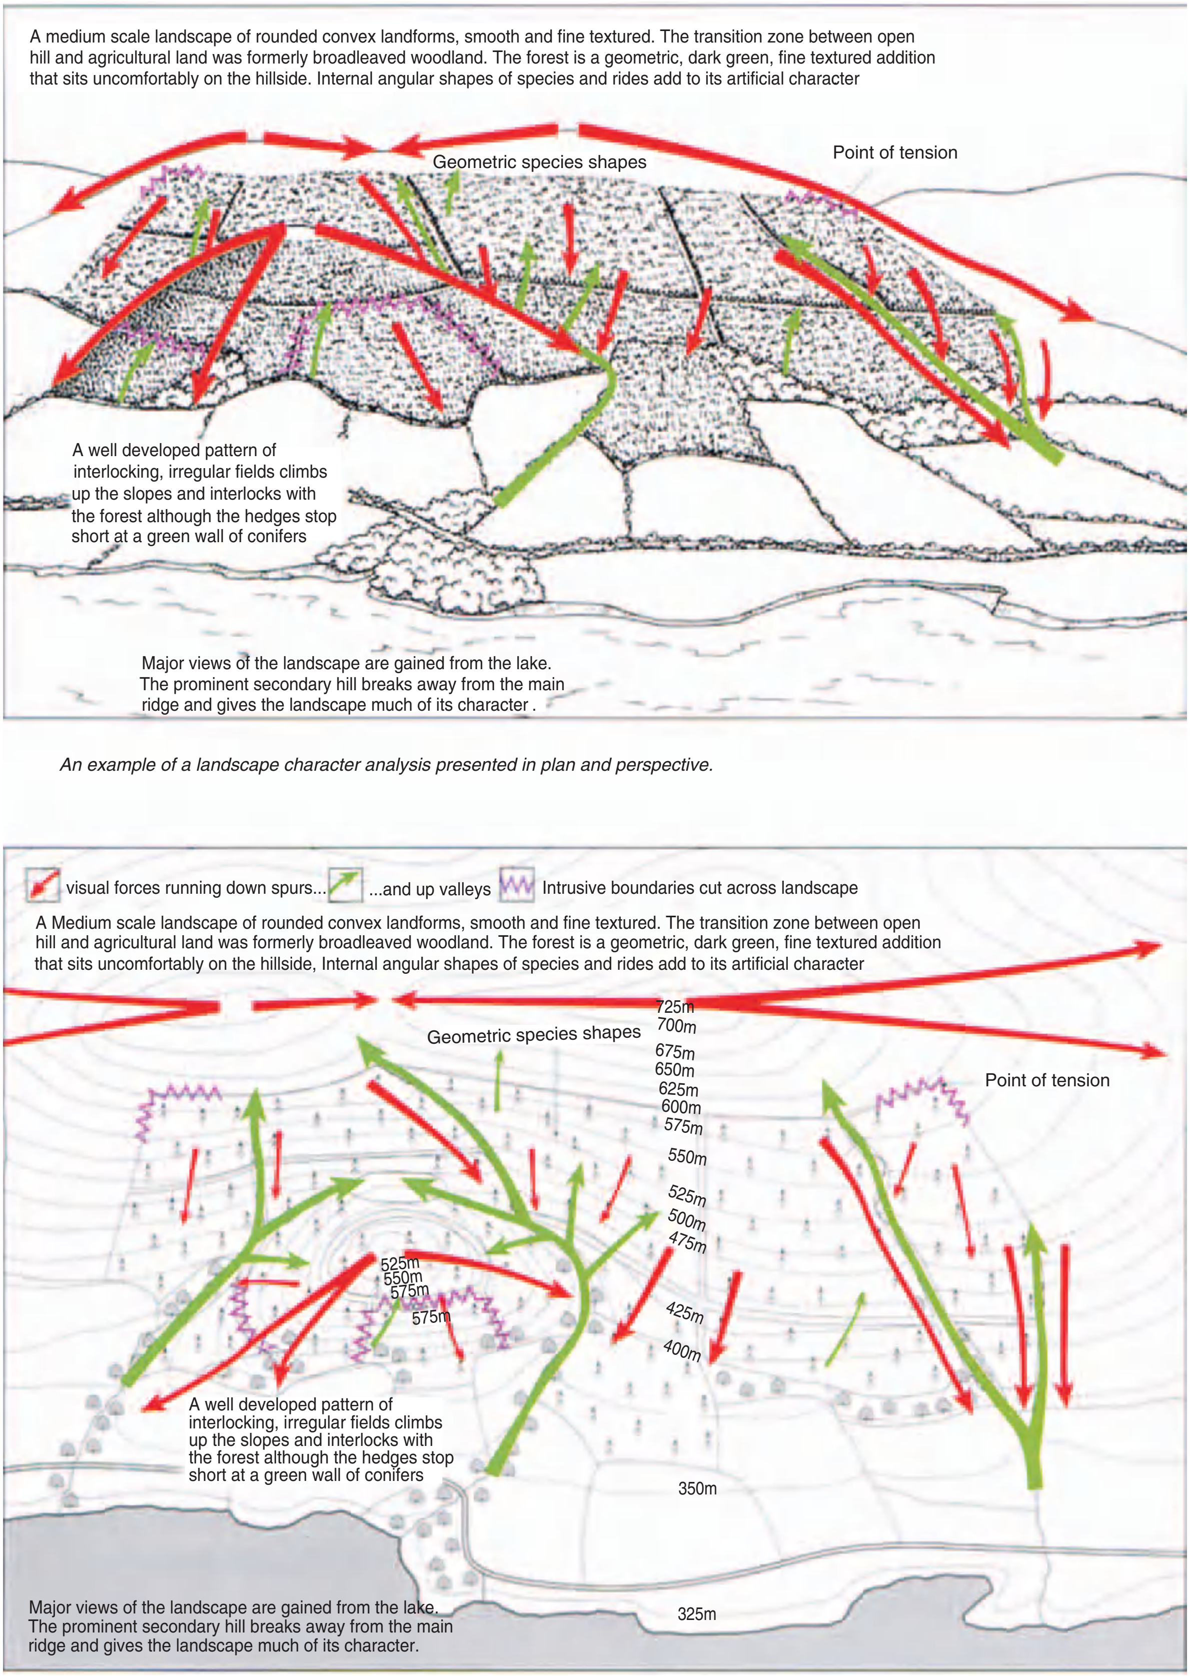

Figure 8 An example showing a detailed landscape character analysis, part of the forest design planning system. © Crown Copyright, reproduced with permission from the Forestry Commission.

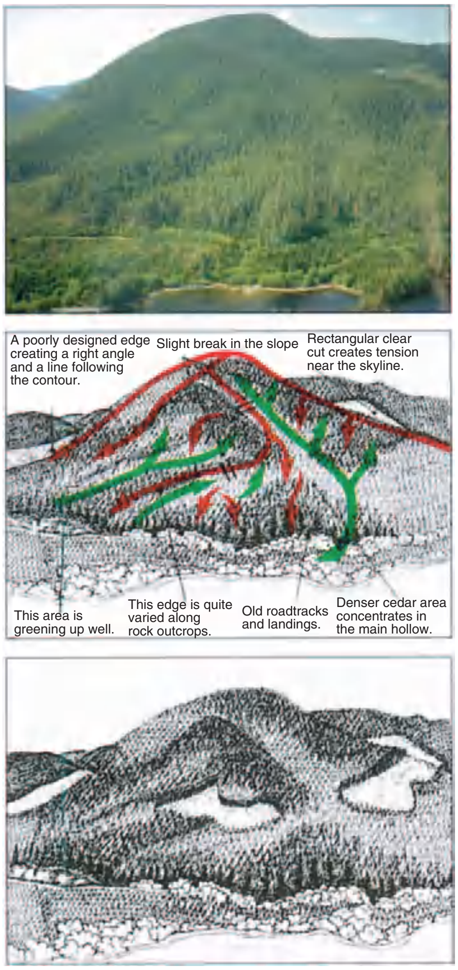

A landscape of rounded landforms, mainly convex but with some useful valleys. Older logging varies between poorly designed and acceptable. Any logging should avoid the upper slopes where the hilltop caps should be retained at a sufficient scale (2/3 of the depth). The main valley may need to be retained for riparian protection purposes. Vancouver Island, Vancouver Forest Region.

The following examples demonstrate how units can be fitted into a range of different landscapes using sketches and photographs.

Landform and land feature analysis.

Two clear cuts are proposed and shown as their basic shapes, which are designed to reflect those in the landform-flowing and curvilinear. They are positioned asymmetrically, one bigger than the other. Implicit in their design is the possibility of further units and unfelled areas. To reduce the contrast, the edges should be thinned and stable trees left within the units toward the edges.

Figure 9 A cutblock design example from the British Columbia Visual Landscape Design Training Manual. From British Columbia Ministry of Forests.

in 1999 a monitoring project across the UK assessed the extent to which the upland conifer plantation forests had reached an acceptable standard according to the guidelines. The results were mixed but showed that most of the design plans would, over time, meet the standards; one of the problems is the long timescale of forest design implementation. Also in 1999 some evaluation of pilot forest designs was carried out in New Brunswick and Nova Scotia, Canada. These had been developed with public participation so it was possible to find out how well the communities thought that the designs were being implemented and what they thought of the processes used. The results were positive.

As yet, aesthetics has not been well integrated into systems of sustainability criteria and indicators as used in certification programs. There are now a large number of completed projects where forests are being managed for timber, visual landscape, biodiversity, and other resources in an integrated way, avoiding the trade-off problems between aesthetic and biodiversity values found in the earliest US Forest Service planning systems. These will not demonstrate fully their effectiveness in comparison to other systems for some years yet, although the application of adaptive management may help to uncover any problems fairly early on.

Conclusions and Trends

With the increased interest in biodiversity, sustainable forest management, and ecosystem management, it would seem that the impetus for visual resource management of forests has to some extent seen its period of popularity pass by, although it remains in routine use. In fact, while the VRM approach has seen little development since the 1995 revision of the US system, the proactive design approach has continued to develop and to be fairly widely applied in some countries.

The main areas of development have been in the approach to holistic or integrated forest landscape design, where the design process as based on landscape architectural models has been refined to incorporate a wide range of objectives, including visual quality but especially aspects of applied landscape ecology.

The advent of GIS, computer aided design, sophisticated visualization methods (*see* **Landscape and Planning**: The Role of Visualization in Forest Planning), and computer modeling has enabled designers and managers to plan and design the visual resource far more effectively. While many studies of public perceptions and preferences for forest landscapes have been undertaken over the years, recent public preference studies have been used to calibrate design guidance (see above) but more such studies need to be done.

The use of landscape character criteria to develop local design guidance also means that visual landscape issues can be demonstrated to be important and that they can be incorporated into forest planning without serious conflict with other resources, without practical problems, or at unrealistic cost. With the increasing importance of community participation in forest planning, visual quality issues come to the fore once more, but this time require understanding of locally perceived landscape and aesthetic values and expectations for the forest.

Perceptions of Nature by Indigenous Communities

P Maiteny, South Bank University, London, UK

Introduction

The purpose of this article is to provide an overview of how indigenous communities perceive and relate to the bio-ecological contexts of which they are part and on which they depend. The main message is that there is much more to learn from them than information about plant resources or methods to enhance Western-style conservation management. The forest is only one such context and it is possible to discern principles that also apply in others.

There are two possible approaches to take in this article. The first is to compare and contrast particular beliefs, values, and meanings that different peoples ascribe to their surroundings. This is analogous to drawing up inventories of species or habitat types that can then be used as resources to further existing purposes – be they commercial or for conservation – and management methods. However, this approach does little to challenge underlying assumptions or encourage learning from primary cultural perspectives. Einstein once said that problems cannot be solved through the same type of thinking as caused them in the first place. He was referring not to a need to accumulate greater quantities of information but to the need to see and analyze the situation in a qualitatively different way. This entails bringing different meanings, values, beliefs, and theoretical perspectives to bear on the problem rather than assuming that more data applied in essentially the same ways will resolve it.

Evidence of continuing failures in stemming the tide of ecological disintegration in forested and other environments suggests that Einstein was right. It therefore becomes necessary to ask what it is about humans that seems to make us unwilling or unable to act in a way that regulates rather than damages the ecological systems on which we depend. This article argues that the root causes are less to do with quantity of factual knowledge – this will always be incomplete. More significant are the underlying meanings, interests, purposes, and priorities that shape what we decide about the relevance of those facts and how we use them. Understanding our own cultural assumptions and their flow-on effects is therefore as important as gathering indigenous knowledge – perhaps even more so.

For these reasons, this article goes a step further than providing accounts of values and perceptions. Instead it offers a framework developed in ecological anthropology for comparing different cultural views and logics on a level playing field – particularly Western and indigenous – on the basis of whether the behaviors they generate are more or less likely to result in sustaining the ecological contexts on which they depend. Such an approach requires that we step back from the beliefs, assumptions, and cultural interpretations of mainstream science to ask what benefits for forest management might be learned from longer-established indigenous world-views and beliefs. Although the latter inevitably differ in their details, an underlying shared orientation to nature is discernible as expressed through the different beliefs and practices.

There is often a temptation to idealize indigenous peoples as 'noble savages.' That is not the intention here. This article does, however, echo indigenous peoples' views of the world in recognizing that cultural beliefs, values, and meanings are intrinsic parts of ecological systems, not separate from them. This is necessary for a truly holistic approach to ecology. It is also logical, especially now that humans have a more powerful ecological influence than any other species. This influence is shaped by the cultural meanings we ascribe to our relationship with nature, as expressed through decisions and behavior.

The article describes how different types of meaning underpin different orientations to nature and how, in turn, these take the form of human choices and actions that may be adaptive or maladaptive in relation to the ecological processes on which humans depend. It articulates the dynamics of how this occurs. Aspects of Western tradition that retain perspectives more akin to 'indigenous' perspectives are also described. Finally, implications and potential learning for forestry management are considered.

Definitions

Homo sapiens is a species that necessarily lives according to meanings that it itself must invent. Culture is the name we give to the 'screens,' or 'lenses,' of beliefs, knowledge, values, and meanings that are shared by any given group of people, and through which they see and interpret the world. It is the domain of meaning-making. As such, it informs human behavior, interactions, and relationships – social, economic, and ecological. Other terms used more or less synonymously with culture are 'world-view' and 'cosmovision.'

To understand culture entails understanding symbols which, in simple terms, are signs that represent and are associated with something else according to the conventions of the culture concerned. Humans live in cultural – and therefore symbolic – environments. It is in and through symbols that meaning is encapsulated, expressed, and conveyed. Words are relatively simple symbols but they are still symbols. Others are more complex and abstract – for example, notions of the 'invisible hand' of economics, the 'superego' of psychoanalysis, or 'the divine,' conceived in some way by most cultures that have existed. Symbols – meanings – do not only reflect or approximate those aspects of the world that exist independently of humans. Humans, through their symbolic meanings and corresponding actions, also participate in its construction. Humans are physically made of the physical elements of nature. However, we also make ourselves through symbols and cultural meanings that we ourselves conceive – cosmologies, customs and norms, institutions, values, rules, and so forth. In turn, this also contributes to constructing the outside world – to the 'state' of the world. The extent to which nonhuman dimensions of the world – such as ecological 'life-support systems' – are incorporated into representations of them differs from one set of cultural meanings to another.

A key distinction – and relationship – to make in understanding culture in an ecological context is between physical phenomena and the meaningfulness that is ascribed to them. The two are frequently conflated. As anyone involved in participatory decision-making will know, the same external situation is actually many situations when perceived (and felt) through the cultural screens of various stakeholders. A forest, for example, is a source of timber or of other commercial products, an ecological life-support system, a wilderness or collection of species to conserve, a home, a tourist playground, and as many other things as there are interests in it. The same goes for something as simple as the color red. Individual and group insistence that they see a particular external situation in the 'truest' possible way results in conflicts with others who are equally convinced of their versions of the situation, their 'realities.' This has less to do with the facts of the situation than their interpretation by interested parties. It can be painful to admit that others' perspectives on a situation are as valid as one's own. Yet it is impossible to enter into the logic of other outlooks, such as those of indigenous cultures, without doing so.

Another difficulty Westerners face in entering into other cultural logics concerns the whole subject of religion. All societies are shaped by cultural belief, and most have had some form of religious belief at their foundations. This need not be a worry, especially if we think about religion simply as belief that articulates how a given people see themselves as embedded within a bigger context than themselves alone. Other philosophies and ideologies serve the same purpose. 'Secular religions' such as humanism, Marxism, nationalism, capitalism and, as some would include, scientism provide overarching frameworks that provide a context within which adherents can find a sense of purpose and belonging. The key difference is that, unlike spiritual religions, these secular religions do not conceive of anything beyond the human. It is often argued that they are more rational. However, one of the fundamental lessons of anthropology is that all cultures have an internal logic and that they may well seem illogical and erroneous to each other when viewed from outside.

The cultures of so-called indigenous peoples are generally contrasted with those of Western economistic, industrialized society. Other equivalent terms, such as 'vernacular,' 'first,' and 'primary' refer to the fact that these peoples were living successfully in their ecological contexts long before contact with Westerners. Literally, they were there first. The fact that these peoples have lived for so long in these places suggests that their cultures served them well in adaptive survival terms. In this very practical sense, 'primary cultures' are part and parcel of local ecology as, of course, all human culture is part of global ecology. Humans could not exist without it and we have a profound impact upon it. To distinguish the meaningful and the physical does not mean that they are separate or separable. On the contrary, it is to articulate more clearly how, and through what medium, humans interact with the physical realities they depend on. Although all humans perceive nature through cultural lenses and act in terms of these, we do nevertheless act on physical nature, manipulating, using, and managing it. In turn, physical nature acts upon us 'responding' ecologically and reflecting back the consequences of what we do to it. There is a feedback relationship between culture and nature in any given ecological situation. Anthropologists have used the terms 'cultural ecology' and 'human ecology' to emphasize this systemic interrelatedness.

Some Western scientists, foresters included, often assert that their work is value-free; that their aim is simply to understand forest dynamics and processes in objective terms. So long as this work remains purely descriptive, this is a valid claim. However, there is a fine line between objective description and a values-based assessment. Any assessment, and subsequent decision about a desirable course of action, is inevitably based on values, interests, and purposes that are deemed to be desirable from a particular perspective. The purpose of a forest, for example, might be construed to be timber or non-timber production, natural heritage, conservation of species, habitat, genes, or indigenous cultures amongst others. Such purposes are rooted in foresters' perspectives, beliefs, values, and norms that express their professional and/or societal culture or subculture. Furthermore, choices about what is important to research are also culturally influenced.

All this is not to say that the research, interpretations findings or implications for action are inherently wrong – that would itself be a cultural value judgment. It is simply to illustrate the often fuzzy boundary between science – as a descriptive, explanatory activity – and culturally defined prescriptions about the implications of findings for decision making. Assessments of indigenous cultural views of forests as being 'unrealistic' or 'counterproductive' must be seen in the light of various, and often conflicting sets of values and interests. Conversely, so must indigenous assessments of the appropriateness of modern methods of managing forests or other ecosystems. Each perspective may have much to learn from the other. If mutually respectful dialogue can be achieved, new synthesis could emerge that provide benefits for all stakeholders groups concerned.

As ecological anthropologist Roy Rappaport emphasizes, the logical – and critical – bottom-line test for human ecological sustainability is not so much whether any particular cultural approach is good or bad in its own terms but the extent to which the practices and behaviors it generates support or undermine physical life-sustaining processes, without which all human futures are jeopardized. This perspective is critical of cultural relativist positions that emphasize the equal legitimacy of world-views in their own terms without taking into account their impacts on ecological life-support systems.

As should now be clear, an underlying theme of this article is the role of culture in adaptation and sustainability. A definition of adaptation in relation to human ecology is therefore warranted. A particularly apt one has been formulated by Rappaport:

> The processes through which living systems of all sorts – organisms, populations, societies, possibly ecosystems or even the biosphere as a whole – maintain themselves in the face of perturbations continuously threatening them with disruption, death or extinction.

Successful adaptation ensures sustainability and, in human systems, cultural beliefs and practices are pivotal to adaptive processes.

Cultural Meaningfulness and Physical Law

As mentioned already, it is salutary to remember that before modern industrial–economistic culture arose, primary societies had existed successfully for thousands of years. Though small scale, this suggests that they were rather good at regulating their ecological relations. Logically, it also suggests that the cultural lenses through which they mediated these relationships were resonant with – or at least not overly antagonistic to – physical life-support necessities. By contrast, the scale of ecological problems precipitated by Western industrial society suggests such a degree of dissonance between our culturally mediated behavior and sustainability of ecological necessities that we are now feeling its consequences at a global level. This global predicament is, of course, the cumulative result of the smaller-scale activities of individuals, collectives, and professions of all sorts.

Dissonances between physical laws on which humans depend and the maps of meaning that we live by inevitably give rise to behavior that, in the long term, is damaging both to those physical systems and to ourselves. Furthermore, as technological power increases, so does the impact of these context-destroying meanings. Rappaport has warned that humanity's 'most profound problems flow from discontinuities between law and meaning... There is nothing in the nature of human thought to prevent it from constructing self-destructive or even world-destroying errors' – except, that is, the choices, priorities, and values that human thoughts and feelings produce. This, in a nutshell, describes a root cause of ecological problems and the source of their possible resolution.

There are always exceptions, but a certain resonance between the meaningful and physical necessity does seem to characterize many primary cultures. It may be argued that this is illusory and due to the fact that populations were too small and/or their technology too simple to put any great pressure on ecological processes, biodiversity, and so forth. Perhaps, given their populations and technologies, these peoples would have acted in analogous ways to Euro-Americans. Such a perspective neglects the possibility, however, that different cultural meanings themselves bring different priorities to bear on the development and use of technology.

Behaviors that support, or at least do not undermine, physical ecological necessities are not always consciously planned and, as such, can appear irrational in Western scientific terms. Though not based on precise understandings of ecological processes, the traditional beliefs and ritual cycle of the Maring people in the forests of New Guinea, for example, have been shown to generate behaviors that effectively constrain human activities from putting ecologically unsustainable pressures on the environment. Such matching between cultural practices and ecological sustainability is by no means inevitable, however, as illustrated in various Western contexts.

Decisions and behavior, then, are never wholly rational but generated by meaningful beliefs and purposes that are always emotionally charged. Meaningfulness is, after all, a felt experience and the more experiential and emotional it is, the more meaningful. This applies as much in Western contexts, including the meanings we apply to science, as in indigenous contexts. In both cases, it is meaningfulness, and therefore emotional attachment, that drives behavior more than purely descriptive scientifically derived information. This is the main reason for focusing this article on types of meaning: so as to shed light on the motivations underlying human impacts on nature in different cultures, and whether they are contextually adaptive or maladaptive.

The rest of this article describes three basic types of meaning that humans experience. They are described with reference to examples of beliefs from both primary and Western cultures. Their significance to the peoples concerned in terms of how they view human–nature relations is described, as are their implications for ecologically adaptive behavior.

Meaningfulness and Traditional Ecological Knowledge in Primary Cultures

The term 'culture' refers to the way of life of the people of a given social grouping, to the foundations of that way of life in experience and to the frameworks of belief that give meaning to it. When scientists extract and build into databanks information about the distinctiveness of plant uses, habitat management techniques, and so on, they are harnessing only one of the benefits to be derived from primary peoples' knowledge. It is the tip of the iceberg of what could be learned from them. This, however, is bound to be the case so long as the information extracted is interpreted solely in terms of their own cultural meanings and applied to their predefined purposes. The legitimacy of other possible meanings and purposes can be obscured, or actively rejected, when they do not correspond with Western goals and priorities.

Compared with Western culture, primary peoples tend to see the particular 'parts' of, for example, a forest in the broader context of the forest (or other environment), perceiving, making sense of, and therefore experiencing them as dimensions of a whole system. A systematic analysis of a forest or other ecosystem must recognize human cultures as intrinsic dimensions of these ecosystems. In acknowledging this, the typology of meaning described below can help us to expand our cultural perception of indigenous cultural knowledge as merely sources of 'useful information' for our databanks. It can thereby help us expand the range of what we could learn from people about environments as whole systems, in the process learning more about ourselves and our human–nature relations.

The typology describes meanings that range from the descriptive, quantitative, and analytical – where the emphasis is on discerning differences and creating categories – through more qualitative, conceptual, inclusive, and experiential forms of meaning through which humans discern the similarities and connections underlying distinctions. These more synthesizing forms of meaning are necessary to begin answering questions such as 'What does it all mean?' It is these forms, therefore, that are more influential in shaping behavior. Analysis is necessary for this but not sufficient on its own.

Logically, qualitative meaning always encompasses and forms the context for the quantitative. To quantify is to translate qualitative values into measurable criteria. Qualitative appreciation of value is always prior to quantitative measurement of it. Analogic sound exists before its digitized equivalents, not vice versa. Meaning is always prior to evaluation.

On the other hand, the existence of quantitative criteria of value always implies a qualitative context of value and meaning in the background that is assumed and often remains unstated. Hence, economic criteria such as growth in gross domestic product are used as measurements of increasing human development and well-being. This assumes and indicates a cultural world-view that increases in material consumption and accumulation are the most important factors in enhancing quality of life and developing a fairer, more fulfilling and generally better society.

The suggestion in this article is that, by entering empathically into the logic of other cultures, improving our understanding of them and comparing their logics with our own, Western natural scientists could interpret the data they collect in a more meaningful, contextualized way, and potentially learn new ways of perceiving ourselves and our purposes that are more adaptive in relation to how we engage with our own and others' environments.

Type 1 Meaning: Distinction and Classification

The first type of meaning emphasizes the need to make distinctions between one thing and another. It is the sort of meaning that classifies and categorizes, a process that is necessary to all people in order to function. Types of tree must be distinguished and defined as being useful in different ways. Human needs are distinguished from those of other species and villages from the surrounding forest or other ecosystems.

In Mali, as elsewhere, different ethnic groups have specialized in complementary subsistence strategies corresponding with particular ecosystem types. The Bozo live by rivers and their main traditional activity is fishing. The Bambara and Songay cultivate the more fertile land and forests. The Fulani pastoralists graze their animals on the lowlands. The Tuareg are traditionally more nomadic transhumant pastoralists, traveling great distances with their livestock to make the most of what vegetation is available in the more arid regions. None of this would have been possible without the essentially quasiscientific capacities of observation and discrimination.

Similarly, the Mende people in the Gola forest, Sierra Leone, traditionally distinguish between the 'red' forest which is wild and uncontrollable, 'white' homes and villages that are tame, and transitional areas such as ruined villages and farmland.

This type of meaning is often focused on identifying what is necessary to serve particular human interests. It is essentially self-orientated, be it towards the person, family, community, or ethnic group. Awareness of the impact of one's actions on other people and wider contexts is of relatively minor importance at this level of meaning. Such awareness comes into the picture with the meaning types 2 and 3.

Much professional interest in forestry is focused on tapping into this type of meaningfulness through building up inventories of species, identification of food, medicines and other materials, cultivation of plants with commercial, consumeristic potential, and biodiversity surveys to assess conservation value. Such activities must be seen in the context of Western society's prevailing norms, interests, and priorities, as expressed, for example, by commercial desires to patent plant material and ancient knowledge as intellectual property. Traditionally, such knowledge has not been seen in Western terms of ownership. Recent threats to limit access have started to change this.

Primary knowledge is therefore not only of value in identifying or extracting commercial or other benefits, outside the original ecological and cultural contexts. Beyond methods, knowledge, and management practice, there is also much to be learned about how relations between humans and nature are construed. This, too, is primary knowledge that has served people well for thousands of years. Evidence is emerging, for example, of conceptual understanding and application of sustainable principles, indicators, environmental education, and other practices that would be recognizable to ecological, forestry and other natural resource professionals. Such practices, however, are framed by, emerge from and are still embedded within traditional beliefs and worldviews. These have been termed 'traditional (i.e., primary) ecological knowledge' (TEK) and have been found to add to Western professional knowledge. To understand the contexts of belief and world-view in which knowledge and practices are grounded is itself of great benefit to management and policy, especially when it is recognized that these, and not information and practices *per se*, have a far greater regulating influence on behavior. This leads on to considering the next type of meaning.

Type 2 Meaning: Synthesis and Continuity

This type of meaning-making is about synthesizing and theorizing. People develop their understanding by creating frameworks, discerning similarities, patterns, and relationships between facts and information to form a bigger picture. This constitutes the cultural worldview or 'cosmovision' of the more technical type 1 meaning. It is through type 2 meaning that the world and everything in it becomes emotionally meaningful and therefore a greater influence on behavior. Human existence comes to be seen – and experienced – not only in a self-interested way but also in the context of a 'wider scheme of things.' This may extend to experiencing being part of this larger whole – of a sense of place – and of having a role to play within it. *Homo sapiens* becomes just one species amongst many, all of which have their place within the larger 'being.' Individuals feel a belongingness, connectedness, and purpose within their various contexts – family, community, society, and nation, forest and nature in general and, beyond that, the biggest possible context that is described in terms of sacred Ancestor Spirits, the Divine Creator and Sustainer, and other abstract concepts. The Islamic prayer, 'Allah-u-akbar' gives a flavor of this, when translated as 'God is Big' (to avoid the coercive connotations of the usual translation 'God is Great').

In more familiar terms, the emotional satisfaction when an understanding or discovery falls into place for a scientist gives a flavor of how type 2 meaning is experienced. The scientist feels they have contributed something to their professional context and will be recognized for this. They feel they have fulfilled part of their role in their professional community and, perhaps, in society generally. Some have even described a sense of awe in tapping into something that is much greater than themselves of which their particular discovery is a tiny part.

Primary worldviews warn against seeing the world solely in terms of dichotomies (i.e., distinctions) between, for example, nature and culture or mind and matter, whilst recognizing the need for them in day-to-day life. More often than not ecosystems are seen as encompassing humans in a way that informs the meaning of human life. This links with another feature of type 2 meaning: the meaning that comes from a sense of continuity between human generations, and between humans and nature. Understanding of ecological and other cycles is, for example, often expressed in traditional myths.

The Mende classification of the forest into wild, tame, and transitional areas was mentioned earlier. These distinctions are related aspects of a wider symbolic view of forest–human relations whereby different qualities of the forest are symbolized by spirits. The two transitional areas – ruined villages and farmland – are respectively associated with the dominance of nature over people and the control of nature by people. Since the latter always requires effort, nature is ultimately dominant, encompasses humans and is, therefore, to be respected. Forest spirits are uncontrollable and dangerous, though under certain conditions, they can proffer powers on people who are then also feared by others. Spirits symbolizing the village–forest boundaries such as Ancestors and the original forest people ('pygmies') who pre-dated the Mende also command respect. They are both of nature and of culture and, in some sense, represent the relationship and continuity between the two.

In Zimbabwe, Ndebele people – and they are by no means unique in this – actually define culture as continuity that is essential to survival and well-being; continuity of identity, belief, knowledge, skills, and trades passed from one generation to the next. There is a special power in its continuity which, if lost, will also result in loss of cohesiveness and an inability to survive in the long term, especially in times of hardship.

This continuity is often construed as being 'intended and approved by God and the ancestral Forebears.' Problems will arise if it is lost because 'you have done something against God's will.' Losing it will bring benefits in the short term but great problems later which 'you will not know how to deal with because the solutions are embedded in your culture.'

Similar thinking applies to the importance of continuity between humans and nature. An old Malozi belief is that 'without nature there'll be nothing.' Many elders there, as in other cultures, understand that society is nested within and dependent upon nature, and this is given as meaningful a place as human well-being, *per se*. All cultures have it embedded in their beliefs in different ways. Cultural ecologists point out that the mere fact that traditional cultures have sustained societies and ways of life for thousands of years – longer than any urban-based civilization – suggests that they are ecologically (and socially) adaptive. Such ways of thinking are, however, becoming less significant under the influence of Western beliefs.

As mentioned, a lesson from primary cultures is that human–nature relations are influenced more by world-views and beliefs than by facts and information. In any culture, the latter are necessarily framed, interpreted, and applied in line with meanings, values, beliefs, and priorities. If these are only instrumental and utilitarian, without practical regard for ecological contexts – or traditional cultures that so often express understandings of them – the trajectory set is likely to be detrimental to those contexts. Later in the article we return to this problem. At this point it is worth mentioning that conceiving of oneself as one element in a wider context on which one also depends – familial, tribal, societal, ecological, and spiritual – is more likely than type 1 meaning to constrain behavior against excesses that would threaten that context. Some anthropologists have also convincingly demonstrated that the wider, more encompassing and, in some sense intangible and irrefutable is the contextual belief (as with strong beliefs in spirits and the divine), the more effective will they be in constraining damaging behavior. It is, of course, people themselves, acting according to the beliefs, who constrain their own behavior or that of others who are, as it were, overstepping the mark. Even when constraining mechanisms are conscious and deliberate, they are still belief-based. This is the case in Western societies too, except that social pressures here tend to have positive economic effects that are detrimental ecologically.

In sum, type 2 meaning extends beyond merely instrumental interest in what 'use' things are to 'me' or 'my community.' Rather, it is about feeling I have a meaningful place, and perhaps a role to play, within a bigger context. To live and take my role, I need to use resources from my environment. However, they are not seen as 'mine' and 'my interests' are not solely my own. In these senses, type 2 meaning is of more religious and philosophical than type 1 meaning. Indeed, it is often expressed through religious practice, ritual, metaphors, art, storytelling, and poetry.

Type 3 Meaning: Identification and 'Unification' with Context

Type 3 meaning deepens type 2 meaning but is much less widespread, especially in Western, scientistic cultures. It is also the type that provokes the most scepticism in Western society, although it is recognized by psychoanalysts and the mystical traditions of Western religions. All these may be reasons why it is so rarely written about even in the literature on indigenous culture. It cannot, however, be ignored because, first, it is a feature of most, if not all, primary cultures. Second, those who experience it carry a great deal of legitimizing weight in the cultures concerned. In this sense, it constitutes the strongest evidence for the truth or validity of the type 2 world-views that inform attitudes and behavior in the cultures concerned.

It is difficult to describe this type of meaning in intellectual terms, as it is not referential like the other two, is less intellectual, and more emotional and experiential. The experience results in 'esoteric' knowledge and is therefore associated with certain respected members of society, such as priests, holy men and women, shamans, and healers. It is grounded in profound all-encompassing feelings of identification, absorption or unification with context and, as such, might better be described as a state of meaning. This often occurs through the practice of religious ritual or devotion. The distinction between subject (person) and object (context) is blurred. It is the sort of experience depicted in feature films as possession by, for example, a totemic animal or a forest spirit. It can engender fear and awe in spectators as well as great respect for the 'object' of identification. In both these senses, it is taken as first-hand experiential evidence of the human–context relationship, a relationship that, in type 2 meaning, is construed more in terms of faith and belief. Those who can experience it directly in type 3 meaning are, for this reason, also held in particular esteem as they are deemed to have a direct link to the contextual 'forces,' and as being agents or vehicles through which they communicate. This, for example, is the case for those special people in the Gola forest who are proffered powers by the forest and transitional spirits.

All three types of meaning are interrelated but any one of them may be more evident at different times. All of them are also necessary. Although types 2 and 3 increase experience of meaningfulness, to see the world only in terms of synthesis or identification would obscure crucial distinctions, making it impossible for a person to live a normal life. On the other hand, a world seen only in terms of type 1 meaning (which is equivalent to uncontextualized information) encourages fragmentation, lack of relationship with and alienation from necessary social and natural contexts, with resulting tendencies towards divisiveness. Values, purposes, and action founded on types 2 and 3 are more inclusive, relational, and demanding of reflection than type 1 meaning. They are more likely to take wider systemic issues into account and to generate attitudes and behavior that are more conducive to ecological sustainability. The ultimate expression of the synthesis and relational wholeness to which they refer is often expressed in terms of sanctity and divinity. Particular behaviors deemed to be excessive or destructive are seen not only as corrupting or disrespectful to that divinity but also self-destructive, given that actors are themselves part of the wholeness it represents. Persons who live according to meanings and values of this sort, who are not motivated solely by instrumental and self-orientated interests, are therefore likely to be more conscious of the impacts of their actions on the wider, more tangible systems of which they are parts and on which they depend.

The Cultural Context of Western Forestry and Sustainability Science

This article has taken an unconventional approach focusing on the internal conceptual logic of indigenous culture. Implicitly, it has also highlighted a key source of difference between indigenous conceptions of the human–nature relationship and Western values that shape the behavior of individuals and collectives, including professions such as forestry. Considering the latter in the light of the typology of meaning, it is necessary to ask what is the most important contextual reference of Western culture. On the basis of observation, answers might include consumer democracy, the Western way of life, economic development or growth, the global market or market forces, the individual (as the basic economic unit whose interests the market is deemed to serve), and the invisible hand. All these 'ultimate' secular meanings share two important features.

First, the object they ultimately serve is human beings themselves. They are anthropocentric beliefs, self-referentially self-serving. There is no sense in any of them of a meaningful context – a bigger whole – from which human beings have emerged, that encompasses us, that would in some sense continue without us and within which we conceive ourselves as playing a role.

Second, the dominant way of assessing and assigning value, and making decisions in all of them is quantitative rather than qualitative – namely, through the metric of money. Money dissolves qualitative distinctions so making everything comparable with everything else on the basis of quantitative measures. In reality, the qualitative world on which the metric is imposed can, logically, never be as simple as the metric itself. The uses or commercial, monetary value of timber cannot ultimately substitute for the ecological processes of the forest. It is almost tautological to say so, but when a people loses touch with the qualitative ecosystemic processes and functions on which they depend, the logical and inevitable consequence is that they come to prioritize the maximization of value purely in quantitative terms – for the 'potential' of these processes once they have been converted into money. Hence, if all value is seen in terms of money then, logically, money itself comes to be seen as the ultimate value. The survival functions of forests themselves (and of other ecosystems) come a poor second place.

Seen in the light of the typology of meaning, both these features of Western culture elevate type 1 meaning to the status of type 2 meaning and subsume the qualitative, contextual dimensions of type 2 into it. The distinction between humans and the rest of nature has become more meaningful than recognizing ourselves as aspects of one synthesized and integrated system. The practical implications of this are that the interests of a special subsystem (humans and our creations) – and perhaps of other special interests within it (political, economic, commercial or ideological) – are given priority over the more general purpose systems that, in physical fact, do encompass us and on which we are inevitably dependent. Most importantly, decisions about policy, management, evaluation, and behavior are made on this basis.

In the context of the forestry profession, the pressure is always to underpin and justify all proposals and decisions in quantitative terms of monetary costs and monetary benefits, be it for commercial forestry or forest conservation. In the latter, there are pressures to couch arguments in terms of quasiquantitative 'biodiversity' rather than the more qualitative 'nature' or 'ecological processes' and to devise complicated surrogate evaluations of monetary costs and benefits. No amount of quantification will ever be able to provide a full picture of qualitative complexity. It is logically impossible.

All this is in stark contrast to primary worldviews where type 2 meaning remains qualitative and contextualizing of humans in a context that is bigger than them, rather than squeezing everything into a human context for human purposes. Far from devaluing human beings, such perspectives enhance their meaning by giving them a participatory role in the wider system. They also influence decision-making and behavior in such a way as to insure against disintegration of life-supporting contexts. Perhaps paradoxically, such world-views ultimately serve physical human purposes (i.e., ecological sustainability) but by way of emotionally meaningful belief systems that conceive of human lives being about serving something greater than themselves. Such perspectives also seem to provide an expanded sense of meaning and purpose for individuals themselves, one that is rooted in something other than maximizing material gain and consumption. Interestingly, some esteemed Western scientists have, for some years now, been advocating the need for a modern contextualizing world-view of this sort which is also scientifically rigorous and philosophically logical. Edward O. Wilson's 'Evolutionary Epic' and his Pulitzer Prize-winning book, *On Human Nature* (1978), Sir Julian Huxley's *New Bottles for New Wine* (1957 and see quotation below), and the emerging discipline of earth systems science (an alternative name for science informed by James Lovelock's Gaia theory) are important examples.

This article cannot offer recommendations about how to improve the effectiveness of forestry practice, within its existing parameters, assumptions, and priorities – that is, within the disciplinary culture according to which foresters currently operate. Plenty of other articles attempt to do this (*see* **Social and Collaborative Forestry**: Common Property Forest Management; Joint and Collaborative Forest Management; Social and Community Forestry). The purpose here has been to indicate how indigenous cultures, which are rapidly becoming extinct, quietly point to the need for changes to the basic meanings and orientations that inform Western attitudes and practices. It suggests that the existing disciplinary culture of forestry (amongst others) might benefit from being more receptive to learning from the perceptions and values of people who live – or used to live – in the places where foresters work.

It is appropriate to end by showing that perspectives described in this article are not limited to 'indigenous' primary cultures. The following quotations illustrate that, though neglected, they also exist in Western scientific and religious cultures. The final quotation is a contemporary native North American perspective.

First, from Sir Julian Huxley, originator of the International Union for the Conservation of Nature, first Director General of UNESCO and winner of the Royal Society's Darwin Medal:

> The universe is becoming conscious of itself, able to understand something of its past history and its possible future. This cosmic self-awareness is being realized in one tiny fragment of the universe – in a few of us human beings… On this, our planet, it has never happened before… It is thus part of human destiny to be the necessary agent of the cosmos in understanding more of itself, in bearing witness to its wonder, beauty, and interest… Most extraordinary in principle, it (evolution) has generated values… Evolution thus insists on the oneness of man with nature, not merely in respect of biological descent and chemical composition, but because nature is the indispensable basis of his material existence, and also the indispensable partner in his mental and spiritual achievements… For man to fulfil his destiny, he must think of himself as in partnership with the cosmos.

(From Huxley (1957) *New Bottles for New Wine*. London: Collin).

Second, a perspective from twentieth century Kabbalistic Judaism:

> Putting themselves in relation with all things, humans will then remember that in the deepest being of all that exists is hidden the Divinity to which they themselves feel 'connected' and by which they are conscious of being inhabited. They will feel that the *Shekhinah*, the Divine Presence, desires to dwell in them… Humanity and nature. Ecological necessity: Humans, humble in front of their Creator and recognizing Its goodness, regard nature with respect and come close to it without expecting gifts… Always, while contemplating these wonders, humans sense their Creator who reminds them: 'See how beautiful is My work!… Be careful not to corrupt it… because if you corrupt it no one after you will be able to repair it!'

(Author's translation from Safran A (1998) Florence, Italy: Giuntina, *La Saggezza della Kabbalah* transl. P. Maiteny).

Finally, there is a striking similarity of meaning between the above quotations and the following, written by contemporary native North Americans:

> For all the people of the earth, the Creator has planted a *Sacred Tree*… The life of the tree is the life of the people. If the people wander far away, if they forget to seek the nourishment of its fruit, or if they should turn against the Tree and attempt to destroy it, great sorrow will fall upon the people. Many will become sick at heart. The people will lose their power. They will begin to quarrel among themselves over worthless trifles. They will become unable to tell the truth and to deal with each other honestly. They will forget how to survive in their own land. Their lives will become filled with anger and gloom. Little by little they will poison themselves and all they touch. As long as the tree lives, the people will live. It was also foretold that the day would come when the people would awaken. They would begin to search again for the *Sacred Tree*.

(From Bopp J, Bopp M, Brown L, and Lane P Jr (1985) *The Sacred Tree: Reflections on Native American Spirituality*, 2nd edn. Alberta, Canada. Four Worlds International Institute for Human and Community Development.)

Urban Forestry

C C Konijnendijk and T B Randrup, Danish Forest and Landscape Research Institute, Hoersholm, Denmark

Introduction

Urban forestry is an integrated concept, defined as the art, science, and technology of managing trees and forest resources in and around community ecosystems for the psychological, sociological, aesthetic economic, and environmental benefits trees provide society. It emerged as a discipline in North America in response to better ways to deal with the growing importance of tree-dominated urban greenspace, as well as growing pressures on green areas. During recent decades an international urban forestry research community has developed, as has an increasing body of knowledge as well as new approaches and techniques. Urban forestry has close links to forestry, but tends to be more multidisciplinary.

Concept of Urban Forestry

According to the Society of American Foresters' *Dictionary of Forestry* (1998 edition), urban forestry is defined as 'the art, science and technology of managing trees and forest resources in and around urban community ecosystems for the physiological, sociological, economic, and aesthetic benefits trees provide society.'

The concept and scope of urban forestry is summarized in **Table 1**. Urban forestry has the urban forest as its domain. An urban forest is defined as

Table 1 The urban forestry matrix, representing the scope of urban forestry

	The urban forest		
	Individual trees		Urban woods and woodlands
	Street and roadside trees, and associated vegetation	Trees in parks, private yards, cemeteries, fruit trees, etc., and associated vegetation	(forests and other wooded land, e.g., natural forests and plantations, small woods, orchards, etc.)
Form, function, design, policies and planning

comprising all tree-dominated green areas in and around urban areas. Thus it includes, according to Food and Agriculture Organization (FAO) definitions, forests, other wooded land, and trees outside forests, as long as these are situated in urban environments. The terms ‘woodlands’ and ‘woods’ are often used in an urban forestry context to distinguish between the wider urban forest resource and its components that have traditionally been defined as ‘forest.’ At a strategic level, urban forestry includes attention to the form and function of urban forest resources, as well as policies, planning, and design policies related to these. Urban forestry involves a range of techniques and approaches in terms of the selection and breeding of the right trees for urban environments and growing conditions, as well as tree establishment. Strategic and more operational aspects are brought together at the level of urban forest management.

The strengths of the urban forestry concept include the following characteristics:

- integrative, incorporating different elements of urban green structures into a whole (the ‘urban forest’)
- strategic, aimed at developing longer-term policies and plans for urban tree resources, connecting to different sectors, agendas, and programs
- multidisciplinary and aiming to become interdisciplinary, involving experts from natural as well as social sciences
- participatory, targeted at developing partnerships between all stakeholders, and aimed at multiple benefits, stressing the economic, environmental, and sociocultural benefits and services urban forests can provide.

Brief History of Urban Forestry

The earliest interest in trees and green areas at large as contributors to more attractive cities dates back to for example the ancient Greek and Roman civilizations. During the Middle Ages, many European cities took an interest in protecting the surrounding woodland resources, for example for providing food, fuelwood, construction wood, and fodder, as well as a reserve in times of war. Green areas inside the city walls often had a similar utilitarian role, being used as areas for agriculture, for example. Interest in the more aesthetic and recreational benefits of urban green space developed during the mercantilist and Renaissance periods. A new class of wealthy citizens emerged and showed an interest in estates, parks, and other green areas for leisure as well as for economic and prestige purposes. City authorities, often with the support of industrialists, took a greater interest in their green areas during the time of the Industrial Revolution. Large groups of workers had moved to the cities and needed to be provided with socially acceptable ways of spending their leisure time. Formerly closed-off royal and private parks and domains were opened to the public, and new green areas very much focused on active uses were created. Green space planning and management became more established parts of municipal activity during modern times (**Figures 1–3**).

With increasing urbanization and a growing demand for and pressures on urban green areas, the call for more comprehensive and integrated natural resource management emerged during the twentieth century. Various elements of urban green structures had traditionally been the domain of different professions. Individual trees along streets and roadsides had been given attention, for example through shade tree regulations in North America, and later became the domain of arboriculture. Horticulturists, landscape architects, and park managers had primarily been concerned with inner city public green space such as parks. Foresters, finally, had been hesitant to be active inside cities and remained at the urban fringe, where larger woodlands and other green areas are situated. A range of other professionals, including ecologists, biologists, and planners had also been involved.

The concept of urban forestry emerged in North America in response to increasing pressures on urban green spaces, and in recognition of the primary role trees play within urban green structures. Graduates of forestry schools were more frequently hired to manage municipal tree management programs because of their biological, quantitative, and

managerial skills. The term 'urban forestry' was introduced in 1965 as part of a study on the success and failures of a municipal tree planting program. In spite of initial resistance to the term and concept from both foresters as traditional urban green space professions, urban forestry gradually found wider scientific, political, and professional backing in North America. Other parts of the world, including Europe, took notice of the concept during the 1980s, but only during the past decade has a more established global research community within urban forestry emerged. Forestry has played an important role in the advancing of urban forestry, as have many other disciplines, including landscape architecture, landscape ecology, horticulture, arboriculture, soil sciences, as well as planning and social sciences.

Urban Forest Resources

Comprehensive assessments of urban forest resources have been scarce. Most assessments have been at the local level rather than national or international. Moreover, they have focused on only one or several components rather than the entire urban forest resource. While woodland data are often not very difficult to obtain due to existing inventories according to set definitions for 'forests' it remains difficult to assess the urban share of overall resources.

An exception has been the comprehensive assessment of national urban forest resources carried out by the US Department of Agriculture Forest Service. The study focused on tree canopy cover as the main indicator and combined methods using satellite imagery, existing statistics, and more detailed assessments at the local level. The assessment showed that about one-third of metropolitan areas defined in terms of administrative jurisdiction, in the adjacent USA is covered by tree canopy, i.e., approximately 8% of the entire country and about one-fourth of all US trees. When looking more narrowly at urban areas (cities, towns, and other built-up areas), urban trees still cover about 1% of the entire US land area. Less comprehensive assessments in Europe, often looking at land use categories rather than tree canopy cover, found green space cover of major cities to range from 5% to more than 60% of city area. Other comparative studies indicated a share of woodland within the municipal boundaries of larger cities to range between less than 1% to more than 40%. Although woodlands in and adjacent to urban areas mostly comprise a small percentage of the entire woodland base of a country, this still means several millions of hectares for Europe alone.

Urban Forest Functions

Social Benefits

The recreational values of forests, parks, gardens, and other urban green areas are especially well documented in the Western world. Urban woodlands in Europe, for example, attract as many as several thousands of visits per hectare per year, thus by far surpassing the average visitor number for woodlands. As people tend to prefer outdoor recreational areas close to their homes, urban green areas are the most popular outdoor recreational areas. Urban dwellers often form strong attachments to trees and green areas close to their homes, which often leads to controversy in cases of tree removal. Recently the health impacts of urban green space have also been studied. Urban green space can have a positive impact on physical and mental health, for example by providing settings for physical exercise, reducing ultraviolet radiation and air pollution, and reducing stress. By being actively involved in tree planting and management, local communities can be strengthened. In many developing countries, trees often have cultural and spiritual values that could assist new urban dwellers in finding their place in cities and towns. Urban forests also have high educational values by representing nature and natural processes in cities and towns, and they have often been used as testing and education areas for forestry and other disciplines.

Economic Benefits

Timber and other wood products from urban forests are in many Western countries often not very highly prioritized. But in other parts of the world they are crucial. Large parts of the urban population of Africa, for example, are still heavily dependent upon fuelwood. Systematic planting of street trees for timber production is widely practiced in countries of Southeast Asia; urban green areas, in which trees play an important part, provide non-wood forest products such as mushrooms, berries, medicinal herbs, rattan, and so forth. In addition, trees play an important role in urban agriculture, which provides an important source of livelihoods in developing countries. The focus in the Western world has been on additional economic values such as green areas contributing to more attractive cities for people to work, live and relax in. Studies in Denmark and Finland, for example, have shown the positive impact of nearby forests and green on house prices. Cities across the world have turned to planting trees and other greening efforts to attract investment and taxpayers.

Environmental Benefits

Trees and other vegetation intercept particles and gaseous pollutants. Moreover, they act as carbon sinks in the equations relevant within the context of global warming. Important in both the developed and developing world is the role urban vegetation plays regarding water. Trees reduce stormwater runoff and can assist with processing wastewater and minimizing air pollution and diseases from sewage water through its use for tree planting. Many cities have established and conserved forests for protecting their drinking water resources. Urban forests protect soils and moderate harsh urban climates, for instance by cooling the air, reducing wind speeds, and by giving shade. The shade effects of trees have proven to be significant in, e.g., the USA. Here shade provided by trees may result in building energy saving and lowering air conditioning cost. In arid regions, forest shelterbelts around cities help combat desertification. The level of biodiversity of urban green areas is often surprisingly high, representing nature close to where people live. Cities such as Rio de Janeiro and Singapore still have tracts of tropical rainforest within their boundaries. In Europe, national parks are found at the gates of large cities such as Warsaw, Moscow, and Vienna.

Pressures on Urban Forests

Urban forestry has to deal with growing trees in often very harsh urban environments. A first challenge is to protect green areas and trees against encroachment and annexation by other types of urban land use. The competition for land in and near cities is fierce. If urban forests can be conserved, they have to be protected against a wide range of biotic, abiotic, and anthropogenic stresses. Limited urban resources are very intensively used, and wear, tear, and ecosystem degradation by for example trampling, disturbance, and vandalism occur. Moreover, not all uses are easily accommodated and conflicts of interests are very common. Anthropogenic stresses are also caused by the presence of traffic installations and all kinds of infrastructure. Growing spaces for trees, and especially for those growing along streets, are limited. Levels of soil, water, and atmospheric pollution are often high, and climatic conditions can be harsh due to the artificial environment created by human structures. The use of deicing agents often has a detrimental effect on street and roadside trees. Consequently a large share of the trees planted in urban environments dies within the first years after planting. While pressures on urban forests in urbanizing societies are multiple, urban forest planners and managers are facing budget cuts and municipal reorganizations.

Urban Forestry Practice

Inventory and Evaluation

The starting point for urban forestry programs, policies, and planning is to assess the potential of the urban forest resource in terms of form and functions, as well as urban society's preferences regarding the benefits and services the urban forests should provide. Comprehensive urban forest resource and function inventories and monitoring are thus required to support decision-making. During recent years various (computerized) information systems to support policy-making and planning have been developed. A rapidly expanding body of research aims to assess the different social, environmental, and economic values urban forests can provide. In North America, for example, the environmental values especially of urban trees have been quantified in monetary terms, for example through assessing the cost avoided for air pollution reduction and cooling by using trees. Cost–benefit studies have shown that benefits of urban trees generally extend far beyond the cost of planting and management. This information is also very important for effective and efficient urban forestry. More efforts have also been made to determine what society's preferences are with regards to urban forests. Tools and procedures for public consultation and participation are increasingly used, in order to generate optimal benefits from a rather limited resource. Public participation is not only important at the strategic level, but also in establishment and management, for example to create a feeling of shared ownership.

Policies, Planning, and Design

One of the characteristics of the urban forestry concept is its strategic nature. Strategic programs and policies for urban forestry, however, are still not very common across the world. Exceptions are the Community Forests in the United Kingdom, embodying a long-term program aimed at generating socio-economic and environment regeneration of 12 urban agglomerations through forest and tree establishment and management. Another problem is the lack of integration of urban forestry with more general urban and regional policies and planning.

With only limited resources and a large societal demand, proper design of urban forests is crucial. Aesthetic aspects are of course important, as is the tradition in garden and landscape architecture, but design should also recognize the different roles urban forests play. Trees are living organisms, which requires a thorough knowledge of their development and possibilities as basis for design. Design has to build on strong links with future management, in order to develop a sustainable and multifunctional urban forest resource. The woodland part of urban forestry also requires extensive design, e.g., in terms of zoning different functions and providing attractive and safe environments for various forms of recreation.

Species Selection and Establishment

Urban conditions are very different than the conditions in rural or natural areas. Complex and often rather hostile urban growing conditions require a careful selection of the right tree species. There is a need for integrated focus on the identification and selection of cultivars and species for urban forestry, based on sound knowledge of site conditions and tree characteristics.

Urban trees have to endure a wide range of threats, as described before. As urban tree populations are often dominated by only a few tree species or families, the risks related to pests and diseases are larger. The dramatic impact of Dutch elm disease in North America and Europe is an example of this. In order to develop a more resistant urban forest resource, it is advisable to provide for sufficient variation regarding tree species, genus, and family.

The use of exotic versus native species has also been a topic of concern. Urban forests often include a high share of exotic tree species. There are several reasons for this, including the fact that some of these species might be better adapted to artificial environments, for aesthetic reasons, or interest in exotics as a result of the colonial era. The trend is towards increasing the use of native species, because of the demand for more nature-oriented management of green area's and interest in maintaining genetic resources.

The establishment of trees in urban environments often requires a major effort, especially when paved areas are concerned. Consideration should be given to the growing conditions below the surface, as sufficient space should be provided for root development. Special soil substrates have been developed for application in urban conditions. Sound establishment techniques are also needed in terms of planting holes, adequate water supply, protection against threats such as deicing salt, and proper staking if needed. Trees are often planted as part of construction and development schemes, so that the process of planting requires special care during the construction activities. In the case of woodlands, establishment of trees often is easier, although more difficult than in many rural forests due to higher trampling and compaction. Natural regeneration can supplement planting and sowing of seeds.

Management

The management of urban forests operates on different levels. At a more integrated and strategic level, management approaches should regard the urban forest as a whole, with linkages between its different components and its form and functions. Specific techniques are then also needed for the different components.

The management of single trees (arboriculture) builds on long tradition and experience. An important tree care activity is pruning, aimed at for example the training of young plants, maintenance of health and appearance (i.e., for aesthetic reasons), reduction of hazard, control of plant size, influence on flowering, fruiting, and vigor, and compensation for root loss. Different pruning approaches and techniques have been developed, but ‘modern arboriculture’ as developed in the USA during the 1970s is now widespread throughout the world. Modern arboriculture is based on a detailed understanding of tree biology, and the tree’s natural reactions to wounds, cuts, and so forth. Related to this is the discussion whether or not to treat wounds. The need to detect hazardous trees and assess tree vitality, however, is now becoming widely accepted as an important urban tree management feature.

Arboriculture also plays an important role in parks and gardens, but here management of other types of vegetation also comes in. More integrated approaches to the management of different park and garden elements are under development. Traditional forest management techniques are often not directly applicable to urban areas. Public scrutiny and different functions of urban woodlands require that management techniques have to be adapted. Education and awareness raising can enhance public understanding of management measures, thus reducing concern and the potential for conflict. Selection cutting methods are often seen as more appropriate for especially smaller-scale urban woodlands. Thinning regimes can be used to provide a greater diversity in urban woodland stands to meet, for example, urban demands for a wide range of recreational opportunities and experiences.

Management activities, just like policies and planning, should be based on detailed resource inventories and monitoring. These should not only provide basic information about the trees (species, age, height, and so forth), but also about vitality, special characteristics and their place in a wider urban forest context, not least related to human demands.

Urban Forestry Research and Education

By its very nature, urban forestry is an approach involving multiple disciplines and their specific body of knowledge and expertise. Urban forestry has also become recognized as a field of scientific relevance in Europe, and gradually an international research community has been formed. A survey of 20 European countries identified more than 400 recent or ongoing research projects on trees and/or forests in the urban environment. Many of these projects focused on only one element of urban forests, with about equal attention for street trees, trees in parks, and woodlands. The discipline of forestry had been involved in about half of all projects listed by national experts participating in the survey. Especially during recent years, however, more integrative research has been developed, focusing on the urban forest resource as a whole, as well as following a more multidisciplinary approach. Natural science gradually has become supplemented by social and planning sciences, although the natural science disciplines are still very dominant in urban forestry research in Europe, as well as in North America.

With growing scientific as well as practical interest, the need to develop urban forestry education also became clear. The USA hosts many degree programs in urban forestry. In Europe, higher education in urban forestry has been less developed so far. Recent years, however, have shown an increase in degree programs and student enrolment. Urban forestry education programs are also under development in other parts of the world, and most notably Southeast Asia.
