Forest Amenity Planning Approaches

C Ward Thompson, OPENspace Research Centre, Edinburgh, UK

Introduction

This article begins by defining forest amenity planning and its relationship with other planning approaches. The benefits of forest amenity are explored in the context of a brief history of forest planning and design. Modern amenity planning is set against the international agenda for sustainability and recent legislation on forest and landscape planning. Examples of different approaches from North America, Europe, and Australasia are used to illustrate the way amenity planning has developed in different world regions, with a particular emphasis on innovative and integrated approaches to forest amenity in the context of broader landscape-planning initiatives. The conclusion points to areas of emphasis and challenge for the future.

Definitions of Amenity Planning

Amenity is generally deemed to refer to something pleasant as well as useful, often (but not always) associated with leisure. Forest amenity planning is therefore concerned with visual pleasure or attractiveness, often termed visual amenity (*see* **Landscape and Planning:** Visual Analysis of Forest Landscapes), but also with other aspects of the forest that make it a pleasant place to visit or to have as a nearby resource. Amenity planning thus places people rather than timber at its heart, and pleasure rather than economic return as its end; this sets it apart from planning for productivity, where the focus is on silviculture and the economic value of the forest products. Environmental impact assessment (EIA) requirements in the planning legislation of many parts of the world, including Europe and North America, tend to focus on the impacts of plans on soils, water, air, fauna, and flora, in other words, ecological and natural heritage, rather than cultural heritage, although this is beginning to change in some regions and countries. Amenity planning implies, at its ideal, an integrated approach to planning where aesthetic issues are combined with recreational and other social needs as part of a holistic planning process. In an increasingly globalized society, amenity planning is also an important tool in preserving the diversity and distinctiveness of different locations and landscapes.

Forest Amenity Benefits

There is a considerable range of potential amenity benefits that forests can provide for people who live or work near them, or who visit them for leisure activities. The amenity benefits that have been identified include functional aspects such as landscape enhancement (especially in areas of dereliction or abandoned agriculture); screening (for example, of mineral workings); noise reduction; dust filtering; summer shade; shelter; wildlife conservation and enhancement; providing the setting for buildings or groups of buildings in the landscape; and providing a location for many different kinds of recreation, from bird-watching and berry-picking to children's play and mountain biking. The perceptual and psychological benefits that are also important in amenities include: contact with nature and the seasons; peace and tranquillity; spiritual and emotional renewal; relief from stress and improved recovery from illness; improving the attractiveness of the living environment and the quality of everyday life; and raising a sense of pride of place and self-worth.

These benefits combine to create an economic argument for amenity forest planning, since attractive and pleasant forests can add to property values and tourism revenues, and attract other, appropriate development in some cases. There have been many attempts to place precise economic values on environmental amenities, including forests, although all have their limitations due to the intangible nature of many aspects of amenity. The economic approach has usually valued forest amenity based on 'willingness to pay' criteria. Hedonic pricing attempts to place a cash value on landscape elements by estimating the value of amenity benefits from the costs and prices of related market transactions, while contingent valuation of a particular change in the landscape uses 'preferred elicitation' models to distill the value of different preferences based on how consumers decide what to purchase. Such methods have been used to show that creation and management of farm woodlands or urban forests for amenity benefits can be profitable in economic terms. However, recent research in both Europe and North America has suggested that a combination of monetary and nonmonetary approaches to values needs to be adopted in coming to decisions on environmental decision-making.

Amenity is a culturally defined term. Cultural differences between countries and regions lead to variations in recreational use and access to forest resources. Berry and mushroom collecting are, for example, very popular in northern and Eastern Europe, as is skiing in winter, while in the UK and parts of central Europe, cycling is a popular tradition that is developing in new ways with the increasing interest in mountain biking. Forest amenity planning approaches should, therefore, define their aims in the context of determining appropriate cultural understandings, expectations, and aspirations on the part of local people and visitors. It is this cultural component which has often proved problematic to incorporate in practice and has led to a rapidly increasing interest in public participation and 'stakeholder involvement' in planning processes in the 1990s and early twenty-first century.

History of Forest Amenity Planning

Forests have been managed for amenity for as long as privileged members of society have had control over parkland and woodland to enjoy at will. The earliest records of hunting parks, e.g. from Assyrian Mesopotamia (thirteenth century BC), or late Shang dynasty China (sixteenth to eleventh century BC), suggest that they were managed to create a beautiful and pleasurable setting for recreational pursuits. While these forest lands were often the exclusive domain of the ruling classes, there is also a long history of more modest forest management for amenity, combining the practical and the pleasurable in local woodland economies. Western European forests in the early Middle Ages, for example, provided sustenance and pleasure for their inhabitants in many ways, from grazing for pigs to a source of berries, nuts, mushrooms, and honey for local people, quite apart from any economic exploitation of the timber itself. In England, the Norman invasion of 1066 brought an end to this in many parts with the creation of huge areas of special jurisdiction, known as 'forests' (not all were wooded), policed at the king's pleasure for the preservation of game. Thus the treatment of woodland as common land varied in place and time, depending on the extent of woodland coverage and the dominance of regulation and restriction over local cultural traditions at different stages in history. Their legacy remains reflected today in contemporary laws and the approach to forest amenity planning taken in different countries and regions.

The grand plans for royal and aristocratic hunting parks in seventeenth-century Europe were an extension of the Baroque articulation of space and visual order, culminating in designs such as André le Notre's plan for Versailles; this took a comparatively modest hunting lodge and set it in an extraordinary landscape of woodland articulated with geometric patterns of canals, allées, and rides which dominated the landscape to the horizon. This was amenity forest and landscape planning at its grandest and most autocratic, and led to a reaction in Britain from which the more curvaceous and undulating lines of the English Landscape style grew. In the eighteenth century, when these landscape designers were making their impact, there was considerable interest in tree planting for amenity as a part of estate improvements, and there was a lively discourse on appropriate species, planting style and management for beautiful, sublime, or picturesque effect, an aesthetic approach which has dominated the English landscape ever since. Such planting was still largely in the private domain of the landowner, however, and came at a time of the Enclosure Acts which removed much land from common use. In the nineteenth century, foresters were primarily concerned with gaining recognition for their role in their country's economy and amenity values were not a major concern. Germany led the way in developing academic institutions to train foresters and developed planning and management concepts such as the sustained yield system, which resulted in chessboard-pattern stands of single-aged trees in contrast to the more natural pattern sustained by selective felling. It was not until the twentieth century that forest amenity planning for the public at large and for local community enjoyment became a frequent duty of public authorities and philanthropic organizations. By the end of the century, nearly all developed countries were committed to sustainable, multiple-purpose forest-planning policies.

Early Amenity Planning – Examples from the UK

The British Forestry Commission, established in 1919 largely to secure a strategic home supply of softwoods, began to address amenity matters in the 1930s with the establishment of national forest parks, planned to provide for the integration of timber production and recreation. Visual amenity was addressed by avoiding straight outlines to plantations and introduction of species variety within plantations and at their margins. The first attempts to liaise with public opinion on amenity matters, through the Council for the Preservation of Rural England, were also made at this time. By the 1950s the Commission recognized that recreation provision should be an aim in all its state forests, wherever desirable and practicable. Sylvia Crowe initiated the integration of planning for nature conservation, recreation, and visual amenity, through her pioneering work as landscape architect and consultant to the Forestry Commission from 1963 to 1975, and the Commission has since been at the forefront of forest amenity planning throughout the UK and internationally.

In the 1990s, Forestry Commission initiatives to encourage planning of amenity forests in an integrated way included development of the concept of community forests and woodlands, supported by woodland grant schemes and community woodland design guidelines. The focus is on planning local countryside near towns and cities for the benefit of the whole community. The concept draws upon other European traditions, such as the Stadtwälder (town forests) of Germany, many of which were created over 200 years ago, and the 895 ha of new polder woodlands in the Bos Park on the outskirts of Amsterdam, created in the early twentieth century as a major recreational resort for the city. Such community woodlands are often developed as a way of reclaiming derelict land in a postindustrial age and so they have been particularly targeted at former mining and manufacturing centers. The National Forest, which covers 502 km^2 in the Midlands of England, and the Central Scotland Forest, covering 1600 km^2 in the central Scottish industrial belt between Glasgow and Edinburgh, are two such examples, initiated in 1994–1995.

North American Developments

Scenic amenity has been a consideration in US forestry planning since the early 1900s. The US Forest Service used landscape architect consultants to develop early guidance on wilderness preservation and recreation plans which recognized scenic values. However, their first official landscape management program was not developed until 1968, based on work done by R. Burton Litton Jr. and influenced by the work of Sylvia Crowe in the UK. This led to the development of visual management systems for scenic amenity and forest plans with scenic quality targets (*see* **Landscape and Planning**: Visual Resource Management Approaches). In 1995 a Forest Service handbook for scenery management entitled *Landscape Aesthetics* gave guidance on forest planning for visual amenity. This has been developed separately from guidance on ecosystem management and nature conservation and on provision for recreation. The social and cultural dimension of amenity planning is not well integrated, by contrast with European systems of amenity planning. The British Columbian Ministry of Forests, Canada, used concepts of landscape character and forest landscape management borrowed from the USA to develop their guidance on scenic amenity in the early 1980s. This has subsequently been refined into a visual landscape management process, with guidance from Simon Bell of the British Forestry Commission, who recommended a more integrated approach to amenity planning as a whole – total resource planning and design. This more integrated approach has been used in parts of British Columbia and the rest of Canada, where high-profile proposals have raised complex and sensitive issues.

The United Nations Conference on Environment and Development (the 1992 Earth Summit) embraced a statement of forest principles and helped define concepts of sustainability in the trio of economy, environment, and social equity, through Agenda 21. Social equity refers to social justice, the concept of equal access to facilities and benefits for all of society's members, and thus has implications for amenity planning. The Local Agenda 21 advice to local authorities supported the notion that global issues might best be tackled at a local level, taking into account cultural issues and the specificity of place. Yet forest-planning approaches in North America have not necessarily adopted a holistic approach that reflects this in practice. Planning for visual amenity, for biodiversity and nature conservation, and for recreation have tended to be undertaken as different exercises with separate goals, leaving out the local and the cultural dimension, but are integrated through subsequent multiattribute planning and decision-making approaches, such as the US Forest Service forest and resource management plans or decision support systems using diverse criteria and indicators.

The Council of Europe's European Landscape Convention

As agriculture in Europe at the turn of the twenty-first century has become ever more intensified, so a new interest in forests has grown: forests which will reclaim marginal agricultural land and create new kinds of amenity for rural and suburban populations. This creates challenges for planning and design as a more enclosed landscape is not necessarily always welcomed by local populations, and may be unfamiliar as a recreational environment. Equally, in a postindustrial age, there are many areas of landscape dereliction in and around major urban settlements, where forestry can make a contribution to improving the environment and reclaiming the land. This is particularly an issue for Eastern European countries whose economic base, agriculture, and heavy and extractive industries are changing more rapidly than elsewhere. As European society becomes more urbanized, the pressures on forests and green areas close to towns are increasing at the same time that land for other uses is being abandoned elsewhere.

The Council of Europe's *European Landscape Convention* was agreed in 2000 and aims to promote landscape protection, management, and planning, and to organize European cooperation on landscape issues. The convention recognizes in particular the importance of public interest in the cultural, ecological, environmental, and social roles of the landscape as a resource. It highlights the way that the landscape contributes to the formation of local cultures and asserts that the landscape is 'a basic component of the European natural and cultural heritage, contributing to human well-being and consolidation of the European identity.' In the light of the perceived acceleration of landscape change, in forestry as in other aspects, it seeks to 'respond to the public's willingness to play an active part in the development of landscapes and to enjoy high quality landscapes.' Signatories to the Convention undertake to establish and implement landscape policies aimed at landscape protection, management, and planning, to establish procedures for the participation of the general public, local and regional authorities, and other interested parties in the definition and implementation of landscape policies, and to integrate landscape amenity with any other planning policies.

Although the Convention does not recommend in detail approaches to landscape planning, it is of relevance to forestry because it sets out a pan-European approach to managing forests for visual, cultural, and social amenity. It points clearly to the need for public and community consultation and collaboration in developing amenity plans for the future of forests, and gives a perspective on the contribution that forests make to shaping people's lives and identities far beyond the economic value of its products.

The next section sets out some recent examples of innovative or distinctive approaches to forest amenity planning from different European perspectives.

Finland and the Nordic Countries

Forestry landscape planning in many Nordic countries focuses on visual amenity and on the local-scale integration of ecology and nature conservation with forest management. There is a legal right to roam in Finnish forests for everyone and thus the amenity of the forest is potentially available to all. One Finn in five is a forest owner, many on a small scale, and so forest amenity planning is often at the level of 'family forestry.' Some of the cultural traditions which used to be common across Europe remain, such as the gathering of berries, mushrooms, lichens, and hunting of game, as well as more modern enterprises such as ecotourism. However, for the forests in and around urban areas, which are often owned by municipalities, multipurpose planning objectives are often lacking. In a joint project a similar pattern of lack of strategic investment and failure to plan for urban forest amenity is seen across much of Europe.

Recent work in Finland and Sweden in the late 1990s has aimed at developing better ways of integrating environmental considerations and biodiversity with sustainable production of forestry, taking a landscape amenity perspective. In a joint project, a geographical information system (GIS) has been developed to provide an easy user interface for forest management planning, allowing for the notion of interactive communication and learning with forest owners over planning proposals. The GIS program divides the forest into management zones and can be used to calculate and analyze the influences of public participation and the requirements set by society on the economics of forest planning at landscape and estate level. It is still in development at the time of writing.

By contrast with Finland and Sweden, Denmark has a comparatively low level of forest cover but rationalization of rural land in response to EU agricultural policies has led to a desire to increase afforestation. In 1989, the Danish government committed to a doubling of forest land from 12% to 24% within a period of 80–100 years. In designating land for afforestation, local authorities were given the power to determine the priorities for criteria, particularly in relation to reduction in agricultural land, wildlife conservation, and outdoor recreation, for their county. The plans for each county, which are reviewed regularly, are now made available using GIS, via the internet, to all citizens, and this allows for an increasingly democratic involvement in amenity planning. Such electronic means of communication and participation are becoming commonplace across Europe and elsewhere, allowing local interests in and definitions of amenity to inform the planning process.

Southern Europe

Compared with northern and central Europe, few southern European countries have highly developed or integrated forest amenity planning strategies, although forests may still have an important cultural role. An example from Turkey illustrates the European Convention's statement on the importance of cultural identities: the forest lands around the Bosporus have, since the 1980s, been designated as public assets which must be protected as part of an initiative to preserve cultural, natural, and historic assets in the Bosporus zone. By contrast, and unlike many southern European states, Slovenia still has a considerable level of forest cover (57%), most of which is private, often in shared and highly fragmented ownership. Perhaps because of this, Slovenia is unusual in having a long-term strategy for forestry that extends to advice and guidance for a horizon of 100 years. However, larger forest owners have pressed in recent times for a reduction in freedom of public access, thereby threatening traditional enjoyment of forests for mushroom picking. The matrix of open fields and forest is also changing as agriculture is abandoned and fields are left to natural succession. Thus, there are new challenges for amenity forest planning in Slovenia as for many countries now entering the European Union.

The UK Forestry Standard

The UK Forestry Standard, published in 1998, sets out a vision for new woodlands that recognizes the need to plan for multiple benefits in an integrated and sustainable way. Of the seven benefits identified as arising from new woodlands, at least three are directly associated with amenity planning: (1) enhancing the beauty and character of the countryside, and contributing to the diversity and distinctiveness of rural and urban landscapes; (2) helping to revitalize derelict and degraded land; and (3) improving the quality of life, especially in and around towns and cities, by creating opportunities for recreation, education, and local community involvement.

The Forestry Standard aims to integrate physical, biological, human, and cultural resource planning, recognizing the importance of cultural heritage and landscape amenity in the last of these. The tools for this include the items identified in **Table 1**.

Assessment of landscape character (**Figure 1**) has been an important tool for planning and design of forests in the UK since the 1960s and was made explicit in design guidelines developed as part of Forestry Commission planning methodologies in the 1980s (*see* **Landscape and Planning**: Visual Resource Management Approaches). Such assessment has since been codified in generic guidelines for landscape planning across the UK, developed separately for Wales and for England and Scotland. Forestry planning now incorporates this assessment, which reflects an increasing understanding of the complex nature of the cultural landscape (**Figures 2** and **3**).

Landscape Character Assessment (UK)

Landscape Character Assessment, promoted in 2002 by the Countryside Agency in England and Scottish Natural Heritage, is an amenity-planning tool designed to serve a range of predominantly countryside planning purposes, including forestry planning. It recognizes the importance of people and place and the cultural/social, perceptual and aesthetic and natural elements of this interaction which determines what we call 'landscape.'

In developing the guidelines for landscape character assessment, a 'character of England' map was produced by the (former) Countryside Commission, building on previous work by English Nature and English Heritage. An equivalent exercise in Scotland produced the Natural Heritage Futures initiative, which promotes integrated management of the natural and cultural heritage. The Landscape Character Assessment Guidelines grew out of these exercises. Examples of the range of possible uses

Table 1 Sustainable forestry management in the UK: amenity and cultural resource planning

Criteria for sustainable forest management	*Source of national-level indicators*	*Forest management unit indicators*
Rural development Access and recreation Quality of life in and around forests Increased awareness and participation Community involvement Other land uses	Surveys of forestry employment Information on employment multiplier effects of forestry Rate of afforestation in areas of strategic importance for other land uses Surveys of visitors to forests, UK Day Visits Survey, Time Use research reports Monitoring of planting in sensitive areas as defined by Indicative Forestry Strategies Inventory–woodlands close to towns National opinion surveys Reports on public awareness and involvement in forest biodiversity conservation	Evidence that: • Access is available along public rights of way and permissive routes • Information is promulgated about recreational facilities and access • Opportunities for walking and other recreational pursuits in woodland are considered • Activities associated with recreation do not compromise unnecessarily any future benefits of forest products or nature conservation • Efforts are taken to mitigate the consequences of vandalism or other antisocial behavior in woodlands • Requests to use woodlands for environmental education have been reasonably considered • Consultations and involvement of communities are reasonably accommodated, especially in relation to work opportunities
Conservation of heritage features Landscape quality	Surveys and registers of ancient monuments Reports of damage to ancient monuments Woodland aspects of rural countryside character and landscape assessments Survey reports for special areas, e.g., national parks, moorlands, coastal plains	Evidence that: • Important sites are clearly recorded • Sound principles for integrating archeological sites in woodland are adopted • Archeological sites are protected and damage is avoided • Landscape principles of forest design are used • Cultural and historical character of countryside is taken into account when creating new woods and when making changes to existing woods

for landscape character assessment in the planning process are shown in **Table 2**.

Landscape character assessment is seen as a two-stage process, the first a relatively objective one in which the landscape, at whatever level or scale is appropriate, is mapped, classified, and described in a (supposedly) value-free way – 'characterization' – and the second an evaluative process where judgments are made using approaches appropriate to different end-uses, e.g., woodland development. Judgments based on the landscape characterization are then available to help in the decision-making processes which lie beyond the landscape character assessment exercise. The main approaches to making judgments about landscape character are identified as:

- *landscape character and guidelines* which focus on the conservation and enhancement of the key characteristics of landscape character types and areas
- *landscape quality and strategies* which provide a strategy for the whole landscape character type or area based on considerations of landscape quality and the physical state of the landscape
- *landscape value and designation/recognition*, based on the relative value attached to the different landscape character types or areas and their ability to match with specific criteria
- *landscape sensitivity and capacity*, i.e., the ability of the landscape to accept change without adverse consequences.

The production of the Landscape Character Assessment Guidelines has been accompanied by a discussion on how stakeholders can help, recognizing the need to incorporate this dimension more fully in making landscape assessments. A discussion paper has identified:

- stakeholders that are 'communities of interest,' e.g., government departments and agencies or special-interest groups such as the Royal Society for the Protection of Birds
- stakeholders that are 'communities of place,' e.g., local residents.

There are a number of benefits to be gained from stakeholder participation in making judgments about the landscape and its future, not least in identifying what it is that particular stakeholders value in the landscape, and why (*see* **Recreation**: User Needs and Preferences). The 'globalized' aspects of landscape designation have involved communities of interest, by and large, in identifying what is valuable in the landscape. Assessments of this type have involved expert judgments on biological rarity and historical significance. The involvement of communities of place in identifying the value of landscapes must be, necessarily, a more local endeavor.

Australia and New Zealand

The New Zealand Forest Service of the 1980s, since disbanded, developed an early model for holistic forest planning, combining visual amenity with recreation and cultural provision that recognized the diversity of the landscape and the need for interpretation. Discussions of amenity planning approaches often focus on the challenge of defining amenity precisely; this has been particularly so in New Zealand and Australia. Amenity values have been defined as natural or physical qualities and characteristics of an area that contribute to people's appreciation of its pleasantness, esthetic coherence, and cultural and recreational attributes. Amenity planning policy in Australia aims to maximize the amenity enjoyed not only by the relevant property owners and occupiers, but also by neighbors and by the community at large. Social inclusion and planning for forest access for less mobile members of the community have become important issues here, as they have worldwide.

The original Landscape Character Assessment for the National Forest was central to the development of the Forestry Strategy. The consultation on the Strategy provided the opportunity for comment on the descriptive assessment and on the Forward Strategy for forestry creation based on the assessment. Consultation techniques included:

- written responses to the full strategy (220 replies)
- 1300 questionnaries returned by the general public from 18000 distributed summary documents of the strategy
- extensive media coverage – press, radio, and production of a video for loan to outside groups
- 30 talks to specialist stakeholder groups
- six public meetings and six day-long manned displays in local shopping centers
- watercolors commissioned to depict the changes in rural and coalfield landscapes over a 50-year period, for use in talks and exhibitions
- community views sought by interviewing six groups from within a typical coalfield village and an urban settlement from within the Forest

International Trends

On the international scene, amenity forestry planning must increasingly take into account the United Nation's Educational, Scientific and Cultural Organization (UNESCO) World Heritage Convention and the International Council of Monuments and Sites (ICOMOS), which advises UNESCO. The protection and conservation of archeological heritage in forest areas are concerns in many parts of the world, particularly where afforestation is increasing. Less attention has been paid to date to the concept of designating forests as cultural landscapes (as opposed to natural landscapes) in their own right but it seems likely that, in future, ICOMOS may designate world-class heritage landscapes on the basis of their cultural forest traditions. This is particularly likely as the European Landscape Convention and other initiatives across the world indicate a shift in emphasis on heritage value from monuments to people.

In some countries, forest planning may need to take into account the distinctive role that forests play in aboriginal cultural traditions. Forest planning in developing regions must also integrate amenity value in the context of subsistence economies and local ethnic communities' needs. Research has shown that recreational enjoyment of woodlands

Table 2 Landscape character assessment contributions to the planning process

Planning
- Capacity studies for different purposes, e.g., housing
- Expansion of settlements at the urban edge
- Input to environmental assessment of development projects

Landscape conservation and management
- Guiding land use change, e.g., woodland expansion

Landscape change for regeneration
- Community forests
- Reclamation and restoration strategies

Wider environmental initiatives
- Local agenda 21
- Environmental capital
- Environmental monitoring

Adapted, with permission, from Countryside Agency and Scottish Natural Heritage (2002) *Landscape Character Assessment, Guidance for England and Scotland*. Wetherby, UK: Countryside Agency Publications.

may often be restricted for women and young people, for older and disabled people, for those from ethnic-minority groups, and for socially disadvantaged groups. Amenity planning is increasingly required to take an inclusive approach which addresses these issues, although planning procedures which do so in practice are rare.

Conclusion

European traditions in forestry continue to provide a far-sighted model for the development of integrated amenity planning tools and multiple-use forest planning. Recent areas of interest in amenity planning in the UK include tranquillity mapping (mapping areas of countryside away from noise and visual intrusion) and mapping of areas free from light pollution, as well as focusing attention on the physical, mental, and social health benefits of living near woodlands, recognizing the potential for forests to improve people's quality of life. Nordic European countries such as Finland, with a different and more continuous tradition of living in and enjoyment of forest landscapes, have contributed to planning models which place an emphasis on the cultural landscape of forests. Early holistic approaches to forest planning in New Zealand have been matched by more recent innovative community-planning models in Australia. Worldwide, with the advancing urbanization of most nations and lifestyles, forest amenity planning has turned its focus increasingly on urban and urban periphery woodlands. For less developed countries, amenity planning for ecotourism is seen as a way to conserve forests while benefiting the local economy but requires strategies that are also compatible with the traditional dependence of local communities on forest resources for their way of life. This calls for integrated and holistic approaches to planning for multiple use that place a high value on social benefits, cultural contexts, and engagement of the community in the planning process.

The Role of Visualization in Forest Planning

S R J Sheppard and J D Salter, University of British Columbia, Vancouver, BC, Canada

Introduction

Modern techniques of computer visualization, involving three-dimensional (3D) modeling, computer animation, and virtual reality (VR), are taking their place among decision-support tools for forestry. This article focuses on the emerging role of visualization techniques that simulate the appearance of forested landscapes in forest resource planning, design, and management.

The Forest Planning Context for Visualization

It is increasingly recognized that sustainable management of forests cannot be effective without the integration of biophysical, socioeconomic, and cultural factors into the decision-making process. Public pressure for good stewardship of multiple forest resources requires more comprehensive and inclusive processes for decision-making. It is important that forest managers communicate with many stakeholder groups, with varying needs and degrees of knowledge on forest sciences. The complexity of these multiple demands on forest planning and management requires sophisticated decision-support techniques; this favors the use of visual communication techniques that can potentially simplify and explain complex information and improve the process of decision-making.

It is widely recognized that pictures can convey more information, more meaningful information, and more memorable information than other forms of communication. Visual information can also be interpreted by people from many walks of life. The general function of communicating scientific information can be achieved by what is called 'data visualization,' which comes in forms such as charts, diagrams, maps, graphics, models, etc. This can be helpful in explaining concepts, ecological processes, overall conditions, etc., which are not well expressed verbally, in text, or as data tables.

More specific forms of visualization, called visual simulation or landscape visualization, attempt to represent actual places and on-the-ground conditions in 3D perspective views, with varying degrees of realism (**Figure 1**). These convey detailed information on the expected future appearance of the landscape under certain forest conditions. Landscape visualizations offer potential to address social implications of site-specific management actions or scenarios, such as impacts on scenic quality, recreation, spiritual/cultural values, general quality of life, and property values. Furthermore, the general health of the forest is often judged by the public (and even experts such as forest certification panels) in part by what they see on the ground.

The two forms of visualization described above, data visualization and landscape visualization, can be combined in various ways. Showing spatial relationships (e.g., by mapping geographic information systems (GIS) data on to a landscape visualization) in the context of a recognizable place to which people can relate (**Figure 2**), can communicate complex information on ecosystem processes and patterns of resource values. This article will focus mostly on landscape visualization alone or in combination with data visualization.

It is widely believed within the forestry profession that the public often has little awareness of long-term landscape changes such as tree growth and death, and of temporal concepts such as succession and harvest rotations. Landscape visualization can depict both spatial and temporal variations in ecosystem conditions. It therefore offers the possibility of improving public knowledge regarding ecosystem management, and may perhaps help the public to strike a balance or trade-off in their own minds between short-term adverse effects on some values in return for long-term benefits to the ecosystem.

History of Landscape Visualization

Visual representations of existing landscapes and objects have occurred as art forms for millennia, with

the rules of visual perspective developing during the Renaissance. Portrayals of future conditions or design proposals in perspective took a major step forward with the work of English landscape architect Humphry Repton, who presented his landscape design proposals in the form of 'before: after' paintings in the late eighteenth century. In the twentieth century, the emergence of land use planning and the design professions of architecture and landscape architecture led to standardized perspective simulations of proposed designs, initially in the form of scale models, line drawings, and color renderings. The availability of quality color photography led to techniques of photosimulation (i.e., photomontage and photoretouching), which were capable of delivering highly photorealistic landscape images many years before computers came into widespread use.

Beginning in the 1970s and 1980s, early computer-assisted or computer-generated visualization techniques were developed, initially for architectural projects, but these were soon expanded to engineering and forestry applications. Various software packages were developed in the 1970s and 1980s to model the appearance of changing landscape conditions. These 3D modelling systems used digital elevation models, building masses, and tree symbols to develop quantitatively accurate but rather abstract computer perspectives (e.g., 'wireframe' models) (**Figure 3**). These could be combined with traditional hand-rendering or photosimulation techniques to produce more realistic finished products. In the 1980s, the first image-processing techniques also emerged, allowing digital enhancement of scanned photographic images.

At the same time, the military and entertainment industries were developing more sophisticated computer-imaging techniques for modeling real or imagined landscapes. Some of these technological advances eventually contributed to the computer-based landscape visualization tools currently available commercially, including two-dimensional (2D) and 3D computer programs with a range of both abstract and highly realistic landscape imagery (see below).

Much of the visualization use in forestry has been associated with visual resource management (VRM) in Western nations, notably in North America (*see* **Landscape and Planning**: Visual Resource Management Approaches). The US Forest Service and other agencies have applied various visual simulation techniques since the early 1970s when the National Environmental Protection Act first mandated protection of aesthetic resources on public lands. These visualization techniques have been used mainly to support visual assessments and forest design, and are quite widely used for this purpose in several countries, such as the USA, Canada, New Zealand, Britain, and Finland.

In the 1990s, the development of spatially explicit stand modeling systems for mainly silvicultural purposes, such as the Stand Visualization System (SVS) at the University of Washington (**Figure 4**), SMARTFOREST at the University of Illinois, and MONSU in Finland, led to 3D visualizations of stand composition and structure, using increasingly detailed tree models. Developments in integrated decision-support systems using spatially explicit ecosystem modeling with multiple indicators are also beginning to link directly with visualization capabilities. Highly realistic viewers are also available to 'bolt on' to the outputs of various forest modeling systems.

Current uses of visualization in forestry can be broadly categorized as shown in **Figure 5**. This hierarchy illustrates the broader range of applications of visualization to research and education/professional extension activities, but consideration here is focused primarily upon practical use in decision-making where social values need to be integrated into the process. Because many forest management models and systems do not as yet explicitly incorporate social values into the process in a participatory way, the use of visualization in this context has not yet become commonplace.

Types of Visualization

This section presents a typology of landscape visualization techniques in current and emerging applications. Any typology in such a rapidly changing field cannot be all-encompassing or rigid in its definitions. It is important, however, to distinguish between the types of visualization models becoming available to generate visualization imagery, and the types of presentation formats through which the visualization products are delivered to their intended audience.

Visualization Models: Image Production

The following approaches to producing forest visualization imagery can be identified:

Geometric modeling This technique uses volumetric data (either from real-world inventory data or

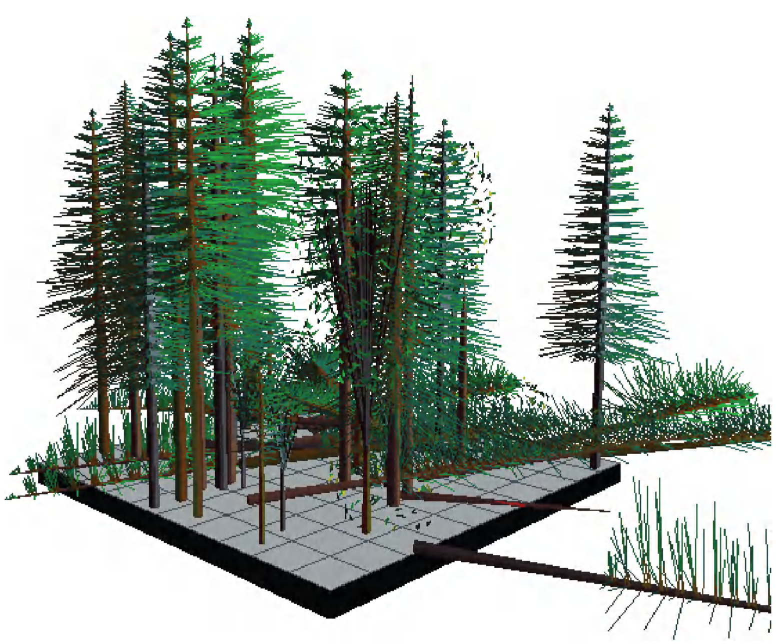

Figure 4 Example of a geometrically modeled stand with a moderate level of realism, from the Stand Visualization System (SVS). Reproduced from the SVS website. Image by Robert J McGaughey, USDA Forest Service.

Courtesy of CAB International, Wallingford, UK.

generated by predictive mathematical models) to construct digital 3D models of landscape forms. Ground surfaces or landforms can be constructed from surveyed elevation points or contour lines in computer-aided drafting (CAD) or GIS programs; vegetation can be generated from cruise data or ecological/growth models at the individual plant or stand level; and proposed roads or structures can be created from development plans. These models can range from simple wireframes (**Figure 6**) to more sophisticated solid models with synthetic textures and light sources (**Figures 4 and 7**). Geometric models may allow animation (dynamic motion or change over time). They can be considered as synthetic analogs of real world landscapes.

Photo-imaging (2D) The application of computer 'paint' programs to manipulate the pixel colors in digital 2D static photographs (**Figure 8**) is essentially artist-driven, but can be augmented by such tools as image element libraries (e.g., tree types, textures, etc.), 3D modeled perspectives to aid in element placement, and mathematical and/or survey techniques to improve image accuracy. Photorealistic images generally require skilled operators, and are too time-consuming for generation of large numbers of images, e.g., to show changing or alternative conditions over many time periods.

Hybrid geometric/photo-imaging Several techniques combine elements of the first two approaches to merge the synthetic elements of geometric models with photographic elements from photo-imaging. These fall into three main categories:

- 2D blend: views of 3D geometric models representing proposed management activities are placed into 2D static site photographs (**Figure 9**), precluding animation.
- Image draping/texture mapping: a 2D image or scanned texture map is draped on to a 3D model to represent surface features. This can be an aerial photo or satellite image draped on 3D terrain, or a texture image (such as grass or asphalt) mapped on to a landscape element. This technique is computationally efficient, and therefore is commonly used for animation and real-time applications. Its main drawback for forestry is that 2D image elements (e.g., an air photo) do not convey the 3D height effects of the trees (**Figure 10**).
- Photo-based objects: an extension of the draped texture map is the creation of discrete 3D objects which can be located with *x*, *y*, and *z* coordinates on a digital terrain surface, and upon which can be pasted individual photographic texture maps. For example, 2D or simple 3D tree models can be created and photographs of actual trees pasted on as 'billboards.' This technique can appear very lifelike, and allows animated travel through the forest model, though it is computationally very demanding because of the countless number of tree objects that need to be rendered (**Figure 11**).

Viewing Formats: Image Presentation

Presentation formats for visualization can be classified by the degree of dynamism allowed in the delivery system, as follows:

- Static 2D images: hardcopy prints, on-screen images, or projected flat single images.
- Immersive static imagery: static images presented or projected in a 3D display, e.g., 'wraparound' projection screens or simulation booths which increase the viewer's sense of involvement in the simulated scene (**Figure 12**).
- Limited animation: allowing movement of the whole image to simulate changes in view direction or viewpoint, permitting the viewer to select different pre-prepared views of static digital

scenes arranged in viewing sequences or wrap-around panoramas.

- Animated viewpoints: allowing true dynamic simulation of continuous movement through a 3D model, along pre-prepared animation paths (i.e., the typical 'walk-through' or 'fly-through').
- Animated conditions: allowing pre-programmed continuous temporal/spatial change in simulated landscape conditions, e.g., trees growing (**Figure 13**) or a fire spreading.
- Real-time interactivity: allowing fuller interactivity between the viewer and the visualization system, whereby viewpoints, travel speeds, certain landscape conditions, etc., can be modified at will and in real time by user commands. Immersive VR systems allow the observer to experience virtual landscapes interactively as though they were within it, using headset systems or sophisticated forms of computer projection.

Assessing the Benefits and Limitations of Visualization in Forest Planning

Do these increasingly sophisticated and powerful visualizations live up to their promise? This section considers the advantages and disadvantages of established and emerging forms of landscape visualization in forest planning, based on research findings, current theory, and practice.

A limited amount of research on visualization methods in planning has been conducted since the

Figure 11 Hybrid image of proposed shelterwood harvesting on the Alex Fraser Research Forest, British Columbia, created with World Construction Set software and using 'billboard' 2D photographs of individual trees inserted into a digital 3D model. 1970s, much of it grounded in the pioneering work of Donald Appleyard and colleagues at the University of California–Berkeley. The research comes from various disciplines, including urban and environmental planning, landscape architecture, computer science, graphic arts, information sciences, environmental psychology, social sciences, forestry, geography, and civil engineering. Implications for visualization in forestry have to be interpreted from the full range of applications. Some studies have evaluated the effectiveness of visualization media, but there have been few comprehensive experiments to assess the quality or validity of visualizations across multiple media or forest modeling contexts, and even fewer longitudinal studies relating predictive visualizations to actual landscape changes. The theoretical framework for landscape visualization is also very incomplete: the most cogent theories include communications theory, addressing the process of communications from source to receptor via certain channels; and various environmental psychology and aesthetic theories on human responses to the visual environment (*see* **Landscape and Planning**: Perceptions of Forest Landscapes). There is much anecdotal evidence to support the usefulness of landscape visualization in project-based decision support for forestry, but very little scientific documentation of real-world applications.

There is therefore considerable reliance on theoretical concepts and anecdotal evidence. The following sections summarize some key aspects of what is known and anticipated about visualization performance, and present a conceptual set of criteria for determining appropriate use of visualizations in the forestry context.

Performance of Landscape Visualization

The performance of visualizations can be thought of in terms of utility (practical usefulness or effectiveness) and quality (validity, reliability, realism, acceptability, etc.). The primary emphasis here is placed on the latter. Aspects of quality relate to the use of visualization to test observer reactions on the social acceptability of proposed forestry alternatives as well as on the acceptability of the visualizations themselves. Social responses can be obtained informally, through structured surveys of attitudes or judgments, or even through physiological measurements of pupillary excitation or stress levels. A variety of response types can be measured: responses can be categorized as cognitive (related to knowledge and

Figure 12 Immersive static image presented on three wraparound screens in the Landscape Immersion Laboratory of the Collaborative for Advanced Landscape Planning (CALP) at the University of British Columbia's Faculty of Forestry. Image by Jon Salter, CALP.

Figure 13 Visualization imagery showing ecological model-driven tree growth over three time periods, using CALP Forester experimental software. Image by Duncan Cavens and Jon Salter, CALP.

understanding), affective (related to feelings, perceptions, and emotions), and behavioral (related to changes in behavior of the viewer). Of these response types, little or nothing is documented scientifically on the effects of visualization on postexperiment behavior relevant to landscape management or forestry.

Specific advantages in utility believed to result from using landscape visualizations in a project planning context include: more meaningful participation of nonexperts in considering alternatives; more certainty for the project applicant and the affected community during the process; faster decisions as a result; better design of projects; less shock on the part of the public when visually disruptive changes occur on the landscape as a result of management; and in some cases an improved public image for the management agency. In theory, social response information can be fed back into the decision-support process to improve the basis of those decisions.

However, many visualization systems, and particularly the newer technologies such as animation and interactive VR, have very practical limitations associated with cost, availability of sufficiently powerful equipment, lack of appropriate data, availability of trained and experienced staff, and operational complexity.

Many of these factors are also believed to influence the quality of visualization. Quality also varies with the type of use or response sought from a given visualization set. With cognitive responses, adequate visualizations are generally understood to accelerate the mental processing of information, improve understanding, and place information in a context or perspective that allows broader interpretation of possible consequences. In practice, with site-specific landscape visualization, it is common that the process leads to new or modified conclusions on a project design or management action. Practitioners can often identify anomalies and errors in their data more quickly than in other ways. These cognitive benefits may be associated with abstract or conceptual (diagrammatic) data visualizations, realistic landscape visualizations, or hybrids of the two. However, there is a strong risk that visualizations may be cognitively misleading if they imply greater certainty than exists in future predictions of forest conditions.

Realistic ground-level views are often necessary for laypeople's fuller understanding of maps and plans. The more realistic visualizations also tend to evoke more affective reactions from viewers. Research shows that more abstract imagery (such as maps and simple computer modeling) provides less opportunity for people to respond to place-based cultural or quality of life issues such as aesthetics or acceptability of forest practices. Photographs and some forms of photorealistic visualization have been shown to replicate people's actual responses to real-world environments, which is the ultimate test of visualization validity (known as response equivalence). Most forestry studies with visualizations have tested responses on scenic beauty and/or acceptability of forest management; less is understood about validity on other questions.

However, visualizations have been criticized in terms of the following quality issues:

- Poor clarity of communication, leading to confusion and misinterpretation by viewers; this is understood to result from poor graphic presentation, too rapid animation speeds, overly complex information displays, etc.
- Low credibility of the visualizations to the audience; this can result from obvious errors, sloppy procedures, low realism, apparent bias in motivation of the preparer, etc.
- Actual bias (lack of response equivalence) in the responses arising from the use of the visualizations, as compared with the responses which would be expected from the corresponding real-world conditions if they were to be experienced. There is anecdotal evidence of misleading visualizations in practice, and some research measuring bias, though the causes are not fully understood.

Bias in responses to visualization can, in theory, be caused by deliberate manipulation (e.g., selective omission of landscape features), or unintentional inaccuracy. There is as yet no comprehensive evidence relating bias in responses to accuracy of the visualization. There is however a strong precautionary principle reflected in the literature, to the effect that, while accuracy may not be absolute or enough by itself to assure validity, it is risky to permit major inaccuracies in visualization content. Researchers such as Orland, Sheppard, and McQuillan have reinforced this view through their concerns about the ease with which realistic-appearing images can be created with today's technology, regardless of the accuracy of underlying data.

It is, however, known that responses to visualizations can be affected by factors other than image accuracy, such as the viewing locations chosen, accompanying information (e.g., verbal delivery or nonvisual data), and possibly the presentation format. Various studies have demonstrated the effects of using certain visualization media. Static imagery showing one or two 'snapshots' in time (e.g. 'before and after' an activity takes place) has been the predominant display technique for landscape visualization in forestry. Such methods offer a very limited window or slice of the information available: this places considerable reliance on the visualization preparer to select the appropriate view and conditions, in order to represent the universe of possibilities that exist over a long period of time, such as a forest rotation.

The general trend in emerging visualization methods appears to be towards more powerful and sophisticated animated graphics and VR displays, more realistic synthetic landscape models, more intuitive graphical user interfaces (GUIs), and wider access to these systems through means such as the Internet. However, the consequences of using this type of information have been tested in very few experiments. Even less information is available on the consequences of using VR techniques in practical resource management. Advanced techniques such as animation and interactive VR programs provide substantially more visual information and flexibility in viewing, and offer to overcome some of the limitations of previous methods. Much of this available visual information can of course be redundant, but there is also considerable potential for animation to provide new information through change of perspective. The ability for the user to control more aspects of the visualization also promises to reduce risks of bias from more limited or selective presentations.

Possible disadvantages associated particularly with newer methods of visualization include:

- The increased risk of raising unrealistic expectations of visualization accuracy, again because of its apparent realism.
- The risk of the novelty factor of dramatic visualizations overshadowing the content of the visualization message.
- The risk that the very sophistication, perceived expense, and 'high-tech' image of the emerging visualization media may cause a negative backlash in the public's mind, leading to rejection of the message regardless of its accuracy.
- The risk of excluding noncomputer-literate sectors of society from the decision-making process, through overreliance on digital media and access to online computer visualization techniques.

Indicators for Appropriate Use of Visualization

Given the incomplete state of our knowledge on visualization benefits and limitations, and the rapidly changing nature of visualization technologies, what guidance exists on the appropriate use of visualization for forest planning?

Previously elaborated principles and guidelines for valid and effective visualization can be used as a starting point, but needs to be extended and re-evaluated in the context of new techniques and modern demands on forest management. The following are principles for project-level landscape visualization where public (laypeople) responses may be expected:

- Representativeness: visualizations should represent typical or important views of the landscape.
- Accuracy: visualizations should simulate the actual appearance of the landscape (at least for those landscape factors being judged) (*see* **Landscape and Planning**: Visual Analysis of Forest Landscapes).
- Visual clarity: the details, components, and overall content of the visualization should be clearly distinguishable.
- Interest: the visualization should engage and hold the interest of the audience.
- Legitimacy: the visualization should be defensible and its correctness demonstrable; visualizations used should be driven by data, not by artistic license.
- Access to visual information: visualizations (and associated information) that are consistent with the above principles should be made readily accessible to the public via a variety of formats and communication channels.

These precautionary principles can be used to guide the ethical preparation and use of visualizations, the validity of which can ultimately be established only after the forest management actions have been implemented. It is therefore important to record

Figure 14 An interactive visualization system prototype (CALP Forester) that allows the user to prescribe management actions through a laser pointer interface and query the underlying model data. Image by Duncan Cavens, CALP.

and monitor the performance of the visualizations over time, so that the guidelines can be adapted as more hard information becomes available.

The current trend towards more public participation in forest management, and specifically toward the inclusion of social values in modern forest ecosystem management, calls for decision-support systems with more stakeholder involvement in and control over the development and evaluation of forest landscape choices. This can be translated into demands on visualization systems for:

- More intuitively understandable visualization methods.
- More transparent and accountable visualization processes/products.
- More involvement of the public in interrogating, interpreting, and even preparing visualizations which allow some user control over factors such as tree growth and management activities reflected in the visualization images (**Figure 14**).
- More choices of views, conditions, and alternatives visualized.

Conclusions

The science of landscape visualization is still young and evolving. There is much that we need to learn about how visualizations work in practice, and how emerging techniques will affect forest decision-making. While much more research is needed, the speed with which new visualization technologies are becoming available means that practicing forest managers cannot wait for research results, but must proceed under interim precautionary principles.

The power of the visual medium means that the preparer of visualizations carries a heavy responsibility to use that power appropriately. It must be recognized that all visualizations carry some inaccuracy, some bias in responses, and considerable uncertainty. This requires expectation management among users, and suggests that visualizations should not simply be plugged in and played without considerable planning and appropriate training for users. Updated guidelines and a code of ethics will be needed. Where possible, computer interfaces which provide access to nonvisual information about forest conditions should be provided, with built-in limitations on potential misrepresentation of data.

We can expect a new class of exploratory visualization tools to emerge that are more user-friendly, interactive, dynamic, and allow the user to navigate through the available 3D data to see forest conditions across space and time. Visualizations may move from being an end-product of planning activities or stand modeling exercises, to acting as a gateway to the planning or modeling process, through which new model runs or 'what-if' scenarios can be triggered directly and results browsed. The potential benefits are that it promises to provide easier and wider public access to the issues of forest management than has ever before been possible. The policy implications and procedural mechanisms to accommodate such public demands have yet to be thought through, however. It is also not clear whether the increasing choice and control by the viewer necessarily leads to greater validity and better decision-making.

In the long term, accumulating research and practice with visualization should fill out the theoretical framework for landscape visualization. Priorities for research include systematic evaluation of existing and experimental visualization techniques in laboratory conditions, and monitoring and evaluation of visualization techniques and effects in practical forestry applications.

Most forest managers are not well trained in methods of collaborating with the public, and often lack needed skills when dealing with affected communities. The use of credible visualization methods may ultimately help them to overcome these shortcomings, transform forest planning, and perhaps increase public understanding of forest sciences in management.

Landscape Ecology, Use and Application in Forestry

N Brown, Oxford Forestry Institute, Oxford, UK

Introduction

Many ecological processes result in or are affected by spatial patterns. However, the relative importance of different processes is very sensitive to the scale of analysis. For example, at a very local scale, species diversity is often strongly affected by competition and trophic interactions between species. In contrast, at the regional scale species diversity is more strongly influenced by habitat dynamics and biogeography. The majority of ecological studies in the past has focused on local level processes, probably because they are less daunting to measure and are more amenable to experimental manipulation. The recognition that the important processes acting at a landscape level are often different from those at a local level has led to the development of landscape ecology as a distinct approach with its own paradigms and methodologies.

Ecologists have traditionally been interested in the spatial patterns of organisms. Charles Darwin's *On The Origin of Species* contains an entire chapter discussing the geographical distribution of species. However, the focus of his chapter, like much of the ecological literature since, is on the processes that create spatial patterns or biogeography. In contrast, an area of prime interest in landscape ecology is the way that spatial patterns affect ecological processes. This article reviews some of the ideas that this perspective has generated and looks at their relevance to forestry.

Why Landscape Scale?

The question of which is the appropriate scale for a particular analysis will largely depend on its objectives. Many issues in applied ecology and particularly those concerning environmental management are most appropriately addressed at a landscape scale. This is certainly true of forestry where many of the key management issues concern processes that operate over large areas. Environmental change, conservation, sustainability concerns, recreation, and public participation all involve considering forests in their landscape context.

The term 'landscape' has no precise definition. It implies an area that is perceived to have some coherence of natural or cultural entities. In practice the lack of a formal description of what constitutes a landscape is no more problematic than the similarly vague definition of the term 'population' in ecology. Both are useful because they demarcate biologically meaningful groups. Just like landscapes, populations can be identified at a scale that is appropriate to the objectives of the study.

The need for a large-scale perspective is not a new one but it is only recently that ecologists have acquired the tools that permit them to carry out this type of analysis efficiently. Remote sensing and geographic information systems (GIS) have permitted the collection and analysis of large quantities of spatial data. Although ecologists use experimental approaches more frequently than many environmental scientists, the possibilities for experimental landscape ecology research are severely limited. It is usually impractical to deliberately manipulate landscapes for experimental purposes and even in those situations where a treatment occurs as a consequence of other action it is usually impossible to replicate or control. Hence landscape ecologists typically measure rather than manipulate; patterns and processes are described rather than being experimentally controlled. Although purely descriptive studies in ecology are often criticized it is only by having accurate quantitative descriptions of landscape patterns that testable hypotheses can subsequently be developed.

Simulation modeling can be used as an alternative to the descriptive–inductive approach to landscape ecology. Aided by huge advances in computing, simulation modeling has permitted landscape ecology to throw off some of the constraints of studying region-specific, observable phenomena. Modeling has been used to identify the ecological implications of changing landscape patterns and of alternative management regimes applied to existing land use configurations. The combination of ecological models with GIS and, more recently, computer-generated visualization have provided a powerful planning tool.

One area that has proved to be a consistent challenge in landscape ecology has been the development of accurate, consistent, and ecologically meaningful measures of spatial pattern. The measurement of spatial pattern is often strongly scale-dependent. The types of pattern that can be recognized depend very much on the scale at which they are viewed. For example features that appear clustered at a small scale can be dispersed when viewed at a large one. Connectivity can change too. Small patches of woodland and wooded corridors between patches can disappear when a landscape is viewed at a small scale (**Figure 1**).

In 1967, Benoit Mandelbrot published a paper in which he concluded that the length of the coastline of Britain depended on the scale of measurement. He pointed out that each increase in scale reveals a new level of roughness and thus an increase in its length. He termed such patterns, which reveal greater complexity as they are enlarged, fractals. Many of the measures that are used to quantify shape and complexity in landscape ecology are similarly dependent on the scale of the analysis. This implies that it is crucial when investigating the impacts of spatial pattern on ecological processes to make sure that pattern is measured at a scale that matches the way the study organism perceives the landscape. A region in which woodland is highly fragmented from the point of view of a wood mouse (*Apodemus sylvaticus*) can be well connected for a more mobile organism like a jay (*Garrulus glandarius*). A further dimension to this problem is the difficulty of obtaining a consistent quality of information over space and time. Some types of measures of spatial pattern are sensitive to the quality of input maps. Very large differences have been found in a number of measures used to quantify landscape structure when the same region is analyzed on different map products.

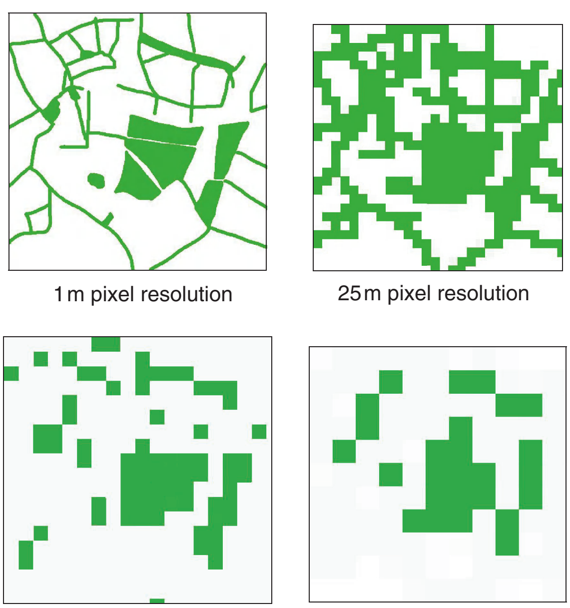

Figure 1 The connectivity of wooded areas in an Oxfordshire landscape changes with the resolution of the image used for the analysis.

Landscape Ecology and Forestry

Both forestry activities and deforestation alter landscape structure in ways that have significant effects on organisms. In many parts of the world different components of the landscape are managed virtually in isolation, with little or no account taken of surrounding land use or landscape context. Such components include forested blocks, agricultural fields, urban areas, and waterways. A consequence of this is that management objectives are often frustrated by the functional dependence of one land area on those around it. For example, recent research in Costa Rica has shown that the diversity of moths in sites outside forest is most correlated with forest cover within 1–1.5 km of the surveyed site. Fragmented management often results in resource use conflicts and environmental stress.

Growing interest in sustainable forest management systems over the last decade has resulted in efforts to apply ideas from landscape ecology to forest management practices, particularly timber harvesting and new woodland creation. A guiding principle has been the emulation of natural patterns. Landscape ecology provides useful ways in which natural patterns can be described and compared with those in the managed landscape.

There are four landscape characteristics that have important implications for forest management.

Fragmentation

Fragmentation occurs when a large area of forest is broken up into smaller, less connected patches. In many tropical landscapes fragmentation of natural forest is occurring rapidly and efforts to protect biodiversity and to understand the ecological processes that determine its survival are becoming increasingly important. In contrast, in many temperate countries, an excess of agricultural land and a concern to increase the area of woodland for aesthetic, conservation, and recreation reasons, have prompted interest in the potential benefits of defragmentation. There have been two types of approach to understanding patterns in fragmented landscapes; those that address issues of community composition and those that examine single species population dynamics. Here, both approaches are described.

The equilibrium theory of island biogeography (advanced in the 1960s by MacArthur and Wilson) has been a cornerstone of our understanding of the processes that determine community composition in a fragmented environment for nearly 40 years. Their theory proposed that the diversity of organisms on an island should decrease as its size decreases and isolation from the mainland increases. This concept has been widely applied to habitat fragments on the assumption that they function like islands surrounded by a 'sea' of more hostile environment. However, it has not generally proved to be a useful tool for predicting species diversity in habitat patches within a matrix of other land uses. This is because the community of species in a patch of habitat will be strongly influenced by the nature of the landscape around it and the sorts of species that inhabit that landscape. The management regimes used in open countryside have been found to influence both bird and invertebrate diversity in adjacent forest patches. Species that inhabit forest patches can be affected by competition and predation from species that inhabit surrounding land use types. For example, in the Midwest of the USA the replacement of forest by agricultural and suburban landscapes has resulted in a substantial expansion in the range of the brown-headed cowbird *(Molothrus ater)*. A relationship has been found between songbird nest predation and parasitism by cowbirds and the degree of forest fragmentation. The implication of studies such as this is that two fragments of forests may have identical areas and be equally isolated but their species composition may be very different as a consequence of their interactions with surrounding land use types.

Models of single-species population dynamics at a landscape level are a much more recent development. A variety of models has been formulated to describe the dynamics of a range of organisms with very different ecologies. Metapopulation theory envisages that a landscape is divided into habitable patches separated by unsuitable habitat and that as a consequence a species population will actually consist of a series of interacting local populations each occupying a patch. Changes that occur in one local population do not necessarily occur in other patches at the same time. This can mean that one local population may go extinct whilst others are thriving. Migration between patches can re-establish a local population should it go extinct. Metapopulation theory predicts that a threshold number of patches is needed in order that the species persists at a landscape level. The dynamics of the metapopulation are not simply a function of local population dynamics since larger-scale factors such as the distribution of patches in the landscape and migration rates between patches are important. The metapopulation concept has important implications for the management of fragmented forests. Silvicultural operations such as felling and coppicing can drastically alter habitat quality and unless there are enough similar habitat patches within migration distance it may be impossible for a local population to re-establish should it go extinct. Many rare UK butterflies are found exclusively in large and non-isolated habitat patches, while small or isolated patches of suitable habitat remain vacant. This distribution pattern is the result of local extinction and colonization processes and implies that long-term population persistence requires networks of suitable habitats, sufficiently close to allow natural dispersal. An extension of metapopulation theory considers the landscape to consist of habitat of variable quality rather than a simple division into habitable and uninhabitable areas. An area in which a species population thrives (with births exceeding deaths) may become a source of colonists whereas poor quality habitat may be a sink (deaths exceeding births). An important implication is that the decline of a local population in one forest may result in declines in adjacent forest patches as mobile species move out to recolonize vacant areas. This may make it difficult to diagnose the cause of a population decline and it emphasizes the importance of conserving habitat networks rather than focusing on the protection of a single site.

The fragmented nature of management planning in many patchy landscapes can make management of conservation networks difficult. Numerous owners and a variety of organizations may be responsible for taking decisions with the result that forest operations are planned on a case-by-case basis with no account taken of what is happening to adjacent forest areas. Landscape ecology has highlighted the importance of making sure that land use policies are aligned across owners and government agencies when sustainability is an essential goal.

Edge Effects

As patch size decreases so a progressively larger proportion of the remaining forest is influenced by edge effects. These can include increases in light and temperature and decreases in humidity. Increases in light have often been found to result in higher density and faster growth of natural regeneration of light-demanding trees along forest edges but also in the proliferation of herb and vine species. In tropical rain forest in the Brazilian Amazon significant increases in liana density have been detected up to 100 m from a forest edge. There is often an increased risk of windthrow on exposed forest edges. This has encouraged the development of special treatments for stand edges in areas that suffer from a high risk of wind damage. These include establishing shelterbelts of wind-resistant species or heavy thinning regimes to encourage well-tapered stems. It is also clear that the pattern of felling at a landscape level can have a significant effect on both the total length of exposed forest edge and wind turbulence.

Small woods have a high proportion of edge to core area. One reason for the creation of new forests in landscapes that have lost most of their forest area is to provide new niches that are not currently available. Large forests offer opportunities for species that require large forested territories, use large home ranges, or which thrive in forest interior habitats (i.e., are disadvantaged in forest edge habitats).

Connectivity

Connectivity refers to the degree to which habitat patches are linked so that organisms can move from one patch to another. Little is yet understood about colonization processes and rates and landscape use by many forest organisms but it is clear that connections in a landscape are organism-specific.

It has often been claimed that connectivity can be increased by the creation of habitat corridors. Strips of habitat connecting patches were assumed to facilitate migration and reduce the risks of local population extinction. However, empirical studies have shown that it is often the structure of the entire landscape matrix (the ‘habitat network’) that determines whether organisms can move. Many organisms can migrate through a landscape using a variety of habitats that they would not live in. Conversely, the provision of habitat corridors does not guarantee movement. Patches that are physically linked by a narrow corridor may not be connected for an organism that only occupies forest interior habitats. Indeed, it has even been proposed that corridors may facilitate colonization by invasive species and species tolerant of disturbed conditions.

Direct physical connections may be necessary for movement of organisms that inhabit old-growth forest and that have highly specific habitat requirements. Such species typically have extremely slow colonization rates. Even with an adjacent source of colonization, the number of such poorly dispersed species that will establish in newly forested areas may be low. Forest management systems need to be designed to maximize the opportunities for the dispersal of old-growth forest specialist species. This may include leaving substantial areas without any form of management intervention, avoiding excessive edge effects by minimizing the amount of harvesting around unmanaged core areas and distributing harvesting to ensure that regenerating forest is not isolated from old-growth areas.

Disturbance

Disturbance regimes determine the structure and composition of natural forests. Large or frequent disturbances (such as wildfires or hurricanes) create forests that have a uniform structure and a predominance of pioneer or colonizing species. In contrast, climax or shade-tolerant species will dominate forests that have only small or infrequent disturbances (such as those caused by the collapse of an old tree). As many of the organisms in a natural forest will be adapted to the prevailing disturbance regime, natural forest management systems that intend to sustain this biological diversity have attempted to match natural patterns. This includes matching the design of harvesting blocks to the pattern and distribution of natural disturbances across a landscape in terms of their size, shape, and frequency.

Natural forest management systems were abandoned during the twentieth century in many European and North American countries as markets for traditional woodland products declined. As a consequence, many seminatural forests have lost the diversity of ages and hence structures that management maintained and that were important for wildlife. There are a number of initiatives to bring neglected woodlands back into management with the primary objective of enhancing their wildlife value. Techniques such as thinning, coppicing, and the introduction of group selection felling systems have begun to re-establish a variety of woodland habitats. An important task is to decide how these different management regimes should be distributed at a landscape scale. Studies of natural disturbance regimes can help in the design of appropriate silvicultural systems but one of the greatest challenges remains the coordination of actions at a landscape scale particularly where this involves a number of different landowners.

Landscape Ecology, the Concepts

E A Simmons, National School of Forestry, University of Central Lancashire, Penrith, Cumbria, UK

Introduction

Landscape ecology is an emerging discipline that aims to understand the environmental processes and patterns influencing habitats and species beyond the site level. It arose independently in the latter part of the twentieth century in central and Eastern Europe and in North America as geographers, planners, and ecologists began to push the boundaries of their subject interests in the search for integrated approaches to land management of sensitive areas. They combined intellectual forces in the International Association of Landscape Ecology (IALE), formed in 1982.

Landscape ecology is based on the initial premise that a landscape can be viewed as a series of patches within an overall background matrix; taken together, patches and matrix make up a heterogeneous landscape mosaic. The significance for forestry is that it can take the focus up a level from the management of stands within a forest to forests within a landscape. Each forest or woodland can be viewed as a patch, within a matrix of other land use. The power of landscape ecology is that its principles can apply at vastly different scales, depending on the landscape or the research question. It has been used equally effectively by natural resource managers in conservation planning of large protected areas such as watersheds or national parks and by those undertaking local-scale restoration projects consisting of a few sites. In Europe the challenge is often to mitigate the effects of development, but landscape ecology can be used more proactively to design for conservation and related benefits. It is equally applicable to temperate and tropical landscapes, and although data constraints are significant, it is more often the speed of landscape change that prevents the full application of the discipline to landscape problems.

Landscape ecology is a broad discipline, with spatial planning at its heart, but it is much more than just mapping, as its twin concern is the time dimension of both natural and human-induced effects. Timescales from hours to years are used to understand more fully the effects of landscape-scale processes such as habitat fragmentation, loss, or restoration. In multifunctional landscape management many concerns can be taken on board in an approach based on landscape ecology, although there are criticisms that, because it is focused primarily on biodiversity issues, it currently fails to elaborate or model fully socioeconomic and cultural issues.

Underlying Thories

The patch/matrix model is in part an extrapolation of the theory of island biogeography in which the patches are islands in an archipelago, and their size and proximity to sources of biodiversity are critical factors in determining their own species load. Larger islands tend to contain more species than smaller islands and those nearer the mainland more than distant islands. Relative rates of colonization and extinction were invoked to explain these findings. It is now recognized that the theory is too simplistic for most landscapes as the critical factors for species and populations in land-locked patches are often more numerous and complex. Landscape ecology addresses the many variables involved, such as the composition of the patches themselves and the nature of the surrounding land use, which can be overriding factors in species dispersal in a landscape.

The notion of functional connectivity between patches, e.g., the flow of genes or energy, is still critical, as in island biogeography, but landscape ecologists consider this in a temporal as well as spatial context. Dispersal of organisms between habitat patches is explained in terms of metapopulation theory, dependent on identifying a series of interlinked subpopulations making up a functional population unit, and the related source–sink theory, in which patches are either net providers or net absorbers of migrating individuals.

Discrete landscape elements do not exist in isolation and there are different ways in which the linkages between elements can be understood. Hierarchy theory views the landscape elements as nested,

> Thus a forested landscape might be hierachically composed of drainage basins, which in turn are composed of local ecosystems or stands, which in turn are composed of individual trees and tree gaps. The landscape system is a nested hierarchy with each level containing the levels below it (Forman RTT (1995) *Land Mosaics*: *The Ecology of Landscapes and Regions*. Cambridge: Cambridge University Press).

The linkages that need to be understood between landscape elements are those disrupted, or created by changes in the processes and pattern in the immediate and wider landscape. They include those to landscape elements at the scale below and above the element under consideration and the landscape ecologist should consider these in addressing research or management questions (**Table 1**).

Interpreting Landscape Pattern

Landscape metrics are used to compare different landscapes or the same landscape over time (**Table 2**). It is important to remember that many metrics are correlated with or derived from each other, e.g., edge length and edge density, and care should be taken to choose a metric appropriate to available data and the conclusions or decisions that will flow from the data analysis. Knowledge of landscape structure and composition may become the basis for making assumptions about landscape-scale processes, e.g., erosion.

Issues of Scale

Selecting the appropriate scale at which to work is fundamental to the success of a landscape ecology approach. Anthropocentric bias must be minimized when considering scale. It is vital to acknowledge the scale at which the target organism(s) themselves are operating: is it tens of meters in the case of a woodland butterfly or is it kilometers in the case of a raptor? This leads us to an understanding that 'patches' overlap, and may even be nested, i.e., the patch for species A may be wholly incorporated within the patch for species B. It is likely that these species will be experiencing a different level of detail or grain in the landscape.

Data Constraints

The principal limitation to a more widespread application of landscape ecology is the availability of robust data sets at the appropriate scale. There are issues of comparability between data sets recorded at

Table 1 The landscape ecology approach

	Action	*Check*
Step 1	Crystallize the research or management need	Consult widely, with stakeholders, subject experts, and policy-makers
Step 2	Identify the appropriate scale at which to work	This must relate to the issue or species but is often dictated by data availability
Step 3	Define the landscape and the time frame	Make transparent the reasons for selection of both the landscape boundaries and the time scale
Step 4	Design optimum data capture strategy	Historical data Fieldwork at what scale and intensity? Design of geographic information systems?
Step 5	Gather date	Check scale and comparability of data sets
Step 6	Analyze data	Focus on identifying the spatial/temporal relationships between data sets
Step 7	Relate data analysis to research or management question and draw conclusions	Review limitations of data and analyses

Table 2 Landscape metrics

Metric	*Notes*
Landscape configuration metrics	
Patch size	The average size of a particular type of patch, e.g., woodland. In general, greater variability in patch size indicates less uniformity in landscape pattern
Patch core area	May be critical to certain species, e.g., those dependent on the more stable conditions in the interior of a forest patch
Patch shape = 0.25 perimeter/$\sqrt{\text{area}}$	With this equation a simple shape such as a square has a shape index = 1. A more complex shape has shape index > 1 Altering the shape of a habitat patch may influence many different processes within it, not least because edge and core measurements may change, and so may have advantages or disadvantages depending on the conservation priorities
For individual patches in the landscape: FD = 2(ln 0.25P/ln A)	Fractal dimension (FD) may also be used as a measure of shape complexity. FD = 1 for square and 2 for complex shape. FD can be computed for each patch and then averaged for the landscape. Because the patches are not usually equal sizes, this metric should be weighted, i.e., obtain the FD for each patch, then weight each value by the ratio of the patch area to the landscape area. This weighted average addresses patch evenness
Nearest neighbor = distance (m) to the nearest patch of the same type	This can be either to the patch perimeter or center
Edge metrics	If these are high it implies greater spatial heterogeneity
Total patch edge and patch edge density: these are not spatially explicit but fit best within landscape configuration	Changes in the total length of edge of an important cover type, e.g., forest, may be the most significant measure of fragmentation available. Many other metrics depend on edge or perimeter data. (In a raster GIS data set, the length of all edges is biased upwards because of the "stair-step" effect when the edge is composed of a series of squares. Edge indices change with the resolution of the image, with finer resolutions giving longer measures of edge)
Contagion If there are s cover types then the probability P can be calculated that in a raster data set, two randomly selected adjacent cells or pixels will belong to cover types *I* and *j* respectively	A high P-value indicates a clumped pattern of cover types over the landscape
Adjacency What is the probability that a grid cell of cover type *I* is adjacent to cover type *j*?	This can be calculated directionally – to find directionality in the pattern (anisotropy) or the average value calculated. High values indicate clumping of cells of the same cover type, i.e., they are likely to be found aggregated together
Landscape composition metrics	
This second group of metrics is concerned with the relative proportions of the patch types present and not with their spatial arrangement. However, taken together with the configuration metrics above, they help to explain landscape pattern	
Proportion of landscape	This is the proportion p of the landscape that is occupied by each cover type. p is used in other metrics which may then be correlated
Relative richness $R = s/s_{max} \times 100$	If there are data available for a similar landscape which allows one to estimate the maximum number of cover types present ($s_{\max}$) then it is possible to describe a second landscape with number of cover types s as having relative richness R
Diversity and dominance indices: dominance is the deviation from the maximum possible diversity for a landscape having s cover types; a high value indicates that the landscape is dominated by one or very few cover types	These are similar to the measures of plant and animal diversity. There are two parts to each index: richness, i.e., number of cover or patch types present, and evenness or the distribution of the total area among these different types. Different indices are more sensitive to one or other of these, e.g., the Shannon–Wiener diversity index which is more sensitive to richness than evenness, so rare cover types are disproportionately influential. A high level of the index H indicates high diversity in the landscape, although the absolute value is not meaningful except where appropriate comparisons are being made between landscapes These metrics are most useful when comparing change in a known landscape; even then, if the number of cover types and relative proportions remain the same, with a shift in the nature of the cover types between the proportions, then the indices will give similar values and be of limited value. Only one or other should be used as they give the same information about the landscape and they may not be useful where separate information is required on richness and evenness

GIS, geographic information system.

different times and often for different purposes which are drawn on to cover as many variables as possible within the landscape. Analysis of such data sets has become possible with the advent of more user-friendly software tools applicable to natural resource management. Many ecologists, planners, and policy-makers now use geographic information systems (GIS) to analyze and present data and these support a variety of landscape ecology tools. Historic and contemporary maps of infrastructure, vegetation, or soils all provide a useful basis for understanding a landscape's structure but often the corresponding biotic data are lacking.

If, for example, the conservation of a particular forest bird species was paramount, data would be needed on the spatial and temporal variants in the life cycle of the bird, its population, and its habitat needs. It is unlikely that fully comprehensive data will be available to the forest manager but key facts on bird and habitat distribution, breeding cycles, and foraging patterns would be needed to implement landscape-scale management. The minimum level of data required will vary depending on the question addressed. To some extent, this single-species approach is the simplest application of landscape ecology but its success is still dependent on quality data.

At an early stage in a landscape ecological study the landscape boundary must be defined. There are parallels with the ecosystem approach – the concept of an ecosystem is itself abstract – and in some respects it is more straightforward to identify the boundaries of a landscape of interest, acknowledging that these might be arbitrarily influenced by landownership or management. The scale of the landscape however must be informed by the requirements of the target organisms.

A Key Challenge for Landscape Ecology: Reducing Fragmentation

Irreversible habitat loss is the greatest threat to biodiversity worldwide but this is closely followed by the fragmentation of habitats, and ecosystems, within landscapes. In the Brazilian Amazon it has been estimated in 2003 that the area of forest land affected by fragmentation was three times that which had been deforested. Combating fragmentation is a key action for biodiversity conservation both because many landscapes have become degraded as a result of habitat fragmentation and because many nature reserves and other important protected areas have become isolated fragments, with the associated pressures on the biodiversity under protection.

Fragmentation occurs when formerly extensive areas of natural habitat are divided into smaller fragments as a result of human activities, including the building of roads, railways, pipelines, and other communication lines. It may accompany larger-scale habitat destruction due to housing, industrial, or agricultural development. As a result, the remaining fragments of habitat may be separated by a highly modified or degraded landscape that may be inhospitable to species movements beyond or between fragments. As habitats become fragmented, the increased 'edge' is also exposed to a greater variety of microclimatic and biotic influences and human disturbance that typically have a detrimental effect on the remaining biodiversity. As patches of habitat become smaller, so the ratio of edge to interior, or core, increases disproportionately and edge effects may dominate the remaining fragment. The magnitude of edge effects is related to the nature of the matrix surrounding the habitat fragment. The greater the contrast in habitat type and structure, the greater the intensity of edge effect in most ecosystems. Thus an area of forest surrounded by scrubby vegetation is likely to suffer less severely from edge effects in comparison to a fragment surrounded by intensively managed farmland.

As well as the loss or reduction in movement of biota from and between fragmented habitats, the impact of external biota such as domestic stock, predators, or nonnative plant species may severely threaten the integrity of ecosystem fragments. These effects are typically strongest at habitat edges. For example, levels of nest predation by predators such as domestic cats, crows, squirrels, or oppossums on birds dwelling in forest fragments have been shown in a number of studies to be strongly linked to distance from habitat edge. Equally, increased light availability, nutrient enrichment and disturbance as a result of habitat fragmentation may encourage the colonization of invasive, often nonnative species at the expense of the less competitive native flora.

In forested landscapes roads are often a cause of fragmentation. The impacts have been shown to be highly significant for many organisms. Large mammals can be adversely affected by a reduction in the integrity of their domain; others, e.g., deer species, may exploit the increased patchiness of the landscape, and species operating at smaller spatial scales may be influenced by the change in the forest interior to edge ratio or by the fragmentation of other habitats around the wooded areas. Isolation may cause local extinctions within the metapopulation, which will be threatened if these subpopulations are not replaced. Overall, there is an increase in edge habitat and a reduction in core area – this may be offset by road closure when no longer needed but more often the cost of installing forest roads is so high they remain a permanent influence in the landscape.

Population Isolation and Barriers to Movement

The continued viability of populations in fragmented ecosystems may often be reliant on movement beyond the fragment to fulfill resource or habitat requirements (e.g., for hunting or seasonal feeding) and between fragments to maintain greater genetic diversity. Species' perception of 'barriers' will vary from species to species. For example, for small organisms such as invertebrates and some bird species, 100 m across an agricultural habitat may form a total barrier to dispersal, while for other bird species, small intervening areas of inhospitable habitat, such as a road or even a small development, may not radically affect movement between fragments. For small mammals, a road may form a significant barrier to movement due to road kills, while for larger mammals a fence may form a significant barrier to movement. A plant which is dispersed by wind or by birds may be able to disperse across small areas of inhospitable habitat, whereas a plant species with no such dispersal adaptations may be unable to disperse to other areas of suitable habitat.

If the surrounding matrix is an adverse environment for species dispersal, the landscape is described as 'resistant.' It is unlikely that the matrix is made up of one land use and so this heterogeneity must be analyzed to identify the key contributors to resistance where feasible. Resistance can potentially be improved by altering the intensity of the land use adjacent to the forest or by planting different vegetation between wooded patches, but often such intervention is outwith the scope of a forest manager.

The Role of Corridors

To ease the dispersal of organisms and to counteract the adverse effects of isolation, landscape ecologists often identify corridors in the landscape where they exist and propose them where they do not. The designation of corridors within a landscape is usually done in a spatial context and it assumes that linear movement is relevant to target organisms and other matter such as water. It is acknowledged that there are many assumptions made in identifying corridors, as there is little empirical evidence for their role in the majority of landscapes and for the majority of species.

In some landscapes potential corridors may be obvious; watercourses creating riparian corridors would be a good example of this. Corridors may actually have more functions than just acting as conduits (**Table 3**). It is also often forgotten that the corridor functions can vary considerably over different timescales, e.g., within a day, season, or year.

Unexpected effects of corridors can include the transport and spread of seeds by vehicles; this may be problematic if the species are invasive. Disease-causing organisms or pests, e.g., long-horned beetles, may be dispersed via corridors and a forester would need to assess the risk of increasing connectivity in a landscape-scale forest management scheme. It is also necessary to attempt to predict corridors that will be created – often unintentionally – from forest management practices.

Survival Within a Patch

When does a patch become too small or modified to retain its full range of species and habitats and to cease to function as a patch? Accumulating evidence shows that edge effects can significantly reduce the recruitment of new seedlings and aboveground biomass in small fragments drops sharply. Microclimatic changes and elevated wind turbulence are the most significant edge effects – posing a risk to large established trees as well as new recruits. Broken crowns and snapped trunks cause significant loss of biomass even in surviving trees, indicating that fragments may be less efficient as carbon sinks than previously predicted.

Bird richness and abundance also decline in small forest fragments, though guilds differ in their

Table 3 The functions of corridors between patches

Function[a]	
Conduit	Organisms or propagules move along or adjacent to the corridor
Barrier	Resists passage between patches
Habitat	Species, usually generalists or edge species, which use the corridor as habitat for part or whole of their life cycle
Source	A reservoir of propagules or organisms
Sink	Absorbs water, nutrients, and species from the matrix

[a] Function varies with species.

Adapted with permission from Forman RTT (1995) *Land Mosaics*: *The Ecology of Landscapes and Regions*. Cambridge, UK: Cambridge University Press.

response to fragmentation. In tropical forests this has been shown to be due to adverse impacts on food supplies; nectarivores such as hummingbirds may be less affected by fragmentation than insectivores or frugivores. Critical patch size varies as some species are better at exploiting the increased heterogeneity of a disturbed forest. The nature of the surrounding vegetation is critical to minimize edge effects; in some cases secondary growth creates effective links between forest patches.

Fragmentation therefore does not cause an immediate crash in overall biodiversity but it does affect the relative abundance of different species and endemics are particularly vulnerable to its adverse effects.

Woodland Planting to Counteract Fragmentation

What if you are considering planting to consolidate an existing woodland resource? How much is needed to maximize proximity and hence the interchange of species? Thirty percent woodland cover is currently suggested as an appropriate target based on a model which randomly added a 1 ha block to a landscape. However, it is not until this figure is doubled that a substantial increase in woodland core area occurs and this is highly relevant for the conservation of forest interior species (**Table 4**).

In the UK the Woodland Trust (the principal forest nongovernment organization) has considered the evidence for connecting ancient woodland sites to increase biodiversity but has concluded that there is less value in this than in consolidating the significance of individual sites by increasing their area. In turn, they considered the need to target areas where ancient woodlands are already concentrated for new planting of native woodlands to achieve 30% woodland cover. In such areas, the Trust recommended that this should be matched by 30% cover of seminatural habitats and a reduced intensity of management of the remaining land. The England National Forest also has a target of 30% tree cover but development pressure is such that it is not possible to match this with a similar area of seminatural habitat. The principle is sound however; woodland biodiversity gains are maximized when the adjacent land uses are benign.

Table 4 The effect on core area of adding 1 ha seminatural habitat blocks to a 2×2 km landscape

Cover %	*Cumulative core area (ha)*	*Critical threshold*
1	0

The Challenge of Managing Whole Landscapes

Landscape ecology is only one component of an integrated landscape management approach. If applied to the exclusion of other interests, it will not provide sustainable solutions. However, its emphasis on spatial and time-related variables makes it a contender to provide the framework to integrate biodiversity conservation with socioeconomic and cultural concerns.

Spatial Information

T Tokola, University of Helsinki, Helsinki, Finland

Introduction

A common representation of forest characteristics within spatial analysis and geographic information systems (GIS) can often be found in native objects whose interactions are based on simple distance and connectivity relationships. The spatial description of forest objects can be understood as a continuous two-dimensional process as an intensity field, or a collection of discrete locations of spatial objects. Geometrical features, such as points, lines, polygons, and raster cells, are commonly used to describe real-world objects and their characteristics in computerized mapping systems. Data modeling is a process that simplifies and defines real-world objects as database objects. Further spatial analysis may be engaged in when database objects have sufficient characteristics for spatial analysis.

The quantification of heterogeneity in forest areas has long been an objective of forest inventory and management. Heterogeneity depends highly on scale. The spatial and temporal variation of the property that can be detected will often depend on the spatial and temporal scale at which the property was sampled, and the size of the mapping unit. The information levels used in forestry reporting are hierarchically divided into: (1) tree level; (2) stand level; (3) farm level; (4) region level; and (5) country level. The data collection is normally based on measured sample units or subjective field observations that come from reporting units. The spatial pattern of reporting units can be mapped using remote sensing techniques or field observations.

The relative spatial distribution of forests and trees varies, because of changing land use practices, differences in the fertility of soil, and the hydrology, competition, and size distribution of trees. It is well known that the spatial distribution of seedlings in stands of natural generation depends highly on the location of mother trees and soil preparation affects the probability of survival of seedlings. Spatial information is used in forest inventory planning, and the construction of growth models and problems relating to forest regeneration and thinning. For example, the predictors of a spatial growth model for drained peatlands normally include variables such as the distance between the tree and the nearest ditch. The optimal sampling design of forest inventory can be defined if a spatial pattern of large variation is known and the size of a sample unit can be determined when the probability of tree occurrence can be modeled. Different indices and techniques have traditionally been applied to seedling surveys, in order to find out if the spatial distribution of seedling and saplings is regular. In addition, the effectivity of thinning and stand growth estimates depends highly on spatial regularity.

There are many forestry variables that are spatially sparse and scattered. This is often the case when one is assessing coarse woody debris in managed forests, or surveying threatened species. The spatial description of sparse populations can also be problematic. On the landscape level, information about spatial distribution of different key habitats and areas with a high ecological value has also been used to assess the probability of existing rare species. Field data about indicator species and remote sensing data about landscape features are valuable a priori information for estimating the presence/absence probability and for stratifying areas of interest.

Spatiality of Trees

The simplest point process model that can be used for the spatial pattern of trees is the Poisson process, which is typically used to produce random Poisson forests and when there is no interaction between the locations of trees. There are several modifications that stem from the basic model, such as the inhomogeneous Poisson processes, the Poisson cluster processes, and the doubly stochastic Poisson processes. The location of seedlings after natural regeneration is often generated using the Poisson cluster processes. Lattice-based processes are suitable models for spatial patterns of trees in plantations. Pair correlation processes produce patterns in which points either ‘reject’ (regular) or ‘attract’ (clustered) other trees to each other. Hard-core processes reject other trees with such a high intensity that other trees cannot exist closer than the radius of the core area. The Markov point processes and the Gibbs process are often used as well, because interactions between trees can be sufficiently modeled and empirical data can be used to create a probability model.

Different kinds of indices can also be used to measure the deviation of the given tree pattern from the Poisson forest. These methods of analysis can be divided into three groups depending on the measurements done regarding the population:

1. Number of trees within plots are counted.
2. The distance from tree (or random point) to closest tree is measured.
3. All trees in the forest are mapped.

The methods of the first two groups are more suitable for field work, while the latter group gives detailed information about the underlying process, and allows for the estimation of parameters necessary to begin a selected point process. The known field methods include the index of dispersion and the distance-based indices. Ripley's *K*, Moran's *I*, and Geary's *C* are commonly used for testing randomness or clusterness of tree patterns, although Moran's *I* and Geary's *C* have mostly been used for characterizing the autocorrelation. When permanent sample plots of Finland were analyzed, 57% of the plots had a regular tree pattern, while 25% were random, and 18% were clustered. When the basic pattern of trees is identified, it can be utilized directly to determine the sampling unit and design.

One common example in forestry would be the stand representation of discrete forest patches, and the partition of forests into distinct classes or strata. The discrete model is usually adopted when the boundaries of units can be unambiguously delineated. This happens, for example, when there are sharp discontinuities in attribute values. The delineation of stands is typically guided by three criteria: (1) the forest characteristics in different parts of the stand should be similar; (2) the stand should be a practical management and harvesting unit; and (3) the stand should be identifiable to allow for the monitoring and updating of information. Because these criteria can be contradictory, one or more of them are often compromised, and an estimation of stand values is often based on the simple summation of sample data, an approach which sometimes masks substantial variations found within discrete forest stands. This spatial autocorrelation can be studied using a dense network of sample plots within an area of interests, and correlograms/semivariance of variable of interest can be estimated using localized sample plot data. The spatial autocorrelation within forest stands is larger in forests with regular tree patterns than it is in forests with random or clustered tree patterns. In Finland, some studies indicate that within stands, the autocorrelation for the basal area and growing stock volume of trees only exists within a 20–30 m distance, while 5–10 m distance intervals are used. The continuous description of forest characteristics has not received much attention in the forest resource inventory.

Spatiality of Landscapes

Habitat mosaics have been found to affect diversity and dynamics in both pristine and managed boreal forests, and many important processes have also been identified as being driven or affected by landscape heterogeneity. Efforts to quantify the spatial heterogeneity of landscapes began in the 1980s, but have accelerated in recent years, so that at the present there are hundreds of indicators that allow for some sort of quantification of various aspects of spatial heterogeneity at a landscape level. Thematic maps and satellite image-based products have also been used to estimate landscape indicators on a regional level.

Composition

Composition is typically indicated by the number of categories or classes in the map, the proportion of each class in the map, and the presence of diversity. Diversity measures typically combine two components of diversity: richness, which refers to the number of classes present, and evenness, which refers to the distribution of objects that are among the classes. Typical diversity indices are Shannon's and Simpson's.

Spatial Configuration

Spatial configuration of properties attempts to describe the spatial characteristics of individual patches, and the spatial relationship among multiple patches. Patch-based measures of pattern include size, number, and the density of patches. Useful edge information includes the perimeter of individual patches and various edgemetrics that incorporate the contrast between the patch and its neighbors. For example, there is less contrast between a mature forest stand and a young stand than there is between a mature stand and clear-cut areas. Patches can take a variety of shapes, making shape difficult to quantify. Most shape indices use a perimeter–area relationship. A widely used index related to both patch size and shape is the 'core area,' which is the proportion of a patch that is further than the specified distance from an edge. Patch cohesion has been proposed to quantify the connectivity of habitat as perceived by organisms dispersed among binary landscapes. Some pattern indices examine spatial neighborhoods, patch orientation, and isolation. These were developed primarily to predict the relative connectivity of habitat islands.

Contagion

Contagion is designed to quantify both composition and configuration. It measures the extent to which cells of similar classes are aggregated. It is calculated using the frequencies with which different pairs of classes occur as adjacent pixels on a map. This appears to summarize the overall clumpiness of areas of interest.

It has been shown that there are only five independent factors among 55 different landscape metrics. These are:

1. Number of classes.
2. Dominance.
3. Contagion.
4. Fractal dimension from perimeter/area.
5. Average patch perimeter/area ratio.

In Finnish forests, landscapes are transformed into a mosaic of managed forest stands of small size, in which species composition has become more homogeneous, and the age distribution of stands more even. Low values of contagion characterize the Finnish landscape, which is dominated by many small size-dispersed patches. The development of species occurrence and landscape level habitat models, based on National Forest Inventory (NFI) data and environmental information at the national level, highlight small variations among the indicators. This seems to have important implications for the spatial distributions of species. Landscape metrics has been proven to be an efficient method of monitoring forest characteristics, which might have important applications for management planning in order to improve forest biodiversity.

Spatiality of Regions

On a national level, both correlation and autocorrelation functions have been employed to study large structures of forest area, and volume of forests. In Scandinavian forests there is a slightly increasing autocorrelation almost until a 200 m distance, when larger distances are applied. This information is used to estimate the optimal distance between inventory tracts, the overall shape of the tract, and the distance between sample plots within tracts. To obtain a sufficient sampling set-up for the entire nation of Sweden, the country is divided into five regions with marginally diverse correlation functions for different variables.

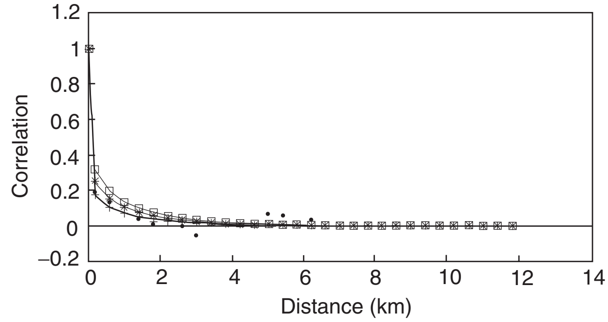

Figure 1 The estimated correlation function and empirical correlations for growing stock volume, as a function of distance between sample plots in three different areas. Reproduced with permission from Kangas A (1993) Estimating parameters of systematic cluster sampling by model based inference. *Scandinavian Journal of Forestry Research* 8: 571–582.

The final sampling design is based on their spatial characteristics and other practical considerations.

The correlograms (**Figure 1**) have also been used to estimate the standard error as regards large areas. The standard errors of systematic cluster sampling can be estimated using model-based estimators, which utilize the parameters of correlation functions. That way, the information about spatial dependency can be utilized in error estimation and spatial structure of forests is taken into account.

Border Effects in Spatiality

Spatial analysis is always connected to edge effects. In addition, edge effect correction methods are often used in inventory procedures, as well as in the analysis of limited empirical data sets. Four main methods are typically applied:

1. Plus sampling: additional data is measured, so that entire neighborhoods can be covered.
2. Minus sampling: buffer zones with a plot radius are generated for neighborhood calculation, and sampling is made in the core area only.
3. Toleroid edge correction, or mirror-sampling: an edge zone with plot radius is copied to the edge buffer, and the neighborhood is calculated from 'duplicated data.'
4. Weighting of observations: neigborhood data are weighted according to the probability of information existence.

Spatial Information in GIS and Remote Sensing

A forest information system contains information for decision-making in forestry, and forest inventory yields data for such a system. The initial and most

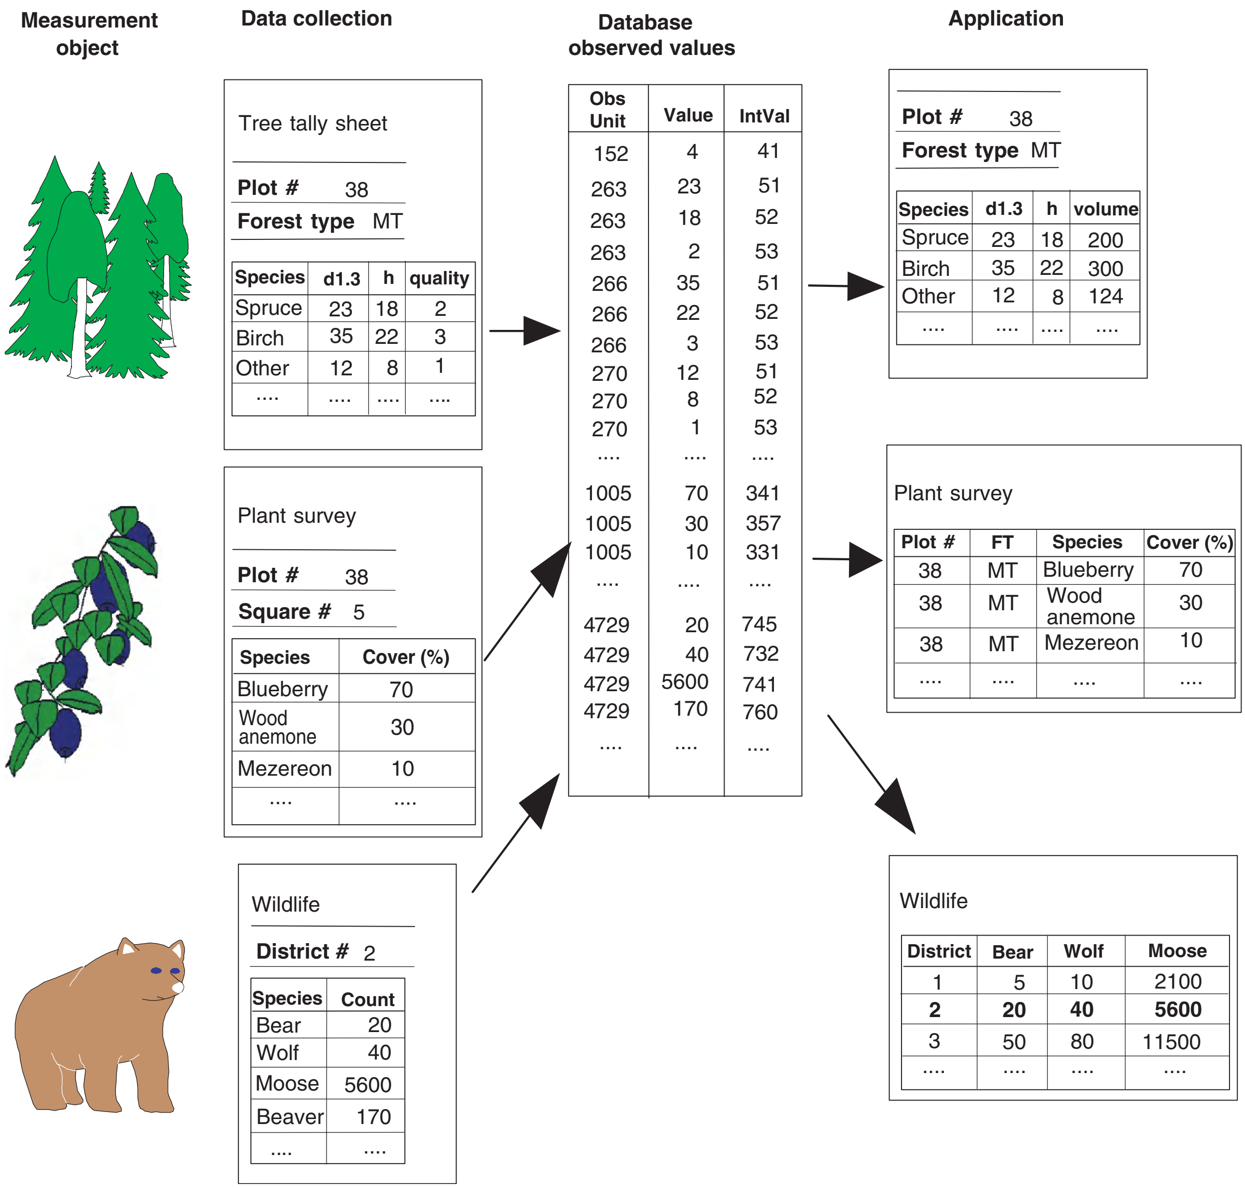

Figure 2 Storage structure for forest inventory attribute data. Reproduced with permission from Tokola T, Turkia A, Sarkeala J, and Soimasuo J (1997) Entity-relationship model for forest inventory. *Canadian Journal of Forest Research* 27: 1586–1594.

important phase of the forest database system design is the construction of a data model, which is primarily used to perceive, organize, and describe data in a conceptual schema. Real-world objects are defined in the data model in such a way that they can be described in databases (**Figure 2**).

Each observation and measurement in a system is linked to the geometry of GIS. The geometry of forestry objects can be presented using vector (point, line, polygon), raster, and dynamic segment-based models (**Figure 3**). Vector-based description is typically used for discrete phenomena (i.e., stand border maps) and raster-based systems (i.e., stratification of volume, elevation) do their best when continuous spatial surfaces are presented. Dynamic segmentation is used for objects which locate near line features, and can be located using the distance measure from known location along the line. Such a feature could be a hydrographic measurement unit along a river that has a particular distance from a known crossing.

The requirements for interoperable, computationally scalable software tools suggest the need for developing open software standards such as the Open GIS Consortium (www.opengis.org). The current Open GIS data model supports geometrical primitives, but requires application-specific definitions from the user side, as well as support for advanced analysis, which needs to be built externally.

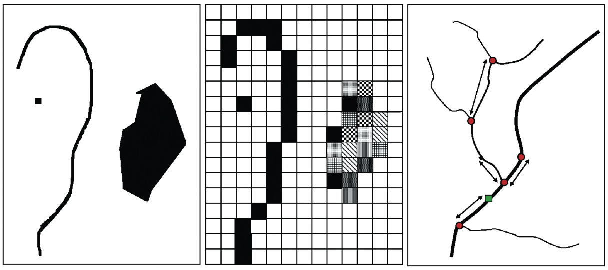

Figure 3 Vector-, raster-, and dynamic segmentation-based models are used to describe the geometry of real-world objects within global information systems. Reproduced from Tokola T and Kalliovirta J (2003) *Paikkatietoanalyysi*. Publications 34. Helsinki, Finland: Department of Forest Resource Management.

Remote sensing is considered to be an efficient tool for data acquisition and the updating of information into forestry GIS system. Yet, the remote sensing sensors can vary a lot, and it is important to realize that the spatial dependency of forest objects also affects the data collections phase.

When the pixel size is larger than the forest objects, information is perceived to be lost because the spatial resolution of images is so low. In contrast, when very-high-resolution images are used, adjacent pixels give the same information, because it is highly probable that they are taken from the same object. Another drawback of high-resolution data is that the amount of data soon becomes too enormous to compute. A worst-case scenario occurs when the use of unsuitable resolution results in erroneous image interpretation, due to the spatial autocorrelation of neighboring pixels. Good examples are the Landsat MSS images which have strong positive autocorrelation between neighboring pixels. It has been found that there are three reasons for this phenomenon: (1) a natural continuity of land cover, compared to the spatial resolution of the imaging system; (2) a positive correlation caused by the imaging system itself; and (3) image processing algorithms such as resampling. Studies with Landsat MSS images have indicated that the radiance of one pixel can affect the radiance of surrounding pixels that are 4–6 pixels apart. With higher-resolution systems like Landsat TM and SPOT, the positive autocorrelation can be even higher. The autocorrelation of pixel gray values in a forest environment is usually clear, and depends on the crown sizes and crown cover proportions of the trees. When semivariograms derived from aerial photographs have been studied in boreal areas, spatial resolution in which the variance was maximized was 2–4 m. Principally, such results have indicated that the local variance curve maximum is dependent on the object size, and a maximum is reached when the resolution is somewhat smaller than the object size. Nowadays, single tree-based digital delineation techniques are often used in various remote sensing materials, and 0.5 m resolution image material is generally used during these interpretation processes.

Satellite image-based surveys often utilize distant field sample plots from target areas. Normally, the margin of error increases when distant field sample plots from existing field samples are used. In one study, the best results were achieved when plots were within a 20-km range. Stand margin areas are also critical in remote sensing. The accuracy of growing stock volume estimation near a stand edge can be much lower than it will be inside the stands.

Simulated Forests

Simulation models of landscape levels are needed to understand large-scale variation, as well as predict the development of forests under different management schemes.

Alternative sampling designs for forest inventories can be evaluated through several means. One way involves carrying out actual manual inventories in the target forest. Computer-simulated samplings offer a cheaper and more flexible option for this. Following the first inventory round, it is possible to use remote sensing data to create a computerized depiction of the selected target area. The main advantages of such a simulation are that by manipulating input variables, a process of controlled experimentation and sensitivity analysis can take place. In spite of certain disadvantages, a simulation approach provides a flexible method for experimentation with prospective sampling designs, and is free from the restrictions associated with the analytical error propagation methods.

Using simulated sampling designs, changes in the sampling error of the estimate can be examined, and one can discover the best cluster design. In the simulation approach, all local small-scale characteristics of spatial variation can also be included in the analysis. In numerous other studies, entire spatial variation has been described by using the average covariance function. Certain simulation models use satellite image-based simulated models of forests. These models normally show a moderate fit with the field data. This type of model can also be used to test different sampling designs for carrying out forest inventory, and seemed to be representative in terms of the sampling error of estimate when compared to the overall structure of the spatial distribution of a given forest.

The standwise interpretation result of small-scale remote sensing materials does not vary within forest stands, and the correlation between neighboring satellite image pixels is relatively high. This correlation is caused by observation characteristics of the satellite sensor. While the small-scale accuracy of Landsat TM interpretation is low, and the tree-level information is missing, the main focus of this type of inventory planning concentrates on the shape of clusters and distance between plots. If small-scale variation was available, it could also perhaps determine the size and shape of plots. Unfortunately, fairly detailed aerial photographs would be needed, if we wished to see a true realization of stand structure taken using remote sensing material.

Most approaches to creating spatially explicit simulations of forest landscapes have been developed in North America, yet a large amount of simulators are available for specific purposes. They have been used to demonstrate the effects of different potential disturbance regimes, and for planning alternative forestry management schemes. Trying to make predictions as regards landscape scale, one has to deal with all of the ecological site types and tree species as well as all possible stand development scenarios. In addition, landscape-level processes have to be incorporated. One solution to such difficulties has been to simplify the description of forest stands by discarding most of the quantitative attributes, such as stand basal area or size of trees, and to use a semiquantitative approach to describe tree stands by the age structure of each tree species. It is important to note that the purpose of simulation models is not necessarily to predict reality directly, but rather to reveal the logical consequences of the assumptions incorporated in the structure of application-specific computer models and parameter values. Complex spatial models are indeed hard to evaluate, because it is difficult to find sufficient empirical data sets, as well as to compare exactly which aspects of spatiotemporal patterns are crucial for either a correct simulation, or a future model application.

Medicinal Plants and Human Health

B K Tiwari, H Tynsong and S Rani, North-Eastern Hill University, Shillong, India

Introduction

Humanity's dependence on forests is probably as old as humanity itself. For most periods of 200 000 years of human existence on earth humans have been deriving all their material needs from the forest. During prehistoric days, virtually all human needs were met from non-wood forest products (NWFPs) except construction and energy. It was during industrial and postindustrial periods that we started looking at the forests as a source of timber, and NWFPs became minor and less important even though the variety and value of NWFPs have always been far greater than the woody forest products. Edible products and healing herbs have been the most important NWFPs since antiquity. Forests represent vast natural pharmacies by virtue of having an enormous stock of biological materials of which the indigenous populations had knowledge of the medical uses. Medicinal plants of forest origin constitute a vast undocumented and overexploited healthcare resource for a majority of the world's population. In the last few decades, due to the pressure of increasing population, the area under forests has been shrinking. Demand for medicinal and aromatic plants (MAPs) has been increasing due to the increased number of users and due also to a resurgence in interest in herbal medicines and cosmetics. The variety, tonnage, and value of medicinal herbs extracted from forests are enormous. For example, more than 10 000 plants are used as medicines by the people of India, 70% of which come from the forests. Almost all medicinal plants collected, either legally or illegally all over Himalayas or even other parts of Asia for various purposes, are collected from the wild and only a very small number of species is cultivated. The medicinal plant resource in forests and in the wild are depleting rapidly so that a number of medicinal plants are threatened with extinction. The extinction of medicinal plants presents a hidden health risk to both developing countries and industrialized societies.

According to an estimate of the World Health Organization (WHO), medicinal plants form the basis of traditional or indigenous healthcare systems used by the majority of the population of most developing countries. The increasing demand for medicinal plants in healthcare is putting pressure on wild sources of plants. The herbalists have to walk increasingly greater distances for herbs that once grew almost outside their courtyards. Disappearance or drop in availability of herbs is forcing more and more rural populations to switch to modern medicines which have not yet reached many rural areas in developing countries. For example, only 3–30% of rural India is covered by modern medical facilities, which is also true for most developing countries. Thus there exists a strong positive relation between availability of medicinal plants and human health. There cannot be two opinions that any reduction in the supply of medicinal plants will adversely affect the health and well-being of people across the world. In recent years however, there has been a phenomenal growth of interest in the conservation of medicinal plants; this has occurred partly due to the increasing demand for herbal medicines in North America and partly due to recognition of the value of biodiversity by governments, nongovernmental organizations (NGOs), and donor agencies particularly after the Rio Summit in 1992.

With tremendous advances in the area of modern synthetic drugs after World War II, the use of herbal medicines declined considerably and lost attention gradually. However, it is now realized that indiscriminate use of antibiotics and synthetic drugs may lead to health hazards owing to the toxicity associated with these drugs. Therefore, during recent times a new trend has emerged in the use of herbal preparations because it is believed that remedies of natural origin are relatively harmless to the systems of the body. Presently, a large number of herbal preparations are being produced in the pharmaceutical industries of developed countries. In America, Europe, and Japan the traditional herbal drugs of the Ayurveda, Unani, and Chinese systems are extensively used. More and more attention is being focused on the development of drugs from natural products, and many manufacturers of Western medicines are forging ties with traditional communities and herbalists for indigenous knowledge and exploring the world of biomedicines for development of new drugs particularly for emerging diseases like AIDS.

People have relied on plants for staying healthy and treating illness for millennia. In the New World tropics, for example, archaeological remains of plants used as medicine have been dated to 8000 BC. Extensive written lists of herbal medicines have survived since antiquity, including the *Pen Ts'ao*, written by herbalist Shen Nung in 2800 BC which lists 366 plant-derived drugs including the familiar *Ephedra*. The history of Western medicine begins with the Greek physician Dioscorides, who wrote *De Materia Medica* in AD 78, describing over 600 medicinal plants, including *Aloe* and *Opium*. The Swiss pharmacist–physician Theophrastus Bombastus von Hohenheim advocated the use of chemical remedies and originated the field of medicinal chemistry in the early sixteenth century; however, Dioscorides' writings remained the standard text until the early nineteenth century. In 1803 the German pharmacist Friedrich Wilhelm Adam Sertürner first isolated alkaloids from plants, a class of chemicals with many potent physiologically active compounds (including quinine, atropine, cocaine, and tubocurarine). In nations with rich botanically based medical traditions, such as India and China, plant medicines predominate. The earliest mention of the medicinal use of plants has been found in the *Rig Veda*, which were written between 4000 and 1600 BC. In the *Atharva Veda*, definite properties of plant-based drugs and their uses have been given in detail. *Charaka Samhita* is another earliest treatise on *Ayurveda* (600 BC) which lists a total of 341 plants and plant products for use in health management. *Susruta Samhita* also dealt with plants related to medicines. Subsequent authors of later treatises on ancient Indian systems of medicine have extended the list of plants to 600 species.

Traditional healers in India use more than 10 000 different plant species, out of which approximately 7500 are used in folk and tribal system, 1800 in Ayurveda, 500 in Siddha, 400 in Unani, and 300 in Amchi. In China where medicinal plant use goes back at least 4 millennia, over 5000 medicinal plants have been recorded, and about 1000 are used in current practice. In Western medicine, respect for the power of plants has largely been lost during the postindustrialization period but it is catching up very fast and today Europe and North America are emerging as the largest consumers of the medicinal herbs of South Asia.

In the remainder of this article, the use of medicinal plants in various health care systems will be described. Modern medicine, trade, threats, and conservation needs of medicinal plants are briefly discussed with the aim of elucidating the interactions among various factors affecting medicinal plants and human health.

Traditional Systems of Medicine

Over 80% of the world's population relies on traditional plant-based medicines for their primary healthcare needs. According to WHO traditional system of medicine refers to:

> the sum total of the knowledge, skills, and practices based on the theories, beliefs, and experiences indigenous to different cultures, whether explicable, or not, used in the maintenance of health as well as in the prevention, diagnosis, improvement or treatment of physical and mental illness.

In many developing countries, traditional and herbal medicines are very much indispensable. Traditional systems of medicine (TSM) may be classified into three broad categories:

1. Traditional medicine, which has written traditions of documentation of knowledge, pharmacopoeias for doctors, often known as *Vaidyas*, *Hakeems*, and *Amchis*, and institutions for their training. This system of medicine is especially concentrated in Asia. Some of the more widely familiar traditional medicine systems are Ayurveda,

Siddha, Unani, Chinese traditional medicine, Tibetan medicine, and Western herbal medicine.
2. Folk medicine. This is orally transmitted and associated with households, communities, or ethnic groups and is most prevalent among tribal and indigenous communities. The number of plants used in folk medicine is enormous, most of which still remains undocumented.
3. Shamanistic medicine. This system has a strong spiritual element and can only be applied by specialist practitioners (shamans/doctor–priests).

Ayurveda

The Ayurvedic system originated in India long back in pre-Vedic period which is believed to be 5000 years BC and is the earliest documented ancient Indian knowledge. Ayurveda recognized the medicinal value of plants and provided specific methods of treatments of several human ailments using plants. To cite one example, for at least 2500 years before the West recognized the medicinal properties of the *Rauwolfia* root, the Indian medicine men had been using it to calm violently disturbed patients. They called it snakeroot and used it to treat lunacy, and a whole range of afflictions, from snakebite to cholera. More than 1800 medicinal plants are used in Ayurveda. The important medicinal plants used in Ayurveda and their applications are given in **Table 1**.

Siddha

The Siddha system is one of the oldest systems of medicine in India. The term 'Siddha' means achievement, and the Siddhars were saintly figures who achieved results in medicine through the practice of yoga. Eighteen Siddhars seem to have contributed towards the development of this medical system. The Siddha system is practiced in Tamil-speaking parts of India, and its literature is in Tamil. The system is also called Agasthyar system in the name of its famous exponent sage Agasthya. This system of medicine developed within the Dravidian culture, which is also of the pre-Vedic period. The Siddha system is largely therapeutic in nature. According to this system the human body is the replica of the universe and so are the food and drugs irrespective of their origin. The Siddhars investigated and studied the causes of many diseases and the effect of many locally available plants and minerals on these diseases. About 500 medicinal plants are used in Siddha.

Unani

This is an age-old system that originated in Greece, from where it later spread to India through Arab and Persian traders. Hence it is also known as the Greco-Arab system of medicine. Indian physicians enriched this system with their local knowledge of indigenous herbs, their own observations, and their experiments to make it one of the nationally accepted systems of treatment. The drugs used are mostly of plant origin. The history of herbalism in Unani medicine goes back to the history of pharmacology. About 400–700 medicinal plants are used in Unani.

Chinese Medicine

The medicinal and pharmaceutical traditions of China have evolved over the centuries as essential parts of its civilization and are widely recognized today as representing its rich cultural and scientific heritage. As this medical knowledge and expertise were built on a land endowed with an abundance of varied flora, it is not surprising that medicinal plants play a central role in Chinese medicine and the country's achievement in the utilization of its native plants in healthcare delivery has been admired and acknowledged throughout the world. The total number of species of medicinal plants used in different parts of China adds up to over 10 000. The official Pharmacopeia of the People's Republic of China lists 709 different drugs. Among these only 40 items are animal and mineral products, the others all being derived from plant material. Plant material accounts for more than 80% of the drugs sold in the Chinese market. About 1000 species of plants are now commonly used in Chinese medicine and about half of these are considered as the main medicinal plants that are in particularly common use. Most plant materials used in Chinese medicines originate from wild sources.

Recent researches in this system of medicine have proved that a synergy between Chinese and western system of medicine can help in formulation of drugs for treatment of some presently almost incurable diseases like AIDS, cancer, and hepatitis.

Western Herbal Medicine

Western herbal medicine has traditionally been used mainly for treating specific conditions, such as headache, cough, arthritis, menstrual problems, skin sores, insect bites, colds, sore throat, etc. It is a curious fact that herbal medicine, as it seems to be most widely known in Canada and the USA, has been so little influenced by the great systems of herbal thought that once flourished in Asia. The use of herbs in the western hemisphere stretches back into antiquity well into the Paleolithic or Old Stone Age. The beginnings of organized study of herbal therapeutics in the West are in the ancient Mesopotamian, Eygptian, and later Greek civilizations. By

Table 1 Some medicinal plants commonly extracted from Indian forests for Ayurvedic medicines

Species	*Medical application*
Acorus calamus	Nervine, antispasmatic, sedative, stomachic, expectorant, emetic, laxative, diuretic
Artemesia absinthium	Anthelminthic
Artemisia vulgaris	Anthelminthic, expectorant
Asparagus racemosus	Galactogogic, antispasmodic, antidiarrhetic, demulcent
Azadirachta indica	Skin disease, blood disease, antibacterial
Bacopa monnieri	Nervine, tonic, diuretic, sedative
Boerhavia diffusa	Diuretic, expectorant, laxative
Boswellia serrata	Antiarthritic, analgesic, anti-inflammatory
Buchanania lazan	Skin disease, laxative
Butea monosperma	Diarrhea, flatulence, anthelminthic
Callicarpa macrophylla	Joint pain, skin disease, blood disease
Calotropis gigantea	Bronchitis, diarrhea, tonic, cancer (?)
Cannabis indica	Insomnia, cachexia, dysmenorrhea
Capsicum annum	Rubefacient, stimulant, tonic
Carum carvi	Flatulence, stomachic
Carum copticum	Spastic bowel, flatulence, dyspepsia
Cassia angustifolia	Constipation, liver disease, joint pain
Cassia fistula	Ringworm, constipation, fever, antibacterial
Cedrus deodara	Fever, diarrhea, urinary disorders
Centella asiatica	Tonic, sedative, alterative, anxiolytic
Cichorium intybus	Emmenogogue, digestive
Cinnamomum camphora	Diarrhea, nervousness, muscular pain, fever
Cinnamomum zeylanicum	Dyspepsia, flatulence, diarrhea, menorrhagia
Cissampelos pareira	Bowel disease, uterine prolapse, alterative
Clitoria ternatea	Constipation, edema, anthelminthic, demulcent
Cocos nucifera	Fever, pharyngitis, skin disorders, alterative
Coleus aromaticus	Kidney stones, conjunctivits, spastic colon
Cordia myxa (obliqua)	Expectorant, colic, dyspepsia, ulcers, cough
Coriandrum sativum	Flatulence, colic, joint pain, antiseptic
Crinum deflexum (asiaticum)	Emetic, inflammatory conditions
Crocus sativus	Nervine, sedative, emmenogogue, aphrodisiac
Cuminum cyminum	Diarrhea, dyspepsia, antiseptic, hookworm
Curculigo orchiodes	Hemorrhoids, asthma, kidney stones, skin disease
Curcuma longa	Arthritic pain, anti-inflammatory, skin disease
Curcuma zedoaria	Cough, asthma, leukorrhea, tonsillitis
Cynodon dactylon	Diuretic, styptic, hematuria, hemorrhoids
Cyperus rotundus	Antiinflammatory, flatulence, fever, estrogenic
Datura metal	Antispasmodic, jointpain, asthma, dysmenorrhea
Dolichos biflorus	Edema, kidney stone, asthma, dysmenorrhea, tumors
Eclipta alba	Hepatic deobstruent and tonic, alterative, emetic, purgative, antiseptic, antiviral
Elettaria cardamomum	Bronchitis, flatulence, dyspepsia, hemorrhoids
Emblica officinalis	Fruit: cooling, laxative, stomachic, tonic, diuretic
Evolvulus alsinoides	Anxiety, diarrhea, bronchitis, memory loss, fever
Ferula foetida	Flatulence, cough, constipation, palpitations, aphrodisia
Ficus religiosa	Ulcers, skin disease, diabetes, constipation
Ficus racemosa	Diarrhea, hemorrhoids, bleeding disorders, antiseptic
Foeniculum vulgare	Cough, flatulence, dysmenorrhea, hookworm, edema
Gmelina arborea	General tonic, to increase strength, antiviral, indigestion
Grewia hirsuta	Diarrhea, wounds, heart disease, fever
Gymnema sylvestre	Diuretic, astringent, hypoglycemic, refrigerant, stomachic
Hemidesmus indicus	Excellent alterative, to increase appetite, cough, skin
Holarrhena antidysenterica	Diarrhea, dysentery, amebiasis, anthelminthic
Hyoscyamus niger	Chronic dementia, hysteria, palpitations, asthma, sedative
Hyssopus officinalis	Cough, asthma, bronchitis, amenorrhea
Ipomoea digitata	Cough, hoarseness, respiratory stimulant, tonic
Justicia adhatoda	Bronchitis, asthma, jaundice, antispasmodic
Linum usitatissimum	Cystitis, bronchitis, boils, expectorant, demulcent
Luffa acutangula	Splenomegaly, emetic, excellent for skin disease, expectorant
Madhuca longifolia	Tonsillitis, cough, rheumatic joints, diabetes, appetizer
Michelia champaca	Gastritis, chronic arthritis (?), emmenagogue, diuretic, colic
Mimosa pudica	Menorrhagia, hemorrhoids, skin wounds, diarrhea
Mimusops elengi	Tonic, cardiotonic, urogenital disease, snakebite, skin sores

Table 1 Continued

Species	*Medical application*
Morinda citrofolia	Acne, eczema, hyperlipidemia, brochitis, diarrhea
Moringa oleifera	Source of vitamin C, colds, boils, fever, joint pain, gout
Mucuna pruriens	Nervine tonic, aphrodisiac, parkinsonism, hypercholesterolemia
Nardostachys jatamansi	Nervousness, anxiety, dysmenorrhea, insomnia, hair tonic
Nelumbo nucifera	Refrigerant, sedative, demulcent
Nyctanthes arbortristis	Liver diseases, constipation, anthelminthic, antihistaminic
Ocimum sanctum	Demulcent, expectorant, anticatarrhal, antispasmodic, anthelminthic
Paederia foetida	Rheumatic joint pain, edema, bladderstones(?), inflammation
Papaver somniferum	Anxiety, diarrhea, aphrodisiac, sedative
Peucedanum graveolens	Flatulence, colic, abscesses, digestive
Phyllanthus fraternus	Jaundice, liver disease, fever, genitourinary disease, edema
Picrorhiza kurroa	Hepatitis, asthma, anorexia
Piper nigrum	Dyspepsia, cough, pharyngitis, headache, diarrhea
Plantago ovata	Constipation, colitis, irritible bowel, cystitis
Premna integrifolia	Flatulence, fever, arthritis, liver deobstruent
Pterocarpus santalinus	Skin tonic, liver disorders, fever
Punica granatum	Anthelminthic (esp. tapeworm), diarrhea, dyspepsia
Randia dumentorium	Fruit and rind are emetic, diaphoretic, and antispasmodic; bark is sedative and nervine calmative
Rauwolfia serpentina	Hypertension, anxiety, insomnia, colic

3000 BC the Egyptians and Sumerians had written traditions of systematic herbal use, and by 400 BC there were numerous medical schools in Greece practicing various forms of natural medicine, including herbology, cupping, and progressive open-air sanitoriums for the mentally ill. In modern times, since the scientific revolution of the nineteenth and twentieth centuries, Britain and Germany have rich traditions of herbal medicine use.

Tibetan Medicine

Tibetan medicine (Amchi) originated with the local folk tradition (known as Bon) that dates back to about 300 BC and was formally recorded by Xiepu Chixi, the physician to the Tibetan King Niechi Zanpu, in 126 BC. Aspects of both the traditional Chinese and Indian (Ayurvedic) medical systems were added later. Ayurveda has had the most profound influence on Tibetan medicine. The medicine of India was introduced to Tibet as early as AD 254, with the visit of some Indian physicians.

Tibetan medicine has been practiced also throughout Central Asia since at least the eighteenth century. The concepts are deeply grounded in the concept of universal compassion associated with the local religions of Buddhism and Bompo; the latter is the ancient religion of Tibetan. Historically, most Amchis (Tibetan medicine men) belonged to a lineage of healers and were taught medicine by their fathers or other elder male relatives. For them the healing value of plants and their precise identification is crucial. Tibetan herbal formulas they brought with them have been available as pharmaceutical products in Europe since 1980.

The modern Materia Medica of Tibet is derived from the book *Jingzhu Bencao* (The Pearl Herbs), published in 1835 by Dumar Danzhenpengcuo. This text has been compared to the famous Chinese herbal *Bencao Gangmu*. Its format includes two sections, one being in the style of the Buddhist sutra with praise of the medicines, and the other being a detailed classification of each substance, giving the material's origin, environmental conditions where it is found, quality, parts used, and properties. The text included 2294 materials, of which 1006 are of plant origin, 448 of animal origin, and 840 minerals. About one-third of the medicinal materials used in Tibetan formulas are unique to the Tibetan region (including the Himalayan area in bordering countries), while the other two-thirds of the materials are obtained from India and China. Although Tibetan herbal medicine includes the use of decoctions and powders, for the most part, Tibetan doctors utilize pills that are usually made from a large number of herbs (typically 8–25 ingredients). In general, Tibetan remedies emphasize the use of spicy (acrid), aromatic, and warming herbs. About 300 medicinal plants are used in Tibetan traditional system of medicine.

Folk Medicine

This system of medicine is very diverse and each type is specific to its own ecosystem and ethnic community. It is an oral tradition purely empirical in nature that exists in all rural, indigenous, and tribal communities of the world. Folk medicine knowledge is considered to be the most valuable asset of human civilization. Some folk medicine practices are described below.

Folk Medicine in India

This is widely practiced throughout the length and breadth of India. Its practitioners include housewives and village elders, herbal healers, bone setters, and 'Visha vaidyas' (poison healers). Almost every hamlet in rural India has a medicine man. An estimate suggests that more than 7500 plant species are used by folk medicine practitioners of India. Several Indian folk medicine plants or their extracts have already been adopted by Western modern medicine, e.g., *Psyllium husk* for bowel problems and *Cassia fistula* for antibiotic activity.

Northeastern India has rich knowledge of folk medicines. Meghalaya, a small state with 2 million population has thousands of traditional herbal practitioners.

Folk Medicine in Africa

People in rural Africa depend almost entirely on folk medicine. Traditionally, rural African communities have relied upon the spiritual and practical skill of traditional medical practitioners, whose botanical knowledge of plant species and their ecology and availability are invaluable. This dependence has led many medical scholars to believe that Africa, the cradle of humanity, is the birthplace of traditional methods of treatment. Folk medicines, as well as traditional practitioners, enjoy a special status in African societies.

There are hundreds of thousands of traditional healers in Africa, e.g., 900 000 in Nigeria, 700 000 in South Africa, 50 000 in Zimbabwe, and 450 000 in Senegal. Traditional healers use powders and other forms of medicines mainly extracted from plants, as well as superstitious practices, such as necromancy.

Folk Medicine in Other Parts of the World

As stated earlier folk medicines are known to almost every community of the world. The traditions of folk medicine are strong in Russia, Central Asia, Iran, Afghanistan, Mongolia and Manchuria. Equally, herbal medicines are an integral part of Brazilian folk medicine. Folk medicines are also popular in primary healthcare in several developed countries like Belgium, France, Germany, and the Netherlands.

Modern Medicine

Homeopathy

Homeopathy is based on the principle that substances that are poisonous in large doses can be very beneficial in small doses. Homeopathy is a form of medicine that treats the body as a whole and helps it to heal itself. Most homeopathic medicine preparations are partly or fully plant based. According to a recent estimate 482 medicinal plants are used in homeopathy. The applications of the drugs used in homeopathy are given in **Table 2**.

Allopathy

Allopathic system of medicine is also known as 'modern,' 'western,' or 'scientific' medicine. It is firmly rooted in the products of synthetic chemistry, as its drug arsenal. Nevertheless, in the developed world, 25% of all medical drugs are still plant-based and in the developing world this is closer to 75%. Allopathy will continue to depend on plants for its drugs and this dependence is more likely to increase rather than decrease. A large number of modern drugs have been derived from plant products, e.g., morphine, steroids, quinine, artemisinin, etoposide, taxol, etc.

Medicinal Plants in Modern Medicine

Modern pharmacology recognizes the therapeutic effects of plants: over 25% of all prescriptions in Western Europe and North America and up to 60% of those in Eastern Europe consist of unmodified or slightly altered higher-plant products. More than 40% of the industries producing modern medicines use plants as their active ingredient, although generally in a synthesized and more concentrated formula. The active ingredient in aspirin, for example, was originally found in the bark of willow trees (*Salix* spp.).

Western medicines produced from medicinal plants include contraconceptives, steroids (e.g., prednisone), and muscle relaxants for anesthesia and abdominal surgery; quinine and artemisinin against malaria; digitalis derivatives for heart failure; and the anticancer drugs vinblastine and vincristine, etoposide and taxol. These cannot be fully synthesized in a cost-effective manner. Therefore their production requires reliable supplies of plant materials, either from cultivated plants or from the wild. These few examples suggest how modern drug delivery depends on continuing availability of raw materials and how vulnerable it is to the exhaustion of natural resources.

Pharmaceutical industries look at biodiverse forests of tropics as an unmatched source of chemicals with potential for new drug development. Several national laboratories in North America, Europe, and Asia and drug industries are actively engaged in screening of plants for medicines. Quite a few

Table 2 Some medicinal plants collected from Indian forests for use in homeopathy

Species	*Application*
Abroma augusta	Diabetes mellitus, dysmenorrhea
Aconite sp.	Pain of abdomen, retention of urine, coldness, respiration, etc.
Azadirechta indica	Malarial fever, liver and spleen enlarged, skin diseases, leprosy
Berberis vulgaris	Peptic and renal disorders with pain in liver and abdomen with gravel in the kidney
Cannabis sativa	Gonorrhea, inflammation of the bladder, thin scanty pus, intense burning and pain, asthma
Desmodium gangeticum	Fever, burning in palms, soles, eyes, and face
Dioscorea	Biliary colic, flatulent colic, flatulent despepsia, gastralgia
Drosera sp.	Whooping cough
Eupatorium sp.	Snake bites, bleeding from lungs with cough, dysentery, etc.
Equisetum sp.	Enuresis
Ficus indica	Profuse mucus and blood in acute dysentery stools, emission of blood followed by evacuation of faccus with colic and tenosmus
Geranium maculatum	Hemorrhage from lungs and stomach
Gynocardia odorata	Leprosy, secondary syphilis, rheumatism, scabies, eczema, cutaneous eruptions
Hypericum perforatum	Injury of nervous tissue, spinal injury, shocks, gunshot wounds, etc.
Jacaranda caroba	Warts, redness after the syphilitic ulcer is cured
Lobelia inflata	Headache, nausea, vomiting
Momordica charantia	High temperature developed due to smallpox, measles
Nyctanthus sp.	Fever with vomiting, constipation, diarrhea, etc.
Passiflora incarta	Tetanus, dysmenorrhea, asthma
Ricinus communis	Stimulates the secretion of the mammary glands
Rauwolfia serpentina	High blood pressure, insanity
Tinospora cordifolia	Chronic malaria, especially after abuse of quinine with enlarged spleen and liver, yellowness of conjunctiva, diarrhea, vomiting
Tribulus terrestris	Impotence, gonorrhea, mental, nervous and physical weakness
Viscum album	Gonogorrheal rheumatism of joints and glands, especially in women

companies have made formal agreements with local indigenous communities and medicine men for the collection of medicinal plants on the basis of sharing of profits.

Trade

The world market for medicinal plant based products is estimated to be US$60 billion year^{-1} with a growth rate of 7% per annum. In Germany and France many herbs and herbal extracts are used as prescription drugs, while in USA herbal drugs are sold in food stores with turnover of US$4 billion in 1996, which was expected to double by the year 2000. The herbal medicine trade is booming business worldwide. In India, for example, there are 46 000 licensed pharmacies manufacturing traditional remedies, 80% of which come from plants. It is estimated that India expected to export crude drugs worth US$600 million in the year 2003 which may grow to US$2000 million by 2010. China exports crude drugs worth US$4400 million and Thailand worth US$2000 million. Europe is the major trading center for medicinal and aromatic plants globally, with imports into one European country or another amounting to 440 000 tonnes in 1996. There are at least 2000 MAPs marketed in Europe, which originate from over 120 countries. In 1999, the world market for herbal remedies was calculated to be worth US$19.4 billion, with Europe in the lead (US$6.7 billion), followed by Asia (US$2.2 billion), North America (US$4.0 billion), Japan (US$2.2 billion) and the rest of the world (US$1.4 billion). Hong Kong is claimed to be the largest market in the world, importing MAPs worth over US$190 million annually. A list of the leading countries exporting MAPs are given in **Table 3**.

Table 3 Twelve leading exporting countries of medicinal plants, according to export volumes (1992–95)

Country	*Export volume (tonnes)*
China	121 900
India	32 600
Germany	14 000
Singapore	13 200
Egypt	11 250
Chile	11 200
USA	10 150
Bulgaria	7 800
Morocco	6 850
Mexico	6 300
Pakistan	4 800
France	4 700

Threats to Medicinal Plants

The increasing population, desire to earn more money, and increasing acceptability of herbs as medicine are among some of the factors responsible for rising trade and increasing threats to the medicinal plants in the wild. Earlier, the harvesting of medicinal plants was the domain of specialist herbal healers but now harvesting has become the domain of uncertain and often indifferent commercial gatherers leading to a decline in wild stock.

The international herb trade, which has grown into a multi-billion dollar business, is depleting the local stock of the medicinal plants. International and national demands have changed a local harvesting pattern to commercial gathering without any regard to the regeneration of species for future yields. Most of Europe and North America's herbal medicine needs are fed from unsustainable wild collections in South Asia. There is a vast, secretive and largely unregulated market of medicinal plants sourced mainly from forests and the wild. The size of the market is growing dramatically, leading to depletion of resource base and making the species vulnerable to extinction.

The total number of plant species estimated to be threatened by IUCN is about 36 000, of which about 10 000 are medicinal plants (**Table 3**). The most serious threats to medicinal plants generally are habitat loss, habitat degradation, and overharvesting. The threats from overharvesting are also due to collection for purposes other than medicinal; for example, the African trees *Acacia sebegal*, *Boswellia papyrifera*, and *Pterocarpus angolensis* are often harvested for timber. Another reason why medicinal plants have become increasingly threatened has been the weakening of customary laws traditionally regulating the management and use of natural resources. The collapse of customary institutions has been connected directly to changes in the ways that medicinal plants were exploited and this has become a widespread phenomenon. Different countries may have different factors which result in the loss of medicinal plants; for example, in Pakistan a majority of medicinal plant species is facing severe threats from extraction, grazing, cutting, deforestation, unawareness, and misuse by the local vendors who are making key traded species vulnerable. In northeastern India and Nepal, deforestation, forest fires, shifting cultivation, overgrazing, and overharvesting have significantly eroded the medicinal plants resources.

Conservation Needs

Considering the importance of medicinal plants for human health and well-being, there is an urgent need for their conservation. Some countries have laws that regulate the commercial collection or trade of medicinal plants. For example, Poland lists species of medicinal and aromatic plants that cannot be

Table 4 Some endangered plants of actual or potential use in traditional medicine

Species	*Family*	*Threatened range*	*Use*
Acorus calamus	Araceae	India	Sedative
Alpina galanga	Zingiberaceae	India	Drug
Arbutus canariensis	Ericaceae	Canary Islands	Vitamin C
Artemisia granatensis	Asteraceae	Spain	Infusion
Catharahthus coriaceus	Apocynaceae	Madagascar	Alkaloids
Commiphora wightil	Burseraeae	India	Drug
Dendrobium nobile	Orchidaceae	India	Dendrobine
Dendrobium pauciflorum	Orchidaceae	India	Alkaloids
Dioscorea deltoidea	Dioscoreaceae	Afghanistan to Vietnam	Cortisone
Diplomeris hirsuta	Orchidaceae	India	Alkaloids
Dracaena draco	Liliaceae	Canary Islands, Cape Verde Islands, Madeira	Gum resin
Gentiana kurroo	Gentianaceae	India	Drug
Lodoicea maldivica	Arecaceae	Seychelles Islands	Drug
Nelumbo nucifera	Numphaecaceae	India	Drug
Paeonia cambessedesil	Paeoniaceae	Balearic Islands	Epilepsy
Panax quinquefolius	Araliaceae	US	Tonic tea
Paphiopedilum druryi	Orchidaceae	India	Alkaloids
Pelagodoza henryana	Arecaceae	Marquesas Islands	Endosperm
Podophyllum hexandum	Berberidaceae	India	Drug
Rauwolfia serpentina	Apocynaceae	India	Drug
Rheum rhaponticum	Polygonaceae	Bulgaria, Norway	Medicine
Rumex rothschildianus	Polygonaceae	Israel	Medicine
Ruta pinnata	Rutaceae	Canary Islands	Balsma-like properties
Santalum album	Santalaceae	India	Drug
Saussurea lappa	Asteraceae	India	Various
Siscymbrium cavanillesianum	Brassicaceae	Spain	Mustard-like properties
Toxocarpus schimperianus	Adelepiadaceae	Seychelles Islands	Pharmacology

collected without a permit from the department concerned. An Italian law of 1931 stipulates that permits for the commercial collection of species that are listed to be of medicinal value will only be issued to people who have degrees in herbalism from any recognized school of pharmacy. Bulgaria has established a quota system for the gathering of certain MAPs that is reviewed annually; they also ban export, as did the Government of India in 1994 for 50 species believed to be endangered in the wild. Nepal's Forest Act of 1993 provides power to ban collections of forest products. Enactment of such laws and their enforcement may go a long way in conservation of medicinal plants.

Botanical gardens and seed banks offer a more attractive way of storing *ex situ* the genetic diversity of the MAPs. However, medicinal plants are poorly represented in seed banks. A major task for conservationists is to create opportunities for the sharing of knowledge to encourage learning, or else there is a risk that much of folk medicine knowledge will be lost. Efforts should be made to document and integrate indigenous knowledge on MAPs, vegetation and forest management, NWFPs, agroforestry, homegardens, and biodiversity. Huge quantities of MAPs collected from the wild are lost during harvest, storage, and processing. The involvement of all stakeholders, i.e., collectors, traders, manufacturers, and consumers, through sharing of benefits can help a great deal in conservation of this resource so vital for human health and survival. Appropriate management and harvesting methods need to be developed to allow regeneration and maintenance of viable population of medicinal plants in natural habitats including forests. Full participation of local communities in conservation and management of MAPs is desirable. Multinational pharmaceutical industries and drug manufacturers need to invest part of their income in conservation and management of MAPs. There is a need for more work to ensure that the benefits from new drugs or botanicals developed and manufactured using indigenous knowledge are fairly and equitably distributed, as required by the Convention on Biological Diversity. Medicinal and Aromatic Plants: Ethnobotany and Conservation Status

N Bhattarai, Government of Nepal, Kathmandu, Nepal
M Karki, Medicinal and Aromatic Plants Program in Asia, New Delhi, India

Introduction

Ethnobotany is a multidisciplinary science involving the traditional use of plants by human beings. Billions of people in the world rely chiefly on herbal medicines. The great majority of medicinal and aromatic plants (MAPs) used locally or entering into trade and herbal industries comes from wild sources and constitutes the source of livelihoods of millions of people.

Ethnobotanical information and knowledge are believed to have contributed to the development of close to 30% of modern medicines. In recent years, the increasing demand for herbal medicines in industrialized countries is being fueled by a growing consumer interest in natural products. As international trade in medicinal and aromatic plants has grown to a multibillion dollar industry, local harvesting patterns have shifted from subsistence local collection to commercial 'mining.' The continued growth in the global raw-material market of MAPs has largely contributed to this trend.

Assessment of the conservation status of MAPs involves consideration of different threat factors including biological and socioeconomic issues such as destructive harvesting, habitat change, species extinction and loss of livelihoods of locals that have contributed towards disturbing trends in species loss. The conservation and management measures adopted so far have proved to be grossly inadequate. Tangible improvements in the livelihoods of local communities and inculcation of conservation values in the minds of people may be more sustainable measures for long-term conservation of MAP diversity and associated ethnobotanical knowledge systems.

Ethnobotany

Plants have been the basis of life on earth. The identification of plants useful to human beings from natural stands commenced in prehistoric times. Experiments and trials were the two main ways through which humans have learnt the various uses of plants. Only a few of the useful plants have so far been domesticated, while a majority of them are still used from the wild. With the advancement of civilization, the plants found in nature have been put more to use in various ways. The importance of plants as a means to fulfill the basic requirements of human beings can be keenly observed in the rural and remote areas of the world.

Harshberger in 1896 coined the word 'ethnobotany' to denote the study of plants used by people living in traditional societies. Later various workers defined ethnobotany variously. Despite considerable variations in definition, almost every worker has accepted the subject of ethnobotany as dealing with the relationship between human societies and plants. Ethnobotany, therefore, has a broad coverage including any traditional use of plants and plant products. The subject is multidisciplinary, involving many interrelated subjects such as history, anthropology, culture, literature, etc.

Ethnobotany being a use-group of plants by human beings, any traditional use belongs to the ethnobotanical discipline. On the basis of variety of uses, ethnobotanical studies may belong to various use-categories (**Table 1**).

Documentation of ethnobotanical information has mostly been based on archaeological sources, oral folklore, and other mythologies, literature sources, study of reference specimens in herbaria and museums, etc. Field-based study is, however, the most popular.

Medicinal and Aromatic Plants (MAPs)

'Medicinal plant' is not a taxonomic but a use-group of plants. Any plant when used in medicine or for medicinal purposes, whether in modern or in organized systems of traditional medicines like Ayurveda, the Unani system, homeopathy, etc., or the widespread indigenous and folk systems, can be categorized as a medicinal plant. 'Aromatic plants,' on the other hand, are those plants containing essential oil, mostly having an aromatic flavor, which may be, but is also not only limited to, medicinal plants. Both the two groups are these days collectively termed as medicinal and aromatic plants (MAPs).

Traditional Medicine and Traditional Healers

In the beginning all drugs were natural, such as vegetable, animal, and mineral products in their crude forms. Until the beginning of the twentieth century all medical practice was what we now call traditional. Traditional medicine is, therefore, used mainly to distinguish the ancient and culture-bound healthcare practices, which existed before the application of science to health matters in official modern scientific medicine or allopathy. Some frequently used synonyms are indigenous, unorthodox, alternative, folk, ethno, fringe, and unofficial medicine and healing.

A large number of individual therapies are currently in practice in different parts of the world, many of them increasingly employed for self-medication accompanied by faith and confidence with considerable extent of effectiveness, with or without the services of the traditional healers (**Table 2**).

The World Health Organization (WHO) has defined traditional medicine as:

> the sum total of all the knowledge and practices, whether explicable or not, used in diagnosis, prevention and elimination of physical, mental or social imbalance and relying exclusively on practical experience and observation handed down from generation to generation, whether verbally or in writing. Traditional medicine might also be considered as a solid amalgamation of dynamic medical know-how and ancestral experience.

> In its *Traditional Medicine Strategy* (*2000–2005*), WHO has defined traditional medicine as a comprehensive term used to refer both to traditional medical systems such as traditional Chinese medicine, the Indian subcontinent's Ayurveda and Siddha, and Arabic Unani medicine and also to various other forms of indigenous medicine.

Various traditional medical systems, with varying theories and formalities, are currently fulfilling the primary healthcare needs of more than three-quarters of the population of the developing world. Considering the coverage and effectiveness of these systems of traditional medicine throughout the world, the Alma-Ata Declaration of the WHO proposed the theme 'Health for all by the year 2000' in 1978. The commitment was reaffirmed by the International Consultation on Conservation of Medicinal Plants, organized by WHO/IUCN/WWF in Chiang Mai, Thailand, popularly known as the Chiang Mai Declaration (1988). It put emphasis on the primary healthcare approach and the principles of conservation and sustainable development, outlined in the World Conservation Strategy. In view of these facts, the World Health Assembly in May 1976 first discussed seriously the contribution that traditional healers make to the healthcare of communities worldwide.

The African Expert Group has defined traditional healer as:

> a person who is recognized by the community in which he (or she) lives as competent to provide health care by using vegetable, animal and mineral substances and certain other methods based on the social, cultural and religious background as well as on knowledge, attitude and beliefs that are prevalent in the community regarding physical, mental and social well-being and the causation of disease and disability.

In almost every part of the world traditional healers are practicing means of healthcare coverage that is culturally acceptable to the local population, dealing more or less satisfactorily with many of their health problems. Conducting religious ceremonies, preaching of supernatural powers and evil spirits, psychotherapy, cauterization, prevention, surgery, use of animal and mineral products, etc., are the important basis of most folk therapies. Herbal medicine is, however, the most popular.

Ethnobotany of Medicinal and Aromatic Plants

Health issues have always been of prime importance for humankind since the very beginning of civilization. The use of plant resources for medicinal purposes is one of a number of practices developed by ancient people. The early use of plants as medicine must have been learnt and developed by humans through constant trial and error, probably at the cost of many lives and sufferings. People adopted various herbs that exhibited curative properties. Due to lack of communication, and varying ways of life, many of these earlier remedies survived only by word of mouth from generation to generation. These remedies not only exist but also are being largely practiced in most parts of the world, particularly in rural and tribal societies. The absence of acculturation has, in many instances, helped in the preservation of this knowledge in almost original form. In most developing countries, the indigenous modes of herbal treatment are a part of the culture and the dominant method of therapy. These remedies, with a considerable measure of effectiveness, are socially accepted and economically viable, and are often the only available source to the rural poor.

Ethnobotanical studies have mostly been employed to study the medicinal uses of plants in general, involving a range of disease and ailments. Medicinal plants used to treat a particular category of health problem have become increasingly popular, e.g., to treat skin diseases, to heal wounds, to kill intestinal worms, to treat digestive and other abdominal complaints including diarrhea and dysentery, to treat amoebic and respiratory diseases, to treat malaria and other types of fever, to treat venereal diseases, to induce antifertility effects, to terminate pregnancy, to regulate fertility, to treat reproductive disorders, to treat cancer, etc. Consequently, ethnomedicobotanical studies have recently been focused on some more specialized health disciplines, e.g., papers have been published under the discipline of ethnonarcotics, ethnopediatrics, ethno-obstetrics, ethnogynecology, ethno-veterinary medicine, etc.

Conservation Status of Medicinal and Aromatic Plants

Estimation and monitoring of the conservation status of medicinal and aromatic plants, in general, is an important but challenging issue that can be realized only after identifying the various threat factors and their extents including use and trade as well as by evaluating the conservation measures and management practices adopted so far.

Medicinal and Aromatic Plants in Folk Medicine

The great majority of species of medicinal plants which are the dominant mode of therapy in almost all developing countries and that are used in folk or ethnomedicine, are collected from the wild. The WHO has listed 20 000 medicinal plants used in different parts of the globe. Other estimates indicate the number to range between 35 000 and 70 000 worldwide.

An estimated 70–80% of people worldwide rely chiefly on herbal medicine to meet their primary healthcare needs. In south Asia only, over 800 million people rely on herbal medicine. In China, 40% of urban patients and more than 90% of rural patients depend on plant-based medicine. Some 10 000–11 250 species are used in ethnomedicine in China, 6000–7500 in India, 2237 in Mexico, 2572 traditionally by North American Indians, and 1600 species in Nepal. Considering the extent of fieldwork ongoing in different parts of the developing countries among various tribes, ethnic groups, and other indigenous communities generating additional information on indigenous medicinal plants, the number of plants known to be used in human medicine is likely to increase considerably in the future.

Medicinal and Aromatic Plants in Organized Systems of Traditional Medicine

Many countries, especially in Asia and Africa, have officially recognized the use of plant-based traditional medicine in their healthcare delivery systems. These organized traditional medical systems employ relatively few species, viz. 500–600 in traditional Chinese medicine, 1106 in Tibetan medicine, 1250–1400 in the Ayurveda, 342 in the Unani, and 328 in the Siddha systems.

The value of traditional medicines in China is estimated at US$571 million per year. In 1995, according to the State Administration of Traditional Chinese Medicine, the countrywide sale of crude plant drugs was at US$2.3 billion. China's demand for medicinal plant material has grown at an annual rate of 9% over the last two decades. In India, there are 7843 registered pharmacies of ISM and 851 of homeopathy and a large number of non-registered small-scale production units. About 240 000 tonnes of crude herbs, representing about 10% of the quantity collected from the wild, are processed per annum by the Indian herbal pharmacies. The herbal product market in Germany in 1989 was estimated at US$1.7 billion. In the urban areas of contemporary Africa, there is a burgeoning demand for herbal-based traditional medicines. The same tradition is active in many South and Southeast Asian countries such as Bhutan, India, Myanmar, Nepal, Thailand, and Vietnam.

Herbal medicine is becoming even more popular in richer countries, a market sector that has grown at 10–20% annually in Europe and North America over recent years. In industrialized countries, the demand is being fueled by an outburst of consumer interest in natural products. The extent of interest on the part of the general public is demonstrated by the fact that in 1990 the trade in herbal remedies in the European Union has been valued at over US$1000 million and rising at 13% year^{-1}. Similar growth rates have been recorded and are expected to continue in rich countries like Canada, the United States, Germany, Japan, and others. In Japan, pharmaceutical expenditures for Kampo medicines (adopted from Chinese traditional medicine) in 1983 was US$150 million.

Medicinal and Aromatic Plants in Modern Medicine

A large number of drugs of the modern system or allopathy were discovered from plants based on their ethnobotanical uses (**Table 3**). Further, many other pure constituents obtained from plant sources are used as drugs in modern medicine (**Table 4**). Today, there are approximately 119 pure chemical substances extracted from higher plants and in use in modern medicine throughout the world. Out of these, more than 90 chemicals have been isolated from plants having ethnic uses; others are either from random screening or screening certain plant families that are known to be rich sources of biologically active compounds.

Approximately 25% of all prescriptions dispensed from community pharmacies in the USA between 1959 and 1973 contained one or more ingredients derived from higher plants. It has been estimated that the total economic value to the USA from plant-derived pharmaceuticals is the total sale of US$12 400 million year^{-1}. Financially, the retail sale of plant-based pharmaceutical products was estimated at US$80–90 billion globally in 1997, with medicinal plants contributing very significantly.

Medicinal and Aromatic Plants in Trade

In many parts of the world there is virtually no cultivation on any significant scale, including for example in Albania and Turkey in Europe, Pakistan, Bhutan, and Nepal in Asia, and most countries in Africa. Large quantities of MAPs are traded into urban centers from rural areas in developing countries, and also regionally and internationally. The global demand for medicinal plants and herbal medicine is very large, estimated at US$40–60 billion year^{-1}, and still growing.

China's output of medicinal plants from cultivated and wild harvested sources, considered together, was 1.6 million tonnes in 1996, with a total value (excluding exports) in terms of finished products of US$3.7 billion. The reported annual global imports of MAP material during the 1990s amounted to an average of 400 000 tonnes, valued at US$1.2 billion, showing a 100% rise from 1991 to 1997. The three leading exporting countries are China (140 000 tonnes year^{-1} over 1991–1997), India (50 000 tonnes year^{-1}), and Germany. Hong Kong is considered the largest herbal market in the world, importing in excess of US$190 million per year. Europe, especially Germany, is the major trading center for MAPs globally, with imports into one European country or another amounting to 440 000 tonnes in 1996. The WHO had estimated the world trade of medicinal plants at US$500 million in 1980.

India exports large quantities of Ayurvedic and Unani herbs and preparations over a very wide geographical area including Bangladesh, Japan, Nepal, Pakistan, Saudi Arabia, the UAE, Russia, and USA, and accounts for 12% of global herbal pharmaceutical trade. The annual herbal medicine sales in Eastern Europe, Asia, Japan, and North America are US$6000, US$2300, US$2100, and US$1500 millions respectively with a total derived from higher plants amounting to US$11 billion. In 1999, the world market for herbal remedies was calculated to be worth US$19.4 billion, with Europe in the lead (US$6.7 billion), followed by Asia (US$5.1 billion), North America (US$4.0 billion), Japan (US$2.2 billion), and finally the rest of the world (US$1.4 billion).

Habitat Degradation and Loss due to Commercialization

The great majority of the medicinal and aromatic plants used locally or entering into trade and used in herbal industries comes from wild harvesting. In China, the annual demand of plant materials for traditional as well as officially decreed medicines has been reported to exceed 1.6 million tonnes, more than 80% of which come from wild sources. More than 95% of the medicinal and aromatic plants of Nepal out of 10 000–15 000 tonnes that enter into trade annually are harvested from wild sources. In India, 90% of the medicinal and aromatic plants that enter into trade and industry are harvested from wild

Table 3 Important drugs discovered from ethnobotanical leads

Drug	*Medicinal use*	*Plant species*	*Family*
Ajmalin	Heart arrhythmia	*Rauwolfia canescens*	Apocynaceae
		Rauwolfia serpentina	Apocynaceae
Aspirin	Analgesic, anti-inflammation	*Filipendula ulmaria*	Rosaceae
Atropin	Ophthalmology	*Atropa belladonna*	Solanaceae
Benzoine	Oral disinfectant	*Styrax tonkinensis*	Styracaceae
Caffeine	Stimulant	*Camellia sinensis*	Theaceae
Camphor	Rheumatic pain	*Cinnamomum camphora*	Lauraceae
Cascara	Purgative	*Rhamnus purshiana*	Rhamnaceae
Cocaine	Ophthalmologic anaesthetic	*Erythroxylum coca*	Erythroxylaceae
Codeine	Analgesic, antitussive	*Papaver somniferum*	Papaveraceae
Colchicine	Gout	*Colchicum autumnale*	Liliaceae
Demecolcine	Leukemia, lymphomata	*Colchicum autumnale*	Liliaceae
Deserpidine	Hypertension	*Rauwolfia canescens*	Apocynaceae
		Rauwolfia serpentina	Apocynaceae
Dicoumarol	Thrombosis	*Melilotus officinale*	Fabaceae
Digitoxin	Atrial fibrillation	*Digitalis purpurea*	Scrophulariaceae
Digoxin	Atrial fibrillation	*Digitalis purpurea*	Scrophulariaceae
Emetine	Amoebic dysentery	*Cephaelis ipecachuanha*	Rubiaceae
Ephedrine	Bronchodilator	*Ephedra sinica*	Ephedraceae
Eugenol	Toothache	*Syzygium aromaticum*	Myrtaceae
Gallotanins	Hemorrhoid suppository	*Hamamelis virginiana*	Hamamelidaceae
Hyoscyamine	Anticholinergic	*Hyoscyamus niger*	Solanaceae
Ipecac	Emetic	*Cephaelis ipecacuanha*	Rubiaceae
Ipratropium	Bronchodilator	*Hyoscyamus niger*	Solanaceae
Morphine	Analgesic	*Papaver somniferum*	Papaveraceae
Noscapine	Antitussive	*Papaver somniferum*	Papaveraceae
Papain	Attenuates mucus	*Carica papaya*	Caricaceae
Papaverine	Antispasmodic	*Papaver somniferum*	Papaveraceae
Physotigmine	Glaucoma	*Physostigma venenosum*	Fabaceae
Picrotoxin	Barbiturate antidote	*Anamirta cocculus*	Menispermaceae
Pilocarpine	Glaucoma	*Pilocarpus jaborandi*	Rutaceae
Podophyllotoxin	Vermifuge, Cancer	*Podophyllum hexandrum*	Berberidaceae
		Podophyllum peltatum	Berberidaceae
Proscillaridin	Cardiac malfunction	*Drimia maritima*	Liliaceae
Protoveratrine	Hypertension	*Veratrum album*	Liliaceae
Pseudoephedrine	Rhinitis	*Ephedra sinica*	Ephedraceae
Psoralen	Vitiligo	*Psoralea corylifolia*	Fabaceae
Quinidine	Cardiac arrhythmia	*Cinchona pubescens*	Rubiaceae
Quinine	Malaria prophylaxis	*Cinchona pubescens*	Rubiaceae
Rescinnamine	Hypertension	*Rauwolfia canescens*	Apocynaceae
		Rauwolfia serpentina	Apocynaceae
Reserpine	Hypertension	*Rauwolfia canescens*	Apocynaceae
		Rauwolfia serpentina	Apocynaceae
Sennoside-A	Laxative	*Cassia angustifolia*	Caesalpiniaceae
Sennoside-B	Laxative	*Cassia angustifolia*	Caesalpiniaceae
Scopolamine	Motion sickness	*Datura stramonium*	Solanaceae
Stigmasterol	Steroidal precursor	*Physostigma venenosum*	Fabaceae
Strophanthin	Congestive heart failure	*Strophanthus gratus*	Apocynaceae
Teniposide	Bladder neoplasms	*Podophyllum hexandrum*	Berberidaceae
		Podophyllum peltatum	Berberidaceae
THC	Antiemetic	*Cannabis sativa*	Cannabinaceae
Theophylline	Diuretic, asthma	*Camellia sinensis*	Theaceae
Toxiferine	Surgery, relaxant	*Strychnos guianensis*	Loganiaceae
Tubocurarine	Muscle relaxant	*Chondrodendron tomentosum*	Menispermaceae
Vinblastine	Hodgkin's disease	*Catharanthus roseus*	Apocynaceae
Vincristine	Pediatric leukemia	*Catharanthus roseus*	Apocynaceae
Xanthotoxin	Vitiligo	*Ammi majus*	Apiaceae

sources. An estimated 99% of the 400–550 species currently sold for use in traditional medicine in South Africa originate from wild sources. Only 130–140 of the 1200–1300 species that are both traded in, and native to, Europe are derived predominantly from cultivation. An estimated 70–90% of the medicinal

Table 4 Some pure constituents from plant sources as useful drugs

Drug	Medicinal use	Plant species	Family
Ajmalicin	Antihypertensive, tranquilizer	*Rauwolfia canescens*	Apocynaceae
		Catharanthus roseus	Apocynaceae
Ajmaline	Antihypertensive, tranquilizer	*Rauwolfia serpentina*	Apocynaceae
Artemisine	Antimalarial	*Artemisia annua*	Asteraceae
Digoxin	Cardiotonic	*Digitalis lanata*	Scrophulariaceae
Diosgenin	Induces sterilization	*Dioscorea deltoidea*	Diodcoreaceae
Emetine	Antiamoebic	*Psychotria ipecacuanha*	Rubiaceae
Gossypol	Male contraceptive	*Gossypium herbaceum*	Malvaceae
Hyoscyamine	Anticholinergic	*Atropa belladonna*	Solanaceae
		Datura stramonium	Solanaceae
		Hyoscyamus muticus	Solanaceae
Ipecac	Induces vomiting	*Cephaelis ipecacuanha*	Rubiaceae
Khellin	Vascodilator	*Ammi visnaga*	Apiaceae
L-DOPA	Antiparkinsonian	*Mucuna pruriens*	Papiloinaceae
Marsilin	Sedative, anticonvulsant	*Marsilea minuta*	Marsileaceae
Pseudo-ephedrine	Central nervous system stimulant	*Ephedra sinica*	Ephedraceae
Rutine	Decreases capillary fragility	*Ruta graveolens*	Rutaceae
Taxol	Overian cancer, breast cancer	*Taxus brevifolia*	Taxaceae
		Taxus wallichiana	Taxaceae
Theobromine	Diuretic, myocardial stimulant, vasodilator	*Camellia sinensis*	Theaceae
Theophylline	Cardiac stimulant, vasodilator, smooth muscle relaxant	*Camellia sinensis*	Theaceae

plant material imported into Germany, the third largest importer, is wild-harvested and only 50–100 species among these are currently propagated on a large scale. The commercial sector of medicinal and aromatic plant is, therefore, facing serious problems due to the excessive dependency of users on resources sourced from the wild.

In addition to factors lying beyond human control, viz. landslides, flood, fire, etc., the most serious proximate threats to plant resources in general and medicinal and aromatic plants in particular are habitat loss, habitat degradation, and overharvesting. Forests are home to more than half the world's terrestrial species, but population pressure and the proportionately increasing demand for forest products are causing a rapid depletion of habitats in almost every part of the world. As the result, more than 50% of the world's original forest cover has already been wiped out and each year alarmingly big areas are cut, bulldozed, or burned. Poor people in the developing countries such as Bangladesh, Bhutan, India, Laos, Mexico, Myanmar, Nepal, the Philippines, and Vietnam, among many others, are pushed to destroy forests in desperate efforts to raise living standards. As a result, countless plant species including medicinal plants are facing considerable danger of extinction due to loss of habitat or its degradation.

Extensive destruction of medicinal plant-rich habitats such as tropical forests, wetlands, Mediterranean ecosystems, parts of the arid zone, etc., are enhancing the rate of extinction of biodiversity including medicinal and aromatic plants. Ninety-three percent of the original primary forest in Madagascar has been eliminated. It has been estimated that 12 000 plant species and probably around 190 000 animal species have been lost in Madagascar. All the forests of Western Ecuador have been destroyed to make way for banana plantations, oil wells, and human settlements, destroying almost 200 000 species of plants and animals.

Worldwide, the verdant tropical forests that existed in 1985 covered only 900 million ha out of 1.5–1.6 billion ha that once existed. Between 7.6 million and 10 million ha are eliminated each year and at least a further 10 million ha are grossly disrupted annually. Like other natural resources the forests of the world are being sacrificed on the altar of development. By giving the definition that affluence is development, the rich countries have set an unsustainable path to achieve human prosperity. Human activities, under the so-called development initiatives, have posed considerable threats to habitats and ecosystems, thus threatening biological diversity, in general. Major human impacts includes a significant lowering of the upper timberline, conversion of forest to arable land, commercial timber cutting, excessive use of timber for domestic purposes, construction of roads, dams, and canals, high-tension electricity cables, etc. One glaring example is the Amazon forests, when Brazil decided to construct a highway in 1970, and deforested an area almost equal to that of India.

It has been estimated that the average background rate of extinction has been roughly 2–3% $year^{-1}$.

Current species extinction rates are estimated at approximately 10 000–20 000 year^{-1} or between 1000 and 10 000 times faster than the natural rate or maybe 1 million times faster than the rates of speciation. This increased rate of plant extinction means loss of immense biodiversity much before these species are properly understood.

Conservation and Management of Ethnobotanical Resources

In some communities, women play a significant role in medicinal plant conservation and cultivation, e.g., the women herbalist in Kabale, Uganda grows most of her herbs in her home compound. The same trends have recently evolved in certain localities of Bangladesh and India. Valuing the forest as a source of medicine, in Manongarivo, a tropical rainforest area in northern Madagascar, the local community has preserved an area of forest as a 'green pharmacy' that, otherwise, would have been slashed and burned for subsistence agriculture. In the same line, sacred groves, which are patches or pockets of climax vegetation preserved on religious grounds by the local communities, are still found scattered in different parts of India, Nepal, and Sri Lanka.

Many countries have little or no regulations controlling the collection of plant material from the wild. In India, however, 29 species of medicinal plants, thought to be threatened in the wild, have been restricted from collection. Nepal has, likewise, imposed different levels of restriction on the harvesting and trade of 16 medicinal and aromatic plant species including 10 species of trees. These restrictions are mainly aimed at protecting the wild flora and encouraging their cultivation practices.

Medicinal and aromatic plants are important components of the local flora, and valuable parts of the ecosystem. However, these ecosystems and communities are being degraded and destroyed and species are being driven to extinction, thus threatening the resource base of MAPs as well. Due to various human activities loss of biodiversity is occurring at all levels. Considering the importance of biological diversity, of which medicinal and aromatic plant resources are an important component, conservationists lay emphasis on the conservation of the entire habitat and the ecosystem to safeguard the biological resources and their inevitable interactions. With the aim of protecting representative samples of natural ecosystems, a number of protected areas of different status have been established in almost every country that cover a significant proportion of the earth's surface.

In India, 87 National Parks and 441 Wildlife Sanctuaries, respectively, cover 34 819 km^2 and 115 903 km^2 of the forestland. This accounts for 4.5% of the land of the country and 14% of the land under forest. In Nepal, 16.71% of the country's land has been brought under different levels of conservation and protection. In Bangladesh, 0.8% of the land of the country has been declared protected area. Bhutan has set aside 10 513 km^2 of its forestland under different types of protected/conservation areas including 535 km^2 as the 'buffer zone.'

The establishment of extractive reserves in Brazil is an important first step in resolving some of the problems like the development of viable extractive economies that is being hindered by destructive harvesting. In South India, a number of Medicinal Plant Conservation Areas (MPCAs) have been established that included the historically/traditionally known areas for rich medicinal plant diversity.

In Nepal, the management of the national forest is being systematically handed over to identified communities of users characterized by a comparatively high level of participation by women. As a group, they share the rights and responsibilities of using and managing the forest. So far, about 20% of the national forest including about 12 000 patches of forests have been handed over to the communities to manage. In most cases the communities have shown their efficiencies in terms of conservation, management, and development of the forest and the program in Nepal has so far been very successful. Many of them have started the commercial harvesting of MAP resources in a sustainable manner although in many cases they had to deal with severely degraded forest patches.

Discussion

Billions of people on earth depend chiefly on herbal medicines that have been significantly contributing to their primary healthcare needs. The curative properties of folk herbal medicines have always been a miracle and almost every folk remedy poses more questions than it answers. However, many of these questions are better answered today than in the past. Because so many people use medicinal plants, or plants as medicine, mostly collected from the wild, in the folk healing systems, it may be considered a serious threat to their conservation. But the problem, as usually repeated, is not always so severe, although it is critical indeed. So far as collection for medicinal purposes is concerned, there is general agreement that collection for household use is not overwhelmingly the problem. So many thousands of species are used in folk medicines, and just because a species has been used somewhere medicinally, it does not follow that it is so used everywhere and at all times. Its designation as a medicinal plant may carry little or no meaning to people living in the neighborhood. In several African, Asian, and some other countries wild harvesting for local requirements has not been experienced as detrimental to plant survival as the quantity collected tended to be small and also most of the material collected came from rather weedy species and common varieties. Ethnic medicinal plants can have other uses than as sources of medicines, and the threats from overharvesting may be due, or partly due, to collection purposes other than medicinal. There may be good reasons, for the purpose of genetic conservation, to conserve particular populations of medicinal plants, as many times a locally endemic or highly fragmented population of plants may have local uses.

The number of species used in herbal trade and industries is relatively small but this group of plants is most threatened in the wild. Despite efforts now under way, there remain many challenges in the conservation and sustainable management of wild medicinal plant resources, and it has now become inevitable to evaluate the threat status and conservation needs of the local and regional floras, more particularly the medicinal and aromatic plant resources. As it is unfair to tar every taxon with the same brush, the first and possibly the most desired step is to identify the potentially threatened species, assess them in terms of threat factors and conservation status, and carry out the recommended measures.

The IUCN-Species Survival Commission's Conservation Assessment and Management Planning (CAMP) exercise has recently been recognized as a suitable mechanism for using available information to assess possibly threatened taxa and to initiate adequate conservation and management planning. The five threat categories, involving evaluation of threat factors and conservation status are Critically Endangered (CE), Endangered (EN), Vulnerable (VU), Near Threatened (NT), and Least Concern (LC), based mainly on information on their distribution, regeneration potentials, productivity, use, interacting threats, etc. CAMP exercises have been successfully used to identify threat factors and to assess conservation status of some species of MAPs in different regions.

The collection of medicinal plants from wild habitats has long been a mode of self-employment for most rural people. Although the wild resource-based herbal trade and industries have remained functional for a long period of time, it cannot always serve as a model for the future. As international trade in medicinal and aromatic plants has grown to a multi-billion dollar industry, local harvesting patterns have shifted from subsistence local collection to commercial 'mining' without regard to the generation of species for future yields, in most cases. The growth in the alternative medicine market in industrialized nations is a significant contributor to this trend.

Because processing and marketing are mostly exogenous to the supply area, control of the system of gathering and trade also tends to be found mostly in the hands of people external to the region. When an outside interest dictates the volume and price of a resource, local biodiversity suffers irreversible harm. The marginalized and poor people generally take the view that 'If I don't pick what I can today, someone else will get it tomorrow.' Consequently, the local people are generally losing control over the conservation and management of their resources.

The threats caused due to overharvesting usually recover with time but the damage due to loss of habitat is irreversible. The loss or degradation of forests and grasslands worldwide has led to the habitats of medicinal plants shrinking in almost every country. This has affected not only the few hundred commercial medicinal plants but also many thousands having no commercial uses but still serving the medicinal purposes of billions of rural people who mostly have no other alternative facilities.

The conservation and management initiatives focused on medicinal and aromatic plants in various countries and among various communities, although laudable, appear highly inadequate to cope with the negative efforts in practice so far. The protected areas network worldwide represents various physiographic and climatic zones, admirably contributing to the conservation of biological diversity, and it is wise to continue to stress the future significance of these efforts. While the protected areas have assured protection of certain species, such protected areas, however, are usually surrounded by damaged habitats, making them habitat islands. Habitats outside protected areas are under continuous pressure from human activities which, mostly, have increased beyond the carrying capacities of the ecosystems. Many of them are degraded and converted into agricultural lands.

In most of the supplier countries, although there is considerable evidence of overharvesting of medicinal plants, quantitative analyses of the effect of extraction on natural populations are lacking. Without these analyses, it is not possible to assess the effect of harvesting on depletion of resources, nor is it possible to formulate appropriate conservation and management strategies.

Conservation of natural resources are necessary for future generations, and this need has been so often repeated that the phrase has almost lost its importance. There is no comfort in thinking that species extinction is a natural process and therefore inevitable for the organisms that are extinct or on the way to extinction. While natural processes are involved, the activity of human beings accelerates and multiplies the means by which extinction can occur. Once a particular species is extinct, literally millions of years of evolution become undone and nothing can retrieve the situation. In the plant kingdom, the time for warning has matured. The destruction of many wild habitats and their inhabitants has already taken place and continues.

In the developing countries that are the major suppliers of wild medicinal plant materials, the overwhelming concern of the majority of the population is meeting their immediate needs. It is, therefore, difficult to conserve and direct resources for the benefit of future generations. The overexploitation of wild medicinal plant resources by rural people is therefore not just a case of preference but also of a situation where there is no other option.

At the community level, local people are the true resource managers, with a vested interest in maintaining the natural resources on which they heavily depend. But poverty, and to some extent ignorance, has forced rural people to continue activities that help them survive in the present but which will cause more severe problems in the future. The conclusion is, therefore, a challenge. Our approach to conserving wild medicinal plants for sustainable exploitation should be targeted at different levels, from improving living standards to changing the attitude of the people.

Tribal Medicine and Medicinal Plants

S Vedavathy, Herbal Folklore Research Centre, Tirupati, India

Introduction

Nearly 80% of the world population is dependent on indigenous medicines for primary healthcare. Tribal medicine is an age-old system of health care practiced by aboriginals in remote villages and forests. Tribal remedies consisting of simple methods of treatment developed by trial and error hold an important place in almost all societies. The study of nature by forest-dwellers started out of necessity. Thus the first study of plants by ethnic communities was undoubtedly a practical study centered on the importance of plants as a source of food for human nourishment, of fiber for clothing the human body, of drugs for the treatment of human diseases, etc. As civilization advanced over centuries rational human beings with their probing intellect and reasoning faculties enquired, investigated, and discovered various biological processes and began to unfold nature's magnificent creations. Even after advancement people remained in remote forests and hilly tracks, far away from the so-called urban civilization, carrying out their existence meeting all their requirements from the environs of forests. As they live in small ethnic groups or tribes, they are nowadays called tribal people or aboriginals.

Religion, magic, and medicine were integral parts of life of prehistoric peoples. Any person in the community with religious bent and knowledge of diseases and spirits assumed the headship of the community or the village and performed the roles of priest, sorcerer, and physician. Apart from the treatment of wounds and broken bones tribal medicine was probably the most ancient aspect of the art of healing for primitive vaidyas (physicians) showed their wisdom by treating the whole man or woman, soul as well as body.

Similarly the ancient peoples in Mesopotamia, Egypt, Babylonia, Greece, and Rome all developed their respective indigenous medicines along the same lines of belief, religion, and experience from exploration of various medicinal plants. The ancient medicine of Mesopotamia was magico-religious, while Egyptian medicine was empirico-rational.

Ethnobotany

The study of the association, interaction, and interrelationships of ethnic human societies (especially tribal communities) with the surrounding flora is termed 'ethnobotany' or aboriginal botany. The term ethnobotany was coined in 1896 by Harshberger, one of the fathers of economic botany of America. Ethnobotany has more recently been defined as the study of the interrelationship of plant environment and primitive societies. There are many subdisciplines of ethnobotany dealing with various aspects of tribal plants such as ethnoagriculture, ethnotaxonomy, ethnomedicobotany, ethnoecology, ethnomycology, ethnogynaecology, ethnotoxicology, ethnopharmacology, ethnopharmacognosy, ethnophytotaxonomy, ethnoveterinary medicine, etc.

Ethnography and the Ethnobotanical Knowledge of Tribes

Plants have profoundly influenced the culture and civilization of tribes in many countries. Many wild plants are in use by tribes for various purposes and most of them have found a place in rituals and ceremonies and some have been accorded sanctity (sacred plants). Many of the practices developed by indigenous tribes are the result of novel experimentation and innovation by people from observing the medicinal herbs and animals.

India has an immense wealth of biodiversity. According to estimates there are about 45 000 species of wild plants, of which 7500 species are in medicinal use in indigenous health practices. The tribal peoples (some 60 million people in India) who depend on forest wealth are the custodians who have safeguarded the medicinal plants till now. The real danger for biodiversity is from the urban elite who destroy the forests for industrialization and for their own needs. In any country, forests should cover one-third of the total land, for the maintenance of biodiversity. Forest cover is far below the desired level in India; it is about 19.5% and the protected area in that is only 10%. Rapid deforestation caused by overharvesting and the exploitative trade in medicinal plants have significantly reduced the availability of medicinal plants. With deforestation the tribal peoples who live in harmony with nature are the most threatened, and the wonderful tribal medicine is also disappearing slowly.

Tribal medicine is not a codified system. Through experience the disease is identified and treated. Even the primitive surgery the tribal practitioners make is their own and is performed in their home setting. There is a strong belief in tribal medicine that the efficacy of the therapy is lost if it is revealed to strangers who have no belief and sympathy on nature and medicine. In the modern sense there seems little scientific or experimental basis to these claims. But the use of a plant for the same purpose in several societies or regions has been taken as one of the criteria for greater credibility in terms of Western science.

Tribal medicine has assumed a new significance in the field of science in the last three decades and has emerged into a new branch of ethnobotany called ethnomedicobotany. This deals with tribal medicine, methods of preparation, mode of administration and their values. The Botanical Survey of India (BSI) and the Council of Scientific and Industrial Research (CSIR) started organized fieldwork and other studies on this subject through their regional centers all over India. Ethnomedicobotanical studies have been established in some universities, and field study results, herbarium collections and literature are being built up (see Further Reading).

Types of Tribal Medicine

Not all the tribals are vaidyas (doctors). Only the people who are interested learn and practice this. In India, tribal therapy is of three types: (1) Raja vaidya (medical therapy), (2) Bhuta vaidya (Witch therapy), and (3) Rakshasa vaidya (fire therapy). These three types of treatments very often overlap and the third type is applicable to animals as well as human beings. The second type is called magico-religious medicine which in modern parlance can be equated with psychotherapy. Elderly members of the community are well versed in the knowledge of different herbs, roots, and plants and their practices i.e., materia medica of tribal medicine. Some of them also maintain small herb farms. Even the scientists depend upon them for the identification and supply of medicinal plants for their research and preparation of medicines. Whenever epidemics such as chicken pox, cholera, and flu breakout the bhuta vaidya who employs sorcery, magic formulae, talismans, and amulets for outward consumption, also uses herbal medicines secretly for arresting these epidemics. These practices become a boon not only to the patient but also to the entire village, as prophylactic measures. The talismans and amulets also contain some powerful herbs or minerals. These practices are in vogue for human beings as well as livestock, which are more important and valuable to the rural people. Mankind developed his own pharmacopeias by making his body as laboratory to experiment. The gradual process might have taken thousands of years to evolve but one thing is certain; this is passed on from one generation to other with refinement.

Contribution to Biodiversity

The concept of sacred groves and thereby preservation of biodiversity is another of the great contributions of the primitive people to modern world. In the same way, the belief that the misuse of nature results in punishment and curse became boon to conservation, in helping to preserve the snakes and other minor animals. Tribal people believe that if any one kills a snake he or she will become sterile and will suffer from chronic skin infections. Tribals never uproot trees and many trees are considered sacred.

Herbal Remedies

Tribal population have learnt to utilize local herbs in different ailments after centuries of trials. Some of the folklore medicines have proved efficacious after detailed pharmacological and clinical trials. *Rauwolfia serpentina* roots are a classical example. This is now prescribed as a remedy of high blood pressure and certain forms of insanity. The seed kernel of *Hydnocarpus kurzii* from the Assam and Tripura hills has proved useful in the treatment of leprosy and skin diseases. The roots of *Nardostachys grandiflora* have provided a safe sedative after detailed clinical trials. The kernel of *Entada pursaetha*, bark of *Premna latifolia*, base of rachis of *Angiopteris evecta* as subsidiary food; the use of powdered dry fruits of *Brucea mollis* in malarial fever; the leaf juice of *Clausena excavata* in muscular pain; and the root decoction of *Ixora acuminata* as a galactagogue by karbis of Assam are interesting. The traditional knowledge of Asurs of Netarhat plateau (Bihar) is significant. They have many herbal cures such as *Andrographis paniculata* for fever with chills, *Schleichera oleosa* for gout, *Iphigenia indica* for cough and asthma, *Anisomeles* sp. For snake bite and poisoning, *Grewia* spp. for debility, and *Celastrus paniculata* as an abortifacient. The tribes such as Kol, Saora, and Koudh from the state of Orissa use more than 100 plant species for various ailments. The Mundas, Orans, Santhals, Lodhas, Kondhs, Bhumjis, Hos, and Mechs of Eastern India have vast knowledge about the treatment of cattle and birds using locally available plants. The tribal peoples residing along the hilly region of the western Ghats in Maharashtra use more than 100 wild species as food. The Todas, Kotas, Irulas, Kurumbas, the Paniyars and the Kattu nayaks of Tamilnadu have rich traditional knowledge and hundreds of plants are used for various ailments. The Jarawas, the Sentinelese, the Onge, the great Andamanese, the Nicobarese, the Shompen, and the Burmans of the Andaman Islands knew many plants, though most of the tribes themselves have not been explored by Western scientists.

The tribal repository contains many medicines for the treatment of one ailment. The medicine varies according to the symptoms and secondary effects and with the tribe and place. For one disease many plants are used basing on the availability. Some therapies recorded during the survey of Herbal Folklore Research Centre, Tirupati, Chittoor district, Andhra Pradesh, India are given in **Table 1**.

Medicinal Plants Research

We already know that traditional medicine developed from clues from forest-dwellers and herders. Documentation of such knowledge has been going on for centuries, e.g., *Hortus Malabaricus* (seventeenth century). The earliest scriptures (4500–1600 BC) of

Table 1 Tribal treatments for various ailments

Ailment	*Plant*	*Part*	*Mode of administration*
Fever	*Asparagus racemosus*	Root tuber	Decoction
	Cyperus rotundus	Root tuber	Decoction
	Tinospora cordifolia,	Stem	Decoction
	Allium sativum,	bulb	
	Zingiber officinale	dried rhizome	
	Andrographis paniculata,	Whole plant	The decoction of garlic is
	Morinda tinctoria,	Root	mixed with the two herbal
	Allium sativum	bulb	powders and given to drink
Head ache	*Catunaregum spinosa*	Fruit	1–2 drops of the juice instilled in the eyes
Indigestion and dyspepsia	*Trachyspermum ammi*,	Seed	Seed powder of the two in
	Carum copticum	Seed	equal proportions mixed with a pinch of rock salt is given
	Ricinus communis/	Seed oil	If the problem is chronic, seed oil is given on empty stomach or fruit juice mixed with a pinch of cumin powder is given
	Tamarindus indica	Fruit	
	Cassia senna	Leaf	For chronic cases two to three teaspoons of leaf powder mixed with a pinch of salt are administered on empty stomach
	Cassia occidentalis	Leaves	Tender leaves are made into curry and used along with food
Eye infections	*Citrus limon*	Fruit	Juice is instilled in the eyes
	Allium cepa	Bulb	Juice of the bulb is put in the eyes
	Curcuma longa	Rhizome	One to two drops of fresh rhizome juice is instilled in the eyes
	Martynia annua	Leaf	Leaf juice is put in the eyes
	Acorus calamus and	Dried rhizome	Rhizome made into ash is
	Zingiber officinale	Fresh rhizome	mixed with ginger extract and two to three drops are instilled in the eyes
Liver disorders	*Cuscuta reflexa*	Plant	Paste made from the cooked plant is applied on the stomach
	Azadirachta indica	Gum	Gum mixed with opium is given
	Phyllanthus niruri	Tender twigs with leaves	Paste or powder is given with buttermilk
	Boerhavia diffusa	Whole plant	Decoction is given with toddy jaggery
Cough and cold	*Pongamia pinnata*	Fruit	Put as garland around the neck for the chronic cases
	Datura metel	Leaves	Inhalation of fumes
	Solanum surrattense	Root	Powder mixed with honey is given to lick
	Adhatoda vasica	Leaves	Decoction
	Ocimum sanctum	Leaves	Juice is given with long pepper powder
	Coleus aromaticus	Leaves	Leaves eaten directly or juice with black pepper
Cuts and fractures	*Ficus bengalensis*	Leaves	Leaves warmed under fire are bandaged
	Dodonaea viscosa	Leaves	Pounded leaves are bandaged on the fractured part using bamboo sticks
	Cassia spp.	Leaves	Leaf paste mixed with white yolk of the egg is applied and bandaged using bamboo sticks
Sexual potency	*Mucuna prurita*	Seed	Powder mixed with honey/jaggery is given
	Asparagus racemosus	Root tubers	Powder mixed with honey/jaggery is given
	Pedalium murex	Whole plant	Juice with sugar candy
	Corollocarpus epigeus	Root tuber	Powder with goat's milk

continued

Table 1 Continued

Ailment	*Plant*	*Part*	*Mode of administration*
	Curculigo orchioides	Root tuber	Powder with goat's milk
	Holostemma adakodein	Root tuber	Powder with goat's milk
	Portulaca tuberosa	Whole plant	Powder with honey/jaggery
	Pueraria tuberosa	Root tuber	Powder with jaggery
Toothache	*Calotropis procera*	Latex	Topical application
	Achyranthes aspera	Root	Paste for topical application
	Zanthoxylum armatum	Stem	Powder mixed with alum is applied on the affected part
	Azadirachta indica	Stem	For brushing teeth
	Pongamia pinnata	Stem	For brushing teeth
	Tridax procumbense	Leaf	Paste mixed with camphor is put on the affected part
For easy delivery	*Achyranthes aspera*	Root	Root paste applied on the abdomen and navel region
	Ricinus communis	Seed	Seed oil is applied on the abdomen and navel region
	Zingiber officinale,	Dried rhizome	Decoction made by mixing the
	Piper nigrum,	Seed	ingredients in equal proportions is given to drink to hasten the pains
	Brassica nigra,	Seed	
	Coriandrum sativum	Fruit	
	Bambusa arundinaceae	Leaves	Decoction of the leaves is given
	Boerhavia diffusa,	Root	A wick dipped in the root paste or seed oil or fruit juice is inserted into the vagina to hasten the pains
	Ricinus communis,	Seed oil	
	Sapindus emarginatus	Fruit	
	Moringa oleifera	Leaves	Juice mixed with a pinch of salt is given
	Calotropis gigantea	Flowers	Flowers fried in ghee is given at half an hour interval
To ensure complete discharge of the placenta after delivery	*Tephrosia purpurea*	Root	Extract is given two to three times for complete discharge
	Azadirachta indica	Leaf	Leaf extract
	Caesalpinia bonduc	Root	Decoction is given along with rice gruel
For expulsion of dead baby from the womb	*Bambusa arundinacea*	Leaves	Leaf decoction with asafetida, salt, and rice gruel is given; this facilitates the expulsion within half an hour
	Prosopis cineraria	Leaf	Decoction prepared by mixing with garlic, millets and black pepper
Snakebite	*Aristolochia indica*,	Root	Paste/powder given internally
	Andrographis paniculata	Whole plant	
	Alangium salvifolium	Bark	Paste/powder, given internally
	Corallocarpus epigeus	Root	Paste is applied on the part and given to lick/instilled in the nostrils if the patient is unconscious
	Strychnos colubrina	Bark	Paste/powder given to drink or instilled in the nose
	Marsedinia volubilis	Leaf	Paste/powder
	Cryptostegia grandiflora	Root	Paste/powder
	Celastrus paniculata	Root	Juice/paste, given to drink or two to four drops instilled in the nose
	Acalypha indica	Leaf	Leaf paste is given

the Hindus, the *Rigveda*, mentions the use of plants for curing various ailments. The history of early Indian medicine is covered elsewhere in this Encyclopedia (*see* **Medicinal, Food and Aromatic Plants:** Medicinal Plants and Human Health).

Importance of Tribal Drugs

Many drugs discovered recently are taking the lead from tribal medicine. The discovery of ephidrin from the Chinese herbal drug *mahuang* has attracted the attention of many. Egyptians have long used the fruit of *Ammi majus* in the treatment of leucoderma. Rutin, now a well-known glycoside originally obtained from *Ruta graveolens*, has been reported from 40 different species of plants and is now increasingly employed in the treatment of capillary fragility. Documentation of such knowledge is needed. Most of the primitive tribes do not accept any other medicine except the ones prescribed by their medicine men. Information on all such knowledge should be recorded, preserved, and scientifically tested for blending into modern-style health systems. More efforts are needed towards establishing an evidence-based approach to promote traditional medicine practitioners into community-based health activities (**Table 2**).

Recent Efforts Made to Document Traditional Knowledge

A new resource database on traditional knowledge has been developed at the University of Illinois at Chicago named 'Natural Products Alert' (NAPRALERT). This new resource contains the world literature on natural products. Comprising data from more than 80 000 scientific articles, abstracts, and books, the database contains a wealth of information primarily on the ethnomedicine, pharmacology (experimental), and chemistry of plants.

Institutional Roles in Protecting Traditional Knowledge

Coordinated efforts to preserve the rare and endangered genetic wealth are required. Not only preservation of plant wealth but also a knowledge base and natural pockets of vegetation such as sacred groves is necessary. If the tribal communities are involved in such activities, they may open up their thinking on positive lines and help in conservation of native plants and knowledge. The programs of tree planting and medicinal plants regeneration need vast quantities of seeds. Tribal peoples could be engaged in selection of the seed, trees, and seed production areas. They could also be engaged for collection of seeds from these known sources.

Patents

Traditional knowledge is easily available in the public domain through gene banks and digital databases. Hence biopiracy/bioprospecting cannot be prevented using the Access and Benefit Sharing (ABS) provisions of International Convention of Biological Diversity and its well-intentioned mandate of prior informed consent (PIC) of traditional practice contributors. Thus ABC conditions must now be imposed before granting intellectual property rights (IPR) to traditional innovations.

The CBD convention recognizes that traditional knowledge, innovations, and practices are of importance to the convention of biological and intellectual heritage in this age of biopiracy and require ownership. If the knowledge is novel, based on innovations and a product of biodiversity it comes under recognition and protection.

Areas that Need Attention

- The concept of the naming (local names) of the plants and any expression of such knowledge related to disease.

Table 2 Contributions of tribal medicine to modern medicine

Modern drug	*Ethnomedicinal use*	*Plant source*
Aspirin	Reduces pain and inflammations	*Filipendula ulmaria*
Codeine	Eases pain, suppresses cough	*Papaver somniferum*
Ipecac	Controls vomiting	*Psychotria ipecacuanha*
Pilocarpine	Reduces pressure in the eyes	*Pilocarpus jaborandi*
Pseudoephidrine	Reduces nasal congestion	*Ephedra sinica*
Quinine	Combats malaria	*Cinchona pubescens*
Reserpine	Lowers blood pressure	*Rauwolfia serpentina*
Scopolamine	Eases motion sickness	*Datura stramonium*
Theophyllin	Opens bronchial passages	*Catharanthus roseus*
Disogenin	Contraceptive	*Dioscorea floribunda*
Digitoxin	Dropsy, relieves heart congestion	*Digitalis purpurea*
Taxol	Wound healing	*Taxus brevifolia*

- Conservation practices of the tribe, the taboos associated with certain plants, and their impact on the ecosystem.
- Tribal peoples have some rules and regulations regarding the medicine practice such as age, gender, and background relating to plants and the reasoning behind the practice.
- The tattooing, painting, dancing, customs, foods need thorough local study for the development of ecocenters.
- Tribes have specific plants for various uses, and their use differs with the tribe; this needs greater attention where the cross-cultural study may lead to many revelations.

Conclusion

There is need for documentation of all tribal health practices and the plants used by them. Deforestation seriously affects the life of tribals who are the 'forest children.' Their health, wealth, and culture depend on the forest and no one can alienate them from nature and it is a crime to deprive their resource base. The elite society that thinks that these people are illiterate and ignorant and need modern medication and education should understand first the dynamic element of the systems before introducing any reform.

Forest Biodiversity Prospecting

S A Laird, University College London, UK
K ten Kate, Insight Investment, London, UK

Introduction

Forests have long been an invaluable source of medicines, foods, crops, and other products based on genetic resources. A wide range of commercial sectors is involved today in 'biodiversity prospecting' as part of research and development programs aimed at developing new products, processes, and ingredients. Although scientific and technological advances have changed the role of natural products in many industry research programs, they continue to contribute significantly to existing sales and new product development. Biodiversity prospecting takes place within a legal and ethical framework that has transformed in the last decade, in part as a result of the Convention on Biological Diversity and the International Treaty on Plant Genetic Resources for Food and Agriculture. Biodiversity prospecting partnerships must now incorporate requirements for prior informed consent, mutually agreed terms, and benefit-sharing with source countries and communities.

Sectors Involved in Biodiversity Prospecting

The collection and trade in genetic resources is as old as human civilization, but the term biodiversity prospecting (bioprospecting) was first defined in 1993 as 'the exploration of biodiversity for commercially valuable genetic resources and biochemicals.' Biodiversity prospecting involves a wide range of commercial industries including the pharmaceutical, biotechnology, seed, crop protection, horticulture, botanical medicine, cosmetic and personal care, and food and beverage industries. These sectors vary significantly in terms of size, and the role of genetic resources in research and development, and markets (**Table 1**).

In some sectors, such as the botanical medicine, horticulture, and agricultural seed sectors, commercial products are 100% natural products. In others, the contribution of genetic resources might be more indirect. For example, in the pharmaceutical, crop protection, and sometimes the cosmetic industry, genetic resources are screened for active compounds. The final commercial products might be chemically identical to the pure natural product, might start with a natural product that is then chemically modified, or

Table 1 Industries involved in biodiversity prospecting: comparison of size in 1998, and the role of genetic resources and traditional knowledge

Industry	*Size of sector (US$)*	*Average size of top companies (annual sales in US$)*	*Percentage of sales dependent on genetic resources*	*Use of traditional knowledge (importance: scale of 1–5)*[a]
Pharmaceutical	$300 billion	>$10 billion	25–50%	3–4
Crop protection	$0.6–3 billion	$2–3 billion	<10%	3–4
Agricultural seed	$30 billion	$500 million–$1 billion	100%	3–4
Horticulture	$16–19 billion	$200–500 million	100%	4
Botanical medicine	$20 billion	<$200 million	100%	2
Personal care and cosmetic	$75 billion	$5 billion	<10%	3–4
Biotechnology (other than agriculture and healthcare)	$60–120 billion	Great variation	100%	4

[a] 1, Very important, central to research strategy; 2, regularly used to identify, develop and market new products; 3, occasionally used to identify, develop, and market new products; 4, currently rarely used, but many products and the roots of the industry are based in traditional knowledge; 5, never used.

Source: ten Kate K and Laird SA (1999) *The Commercial Use of Biodiversity*. London: Earthscan Publications; Laird SA and ten Kate K (2002) Linking biodiversity prospecting and forest conservation. In: Pagiola S, Bishop J, and Landell-Mills N (eds) *Selling Forest Environmental Services*. London: Earthscan Publications.

might result when the parent structure comes from nature, but the final product is synthesized to a design based on a natural template. Interest in natural products has been cyclical over the last four decades in these industries, but naturally inspired compounds continue to contribute significantly to companies' profits. For example, 11 of the 25 best-selling blockbuster drugs in 1997, representing 42% of industry-wide sales and with a total value of US$17.5 billion, are biologicals, natural products or entities derived from natural products. Of the 87 cancer drugs approved by the US Food and Drug Administration between 1985 and 1995, 62% are of natural origin or are modeled on natural product parents.

Contribution of Traditional Knowledge

Traditional knowledge forms a component of some biodiversity prospecting discovery programs. In most cases, this is acquired through literature and databases, but traditional knowledge is also collected through ethnobotanical research with communities. Scientific and technological advances in recent decades have made the role of traditional knowledge more marginal than it once was, but all of the industries involved in biodiversity prospecting have their roots in this knowledge and many products continue to be marketed based on earlier research on traditional use (**Table 1**). For example, of the approximately 120 pharmaceutical products derived from plants in 1985, 75% were discovered through the study of their traditional medical use. In 1997 a study demonstrated that for the base compound in most of the top 150 plant-derived prescription drugs, commercial use correlates with traditional medical use.

Forest species that have been commercialized include the pharmaceuticals *Cinchona* spp. (which yield quinine) from South America; *Chondodendron tomentosum* (D-tubocurarine) from South America; *Rauvolfia serpentina* (reserpine) from Asia; *Pilocarpus jaborandi* from Brazil (pilocarpine), and *Camptothecen acuminata* (toptotecan) from China. Botanical and herbal medicines from forests with large international markets include *Uncaria* spp. (cat's claw) from Central and South America; *Prunus africana* (pygeum) from Africa; *Panax ginseng* and *P. quinquefolius* (ginseng) from Asia and North America respectively; and *Hydrastis canandensis* (goldenseal) from North America. By far the most commercially successful product to result from biodiversity prospecting in forests in recent decades is the case of the Pacific yew trees *Taxus brevifolia* and *T. baccata*, which yield anticancer compounds. Original collections of *T. brevifolia* were made in 1962 in the Pacific Northwest of the USA. Previously considered a waste tree following logging in the region, numerous groups struggled to develop large-scale sustainable supplies of raw materials once the commercial potential of this species became apparent in the late 1980s. By 2000, the commercial products derived from the Pacific yew tree had annual sales in excess of US$2 billion, making this one of the top selling drugs worldwide.

The Policy Context for Biodiversity Prospecting

In the last 15 years the ways in which biodiversity prospecting is viewed, and the ethical and legal framework in which it takes place, have transformed.

The Convention on Biological Diversity (CBD) sets out provisions according to which states should regulate access to genetic resources and associated traditional knowledge. It balances sovereignty and the authority of national governments to regulate access to their genetic resources with the obligation for them to facilitate access for environmentally sound purposes. Access to genetic resources is to be subject to governments' prior informed consent, on terms mutually agreed by the provider and recipient that promote the fair and equitable sharing of benefits. Similarly, subject to national law, access to the knowledge, innovations and practices of indigenous and local communities requires the prior approval of the holders of that knowledge and the resulting benefits should be shared fairly and equitably with the communities concerned.

The 186 Parties to the CBD are developing guidelines to spell out these provisions and translate them into action. When the Parties to the CBD met in The Hague in April 2002, they adopted the voluntary *Bonn Guidelines on Access and Benefit-Sharing* (http://www.biodiv.org). These provide operational guidance for 'users and providers' of genetic resources and serve as information for governments drafting national laws and for governments, communities, companies, researchers, and others involved in access and benefit-sharing agreements.

Figure 1 The Convention on Biological Diversity and 'Access and Benefit-Sharing.'

In particular, the Convention on Biological Diversity (CBD) (**Figure 1**), which opened for signature at the United Nations Conference on Environment and Development held in Rio de Janeiro in 1992, and the International Treaty on Plant Genetic Resources for Food and Agriculture (IT), finalized in Rome in November 2001, promote new principles of prior informed consent, mutually agreed terms, and benefit-sharing. At the same time, researchers and indigenous peoples' groups are exploring the parameters of what constitutes equitable research relationships, and have articulated appropriate terms for collaboration. A range of indigenous peoples' statements and declarations, researchers' codes of ethics, and institutional policies have been developed in response. All of this combines to create a new context in which biodiversity research and prospecting take place, in order to ensure source countries and local communities control and benefit from commercial use of their resources and knowledge.

Biodiversity Prospecting, Benefit-Sharing, and Conservation

The bulk of benefits for conservation and development resulting from biodiversity prospecting in recent years grew from the research process, and an increasing number of partnerships between companies and source countries. Benefits resulting from these partnerships include: information and research results, participation in the research process, technology transfer, training and capacity-building, and in some cases financial benefits in the form of fees, milestone payments, and royalties.

Benefit-sharing arrangements have improved significantly over the last decade, following entry into force of the CBD, and wider awareness of the issues raised by biodiversity prospecting. Benefits resulting from these partnerships can positively impact a country's capacity to undertake research and develop its own biodiversity, and lead to numerous spin-off benefits for research institutions, universities, local businesses and others. The direct impact of biodiversity prospecting on conservation remains modest in most cases, but can include capacity-building and support for biodiversity science; sustainable economic activities based on the supply of raw materials to industry; and in a few cases direct financial contributions to conservation programs and objectives. For example, in the case of INBio in Costa Rica, biodiversity prospecting is directly linked to building basic biodiversity science and management needs, like national inventories, and a financial contribution – 'conservation overhead' – for conservation areas is built into all commercial agreements.

Biodiversity prospecting can also pose dangers to the environment and can poorly serve local groups' interests. For example, poor collection of samples for research purposes can result in localized threats to populations of sought-after species. Unsustainable bulk collection of raw materials for manufacture can endanger species; this is a common concern for medicinal plants, many of which have landed on CITES Appendices as a result of overharvest in the wild (e.g., *Panax* spp., *Prunus africana*, and *Rauwolifa serpentina*). Inequitable relationships with local communities and source countries can mean that they benefit little from commercialization of resources and knowledge, and have limited or no control over the research and commercialization process.

In order for biodiversity prospecting to maximize its potential to positively benefit local groups and promote conservation, a number of basic steps and strategies are required. These include: effective national 'access and benefit-sharing' measures, growing from a solid national consultation process and a strategy addressing these issues; policies or guidelines for research institutions, protected areas, and in some cases local communities, to guide research collaborations; and a trust fund or guidelines for distribution of financial benefits to ensure equity and the service of national and local priorities.

Edible Products from the Forest

B K Tiwari and S Rani, North-Eastern Hill University, Shillong, India

Introduction

Forests are one of the major forms of natural landscape and are the most important natural resources of the world. The term 'non-wood forest products' (NWFP) has emerged as an umbrella expression for the vast array of both plant and animal resources other than wood derived from forests or forest tree species. The forests are important not only for their economic utility but they also influence the social and economic life of humankind. Forests are an important source of food; in fact people were dependent mainly on forest collected food when they were wanderers and the concept of cultivating food came in only after people started living in settlements. The cultivation of food items made life much easier for humans, who not only started cultivating food but also cultivated the selected ones they liked more. Thereby the number of plants that were included in the cultivated list was much less than the actual number of edible plants found in the wild. In the modern world people seem to have forgotten that all the edible things being used by them now are actually derivatives of those that used to grow in the wild once upon a time, and they also seem to be unaware of the fact that many such edible plants still exist in the wild which may be even more valuable and suitable nutritionally than the ones that are being cultivated. However, with increasing awareness of the natural environment people are becoming conscious and many have started exploring the wilds to find more plants that are edible. Eating wild foods has many nutritional benefits and can add another dimension to our diet as well as to our relationship to the natural world. Wild plants are nature's gifts to us and have high concentrations of vitamins, nutrients, and calories to make us strong and healthy. Edible forest products (EFPs) make a particularly important contribution to the nutrition of the tribal and rural poor, who more than others are likely to be dependent on trees for a significant part of their income and food supply. Forest-dwelling hunters and gatherers, the world's 300 million shifting cultivators, and millions of small-holders and landless households living near forests and in the savanna depend on forests for a significant part of their food. Forest foods can offer vital insurance against famine during times of seasonal food shortages or emergencies such as droughts, floods, and wars. It is very common for rural people to depend on forest foods between harvests, i.e., when harvested stocks have been consumed but the next crops are yet to mature. Women in particular count on these resources for supplementary nutrition, emergency foods, and many other important products they need to ensure the nutritional well-being of their families. Forest foods are traditionally used to supplement the staple diet, providing vitamins, minerals, and proteins that are lacking in starch-based cultivated crop food. In the subsequent part of this article various edible products from forests will be described. A few examples have been cited in each case and some data about edible forest products of India have been given in the tables. It was difficult to draw a line between 'wild' and 'forest' because at times these two terms have been used interchangeably. The groups of edible forest products included in this article and issues discussed are indicative only. The names of edible plants and animals listed in the tables or mentioned in the text are by way of an extended example.

Edible Products from the Forests

Any forest produce that can be consumed safely is classified as edible produce of the forest. In recent times wild edible products have gained considerable attention due to their ability to supplement the needs of the changing society. These wild edible products can be classified into various groups and subgroups:

- foods items (fruits and berries, vegetables, roots, rhizomes, bulbs and tubers, nuts, seeds and grains, resins, sap, gums, forest edibles of animal origin, honey, etc.)
- spices and condiments
- beverages
- health foods
- mushrooms
- medicinal plants
- edible oils.

Food Items

Fruits and berries The food items collected most frequently from the wild are fruits and vegetables. Fruits are undoubtedly humanity's oldest food. Before the start of organized agriculture, prehistoric nomads lived on wild game, wild fruits, and berries. When humans took to organized agriculture, they started cultivating grain crops, but surely they grew some fruits in the backyard too. Instead of the many varieties of fruits grown by humans there are still many others that have not yet been domesticated and are still found in the wild. These are the ones that are collected mostly by the forest-dwellers and rural people to supplement their diets, and they are definitely rich sources of many minerals and vitamins. Nutritionally, wild fruits are as rich in vitamins and minerals as cultivated fruits, lower in sugar and calorie content, and free of wax coating, chemical sprays, or artificial ripening agents. And they nearly always taste better than their cultivated counterparts. For example the fruit of baobab (*Adansonia digitata*) far surpasses the orange's famous vitamin C content of 57 mg per 100 g of fruit at 360 mg per 100 g, and one variety of jujube (*Zizyphus jujuba*) reaches levels as high as 1000 mg per 100 g.

In northeast India, which has a rich cover of forests, the locals are still very intimately related to forests and collect enormous amounts of edible fruits from the wild, the knowledge of which has been passed down the generations. For example fruits of wild trees like *Melodinus monogynus*, *Zizyphus mauritiana*, *Phyllanthus emblica*, *Myrica esculenta*, *Elaeagnus conforta*, *Emblica officinalis*, *Elaeagnus umbellate*, *Rubus ellipticus*, *R. niveus*, *R. moluccanus*, etc. are collected and consumed in large quantities. *Zizyphus mauritiana*, *Z. oenoplia*, prickly-pear (*Opuntia dillenii*), Cuddapah almond (*Buchanania lanzan*), Indian black plum (*Syzygium cumini*), Ceylon ironwood (*Manilkara hexandra*), wood apple (*Limonia acidissima*), Indian palm (*Borassus flabellifer*), Manila tamarind (*Pithecellobium dulce*), etc. are some of the common wild fruits used by the ethnic people of

Tamil Nadu in India. In Blue Creek, Belize the fruits of *Orbigyna cohune, Astrocayum mexicanum*, and *Bactris major* are collected from the tropical rainforests and consumed by the local people. Peaches, figs, mulberries, wine berries, chestnuts, ginkgo nuts, and chanterelles are the common wild edibles collected by people in Baltimore. In Ireland wild fruits like pine, hazel, strawberries, blackberries, cranberries, and rosehips are collected. In rural areas of Ethiopia, the most common wild plant fruits consumed are fruits from *Balanites aegyptiaca*, *Ficus* spp., *Carissa edulis*, and *Rosa abyssinica*. The list of wild fruits consumed by various communities can be enormous. The above examples are just indicative. Some more are listed in **Table 1**.

Vegetables Vegetables are also an important part of the diet and supplement it with various types of vitamins and minerals. They mostly comprise of the leafy parts of a plant, even though flowers and fruits are also included many times under this list. The vegetables that are collected from the wild include the leaves of trees and shrubs, leaves and twigs of herbs, or even the entire plant. The commonly used wild vegetables in northeastern India are *Amaranthus companulatus*, *Bauhinia variegate*, *Chenopodium album*, *Enhydra fluctuans*, *Ipomea repants*, *Elaeocarpus floribundus*, *Swertia chirayita*, *Parkia roxburghii* etc. *Allium acuminatum*, *Apocynum cannabium*, *Lewisia rediviva*, *Mentha arvensis*, *Scirpus acutus*, *Clintonia uniflora*, *Typha latifolia*, *Empetrum nigrum*, *Potentilla pacifica*, *Sedum divergens*, etc. are some of the herbaceous plants used by people of western Washington State, USA. Shrubs and trees used by them include *Berberis* spp., *Ribes* spp., *Rubus* spp., *Malus fusca*, *Mahonia* spp., *Prunus emarginata*, etc. *Myrica gale* and Sweet fern (*Comptonia peregrine*) are used as vegetables by people of Canada. In Belize *Sabal mexicana* and *Spondias mombin* are plants found growing abundantly in the rainforests,

Table 1 Names of some frequently collected edible fruit yielding wild plants of India

Sl number	*Wild edible plants*	*Family*	*Parts used*
1	*Polygonum chinense*	Polyganaceae	Ripe fruits
2	*Solanum surattense*	Solanaceae	Unripe fruits
3	*Ficus glomerata*	Moraceae	Fruits
4	*Ficus religiosa*	Moraceae	Fruits
5	*Ficus bengalhensis*	Moraceae	Fruits
6	*Ficus palmata*	Moraceae	Fruits
7	*Gnetum gnemon*	Gnetaceae	Fruits
8	*Grewia hirsute*	Tiliaceae	Fruits
9	*Phyllanthus acidus*	Euphorbiaceae	Fruits
10	*Calamus erectus*	Arecaceae	Fruits
11	*Solanum indicum*	Solanaceae	Fruits
12	*Solanum torvum*	Solanaceae	Fruits
13	*Solanum nigrum*	Solanaceae	Ripe fruits
14	*Berberis aristrata*	Berberidaceae	Fruits
15	*Cordia dichotoma*	Ehretiaceae	Ripe fruits
16	*Pyrus pashia*	Rosaceae	Fruits
17	*Madhuca butyraceoides*	Sapotaceae	Fruits yield butter
18	*Zanthoxylum aceanthopodium*	Rutaceae	Fruits
19	*Dillenia pentygyna*	Dilleniaceae	Fruits
20	*Bauhinia purpurea*	Caesalpinaceae	Fruits
21	*Grewia hirsute*	Tiliaceae	Fruits
22	*Mangifera sylvatica*	Anacardiaceae	Unripe fruits
23	*Prunus nepalensis*	Rosaceae	Fleshy fruit
24	*Myrica esculenta*	Myristaceae	Fruits
25	*Emblica officinalis*	Euphorbiaceae	Fruits
26	*Elaeagnus umbellata*	Elaeagnaceae	Fruits
27	*Elaeagnus pyriformis*	Elaeagnaceae	Fruits
28	*Elaeagnus parviflora*	Elaeagnaceae	Fruits
29	*Rosa macrophylla*	Rosaceae	Fruits
30	*Rosa moschata*	Rosaceae	Fruits
31	*Rubus elliptcus*	Rosaceae	Fruits
32	*Rubus niveus*	Rosaceae	Fruits
33	*Prunus armeniaca*	Rosaceae	Fruits
34	*Prunus communis*	Rosaceae	Fruits
35	*Prunus persica*	Rosaceae	Fruits
36	*Holoptelea integrifolia*	Ulmaceae	Fruits
37	*Madhuca longifolia*	Sapotaceae	Fruits

and their shoots and leaves are consumed raw as well as in cooked form. Wild greens (*Portulaca oleracea*), Capper bush (*Capparis zeylanica*), wild bittergourd (*Mimordica dioica*), poison berry (*Solanum indicum*), prickly amarnath (*Amaranthes spinosa*), Indian fig (*Ficus glomerata*), potato yam (*Dioscorea pentaphylla*), wild date palm (*Phoenix sylvestris*), Bermuda buttercup (*Oxalis corniculata*), heart's pea (*Cardiospermum helicacabum*), prickly leaved solanum (*Solanum trilobatum*), adamant creeper (*Cissus quadrangularis*), and mountain ebony (*Bauhinia tomentosa*) are some of the wild vegetables used by the tribals of South India (**Tables 2** and **3**).

Roots, rhizomes, bulbs, and tubers These are the underground parts, which are usually organs of perennation for the plants. Rhizomes are underground stems which grow beneath the surface of soil; they are frequently fleshy and serve as organs of food storage. Sometimes the rhizomes are condensed into solid swollen forms which are then known as corms. The tubers are also underground parts, which may either be modified roots or stems. They serve both as an organ of vegetative reproduction and storage organ. Rhizomes and tubers have high contents of carbohydrates, proteins, and minerals and are a very good source of food for humans. They have been used by humans as a source of energy to meet their dietary requirements since times immemorial. Tubers and rhizomes still constitute a significant part of human diet in many parts of the world.

Roots of knotweed (*Polygonum* sp.) and wild ginger (*Asarum canadensis*) are used by the people of Mound City, Ohio, USA. *Boerhavia chinensis*, *Pueraria tuberosa*, *Mauera oblongifolia*, *Dioscorea tomentosa*, *D. oppositifolia*, and *Cyanotis tuberosa*

Table 2 Names of some frequently collected edible vegetative parts yielding wild plants of India

Sl number	*Wild edible plants*	*Family*	*Parts used*

13	*Dioscorea wallichii*	Dioscoreaceae	Rhizome
14	*Curcuma longa*	Zingerabaceae	Rhizome
15	*Purearia tuberosa*	Papilionaceae	Root

are some of the wild tubers used by tribals groups in India, e.g., Chenchus, Sugalis, and Yerukalsa of Andhra Pradesh. The roots of cattails (*Typha latifolia*), burdocks (*Arctium lappa*), and arrowheads (*Sagitaria sagittifolia*) are used frequently by people in Ireland. Cattails, thistle (*Cirsium* spp.) and *Bordiaea* are used by people of Pope Valley, California. *Ullucus tuberosus*, *Tropaeolum tuberosum*, and *Oxalis tuberose* are common tubers collected in Peru, Ecuador, and Bolivia (**Table 4**).

Nuts, seeds, and grains Nut is the popular name for many kinds of dry, edible seeds or fruits that grow in a woody shell. The word nut can refer to both the shell and the nutmeat, or kernel, inside or to the kernel alone. Botanists define a nut as a dry, one-seed fruit surrounded by a hard shell that does not open on its own. Prehistoric people probably ate nuts as a regular part of their diet. Some nutritionists believe that, because of food shortages, nuts will again become a widely used source of protein. Seed is the specialized part of a plant that produces a new plant and has a supply of stored food. Seeds serve as a major source of food for millions of people throughout the world. Nuts and seeds are good sources of fiber, protein, minerals such as iron, zinc, copper, magnesium, potassium, and calcium, vitamins such as vitamin E and phytosterols, and a variety of phytochemicals. Grains are the husked parts of inflorescences and are basically seeds of the Poaceae family. Wild grains, seeds, and kernels provide significant amounts of calories, protein, and oil. Their calorific value is frequently greater than that of the cultivated varieties. The results of analysis of the grass grains are impressive with a range of 310–391 kcals per 100 g which compares favorably with *Sorghum* sp. and maize (*Zea mays*) at 355 and 363 kcals per 100 g respectively. Names of some forest plants yielding edible kernels and seeds commonly collected in India are given in **Table 5**.

Forest edibles of animal origin Our ancestors were very much dependent upon wild animals for meeting their daily dietary requirements of protein, vitamins, and many minerals. These foods were not only capable of meeting their nutritional requirements but also gave them variety and taste. The various groups of animals found in the wild are not only eaten for their taste or nutritional value, but they have been

Table 6 Names of some frequently collected edible wild insects of few selected countries of the world

Sl number	*Country in which used*	*Insects*
1	Indonesia (Bali)	Compost beetle larvae, palm weevil larvae, dragonfly, damselfly adults
2	Nigeria	Westwood larva, palm weevil larvae, termites, crickets, grasshoppers, caterpillars, compost beetle larvae, wasp larvae
3	Japan	Aquatic insect larvae, cicadas
4	Australia	Witchety grub, honeypot ants, bogong moths, beetle grubs, *Oecophylla* ant
5	Algeria	Desert locusts
6	China	Cicada nymphs, Wasp larvae/pupae, Ants, Locusts, Dragonflies, Scorpions, Diving beetles, Giant water bugs
7	Philippines	June beetles, grasshoppers, ants, mole crickets, water beetles, katydids, locusts
8	Ecuador	Dragonfly larvae, Cyclocephala beetles, Cicadas
9	Mexico	Cerambucid larvae, lemon ants, ants
10	Papua New Guinea	Grasshoppers, *Atta cephalotes*
11	Thailand	Walking sticks, leaf insects, *Apies florae*, *Apies dorsata*, *Apies cerana*, *Apies mellifera*
12	USA	Termite (*Macrotermes subhyanlinus*), caterpillar (*Usata terpsichore*), *Rhynchophorous palmarum*

found to be highly important medicinally too. Therefore, a wide range of insects, birds, and animals is collected from the forests along with the plants. The commonly collected mollusks in the UK are common mussel (*Mytilus edulis*), flat oyster (*Ostrea edulis*), common cockle (*Cerastoderma edule*), quahog (*Mercenaria mercenaria*), common razorshell (*Ensis ensis*), sand gaper (*Mya arenaria*). Hunting and gathering of animals from the forests is very common across the world, for example, in Kenya, Tanzania, Zimbabwe, Zambia, Malawi, Mozambique, and Botswana thousands of species of insects, birds, mammals, reptiles, mollusks, and amphibians provide a cheap source of protein and livelihood to poor communities that are struggling to survive. Bushmeat (mostly the meat of wild mammals) is sold in departmental stores and served in hotels and restaurants of many African countries. Similarly the Naga and Khasi communities of India also hunt and gather a wide variety of animals for food which include bat, barking deer (*Muntiacus muntjak*), porcupine (*Hystrix hodgsoni*), wild boar (*Sus scrafa cristatus*), mithun (*Bos frontalis*), unio, and fowl, frogs, snakes, etc. (**Table 6**).

Spices and Condiments

The term spices and condiments applies to 'such natural plant or vegetable products or mixtures thereof, in whole or ground form, as are used for imparting flavor, aroma and piquancy to and for seasoning of foods.' Spices may comprise different plant components or parts such as barks, berries, buds, bulbs, floral parts, fruits, kernels, leaves, rhizomes, latex, exudates, roots, and seeds. Spices are well-known appetizers and are considered essential in culinary art all over the world. They add tang and flavor to otherwise insipid foods. Some of them also possess antioxidant properties, while others are used as preservatives in some foods, e.g., pickles and chutneys. Some spices were used for preserving food like meat for a year or more without refrigeration as they contain chemical substances that inhibit the growth of microbes like bacteria. There are many spices and condiments that are collected from forests. Some wild plants used in India as spices are: *Acorus calamus*, *Thymus linearis*, *T. serphyllum*, *Eurya acuminata*, *Garcinia indica*, *Piper longum*, *Cinnamomum* sp., *Piper guineense*.

Beverages

Apart from the most popular beverages, viz. tea and coffee, there are many wild plants that are used as beverages by traditional societies. Leaves, twigs, or fruits of several wild plants are used for preparing beverages. For instance spearmint (*Mentha spicata*), sassafras, mitten tree, ague tree, or tea tree (*Sassafras albidum*), yarrow (*Achillea millefolium*), sweet fern, Labrador tea (*Ledum groendicum*), sagebrush (*Artimesia* spp.), and Mormon tea (*Ephedra* spp.) are widely used in eastern and western USA as beverages. Others include Coyote mint (*Monardella adoratissima*) and clover (*Trifolium* spp.).

Rubus allegheniensis, Fragaria virginiana, Vitis sp., etc. are used to prepare both tea as well as cold drinks, in Mound City, Ohio. The Saskatoon (*Amelanchiar alnifolia*) and pin cherry (*Prunus pennsylvanica*) is used by indigenous peoples of North America as soups and tea. Berries of sumac (*Rhus* spp.) are also used as tea. *Cassia occidentalis* and *C. tora* seeds are used as substitute for coffee in Africa and America. In India, *Albizia julibrissia*, *Coffea khasiana*, *Camelia kissi*, *Eschscholtzia cristata*, *E. polystachya*, *Taxus baccata* (bark and leaves), and *Cassia auriculata* are used as substitutes for tea and coffee, while berries like *Rubus* spp., *Fragaria* spp., and *Hemidesmus indicus* are used in preparation of cold drinks. *Madhuca indica*, *M. longifolia*, and some members of palm family are used in preparation of alcoholic beverages in India. The floral parts and leaves of *Cannabis sativa* is used for preparation of intoxicating drinks and stimulants.

Mushrooms

Mushrooms are yet another very frequently and commonly used products of forests. While most species of mushrooms are almost freely available to forest-dwellers and help them survive or supplement their diets, there are some wild mushrooms, viz., *Morchella esculenta*, which are amongst the most expensive edibles on earth. Indigenous collectors of the northwestern Himalayas sell these to middlemen at rates as high as US$100 kg^{-1}, and they pass it on to quality hotels and pharmaceuticals companies earning a profit of 35–40%.

Apart from adding variety to our diets mushrooms are also an important source of proteins and minerals. Hundreds of types of mushrooms are collected from the wild. While most of them are collected by the forest and forest fringe dwellers for their subsistence and as a food supplement, a small quantity is traded in local as well as regional and international markets.

Medicinal Plants

Since the beginning of civilization, people have used plants as medicine. It came into being when the earliest humans observed the animals mostly the apes and monkeys eating certain plants often to satisfy their hunger and at other times to heal their wounds and to alleviate suffering. This observation and the analysis of such observations probably led them to use plants for maintenance of life and alleviation of diseases. The earliest recorded uses have been described in the Vedic literature, roughly around 4500 BC. This traditional curing system is still being followed in India. In the recent years this practice has been rejuvenated and is being widely used over the other systems. A detailed account of medicinal plants can be found elsewhere in this Encyclopedia (*see* **Medicinal, Food and Aromatic Plants**: Medicinal Plants and Human Health; Tribal Medicine and Medicinal Plants).

Health Foods and Dietary Supplements

A large number of forest products of both plants and animal origin are believed to be beneficial in maintaining good health, as aphrodisiacs, and in increasing resistance to stress. They are probably the highest valued edible forest products on the market today. For example a digger of wild ginseng (*Panax quinquefolium*) in the USA can receive more than US$1000 kg^{-1} of dried root. There is a huge market for ginseng in Asia particularly in Taiwan and China. In 1997, the total export of wild-harvested ginseng from the USA was 191 500 kg worth more than US$32.4 million. Retail sale of *Ginkgo biloba*, another plant of this category, totaled US$90.2 million in 1997, while sales of *Hypericum perforatum* and *Podophyllum peltatum* plants growing in the forests of the USA yielding dietary supplements exceeded US$47 million and US$1.5 million respectively.

Edible Oils

Apart from the traditional uses of edible wild products there are some other ways in which the plants are used. In Brazil, people collect kernels from babassu plants (*Orbygnya phalerata*) which are a very rich source of edible oil, resembling coconut oil to some extent. Black walnuts are also a source of oil for the people of Brazil. In India kernels or seeds of *Prunus armeniaca*, *Juglans regia*, *Prinsepia utilis*, *Madhuca longifolia*, *Ventilago maderaspatana*, and *Fagopyrum esculentum* are used to extract edible oils and fats.

Social and Economic Issues

Wild edibles provide food security and livelihood to millions of rural poor people living around forests, and thus it plays an important role in the socio-economics of these communities. This is particularly important in Asia, tropical Africa, and South America. Forests also offer a great variety of food products of potential market value. The indigenous peoples of Amazon's State, Venezuela, have been selling their own native wild fruits. All indigenous peoples within Amazon's State have the right to hunt, fish, and collect wild products for their personal consumption; thus they have the right to continue their traditional lifestyles. Edible wild plant products are collected mainly for household consumption and for sale in the local market. Wild fruits and fish may be sold legally, but the sale of game animals, birds, and ornamental fish is strictly prohibited by law. The indigenous vendors and gatherers of forest edibles do not put up stalls, but instead sell along the pavement of weekly traditional markets. A similar situation is found in rural northeast India. In the Sudan, however, the perception of the economic importance of wild foods appears to be gender-specific. For women, these foods are an important source of income and with the small amounts of cash that they earn; they buy important non-food items such as soap. One reason that may lead outsiders to believe that there is not much trade in wild foods is that these foods are not usually sold in a prominent place in the market but on the periphery with a significant amount of barter trade being undertaken at village level. In Cameroon, hunting, trapping, and fishing from the wild accounts for an average 27% of annual income, while income from other forest products totaled some 30% of yearly earnings. Earnings from bushmeat are quite high in Peru; a hare hunter can earn the equivalent of US$1350 a month, compared with a laborer's typical wage of US$100 a month. People of Papua New Guinea's swamplands have virtually no saleable resources apart from the crocodiles that abound in these densely vegetated areas. A single skin of a mature crocodile can fetch around US$150. Other notable wildlife products obtained in various parts of the world and traded for high prices include snake venom and frogs' legs. The giant wild snail (*Achatina achatina*) is traded profitably in Côte d'Ivoire.

Cultural, Equity, and Gender Issues

In southern Sudan there is a social stigma attached with wild food items. Generally, male guests will be given sorghum because it is considered more prestigious while wild foods, and any other less prestigious foods are eaten by the women and the children of the household in a separate place. Allocating the best food to a guest is common to most cultures, but this does not mean that other household foods are nutritionally inferior or that they are not liked. There are some wild foods that have a high prestige value, such as the wild grass grains and rice which are particularly favored and will be given to the most important guests at ceremonies. Also, some wild foods are used to make relishes that give flavor and texture to other foods and are acceptable for male guests, e.g., fruits of *Tamarindus indica*, *Nauclea latifolia*, *Portulaca oleracea*, and *Gynandropis gynandra*. Female guests however tend to eat whatever the rest of the household eats. The collection of wild foods is mainly carried out by women and children. It does not necessarily involve expending a great deal of extra energy. Many foods are collected along the wayside whilst going about other chores, while wild leafy greens can be found growing (and are encouraged to grow) in the cultivated areas around the home. Collection of wild foods at a greater distance from the homestead will be undertaken by women who go in groups over a period of days, leaving their children in the care of a relative. These trips can become something of a social event for women, particularly for those who live on the more remote homesteads and have little time for visiting friends and relatives. Gathering some wild foods can be labor intensive, e.g., digging for wild tubers and for grain from termite stores, but people may choose to collect these foods even in normal years for the sake of dietary variety. Wild plant production only involves labor at the time of harvesting and may fit in well with other activities. In the case of grass grains, for instance, which start to ripen at a time when agricultural work is at a minimum, prior to the main crop harvest, there is little conflict of labor priorities. The collection of wild food may become burdensome when these foods become the major part of the diet, e.g., during periods of food scarcity and famine, especially when the foods need to be foraged for at great distances from the home. Whilst out on their errands children often forage for these foods. During this time they learn about the different wild foods and their availability which can stand them in good stead during periods of food deficit. Also, as growing children need food regularly throughout the day, wild foods can provide snacks between their main meals.

In Ethiopia also wild foods are often considered to be of low status, and their consumption is regarded as a source of shame. In normal times only children, youngsters, and the poorest families regularly collect and consume wild food. In Kayissa Kebele, wild food plant species are not consumed by the majority of the population except when there is a serious shortage of food affecting all strata of the population from the poorest to the richest. But for the poorest, collection and consumption of wild food may make up an important portion of their daily activity and dietary intake. Ethiopians generally are constrained to the consumption of the commonly cultivated crops and neglect wild plants like *Amaranthus* and *Solanium khasianum*. Strong traditions, beliefs, and religious taboos still obstruct people's willingness to domesticate and cultivate wild-food plants. In the southern part of Ethiopia, where there are many different tribes still living with their indigenous beliefs and traditions, there are fewer religious and external constraints than in other parts of the country. In these areas the daily diet of most people still comprises an element of wild food, both animals and plants, during certain periods of the year. Here mostly children collect and consume the fruits of wild plants. Other wild food and 'famine food' plants are collected by children and women and prepared by the latter. Women frequently collect wild food when they are on their way to fetch water, to collect firewood, or to the market, and when walking home from their fields.

Conservation Needs

As the area of the earth's surface under forest is shrinking at an alarming rate, so also is the availability of edible forest products. The natural forests of the tropics are the most important source of such products, both in terms of quantity and also in numbers of different edible species. Ironically these are the forests that are also facing the maximum anthropogenic pressures. Millions of rural poor look on the edible forest products as a source of food, researchers and scientists look on them as a possible source of germplasm for breeding, and the urbanites and rich often use them as a recreational food. Probably, it is not an exaggeration to say that modern humans are as dependent on the forest for food and healthcare as were the primitive humans. Also, the quantity and variety of edibles extracted from forests today far exceeds those extracted during remote past when all people lived in forests. For instance, in the past the collection of bushmeat from the African savanna would have been ecologically sustainable, but now it has far exceeded the carrying capacity of these ecosystems. Studies have revealed that at present trade in bushmeat is one of the main causes of falling animal populations in much of Africa, but bushmeat cannot be done away with as it provides a much-needed source of protein to the rural poor who cannot afford to buy farm-produced meat. However, conservation interests and food security interests must work together to balance food needs with long-term wildlife management.

Any strategy for sustainable management of EFPs will have to take a multilevel approach. It must cover documentation and identification of lesser-known EFPs, research on regeneration so as to decide about levels of extraction, improvement of methods of collection and harvest, ways to minimize loss during harvest, storage, and processing, research on substitution of products that come from endangered species, domestication and cultivation of EFP species, market research, resource accounting, education and awareness about conservation and management of EFPs and *in vitro* and *in vivo* conservation using modern biotechnological tools. Involvement of various stakeholders in formulating policies and enacting legislations favorable for EFPs conservation may also be desirable for evolving effective conservation strategies.

Conclusion

Forests are the source of huge quantity and enormous variety of edible products which are used by almost all sections of society through out the world. They provide subsistence to millions of rural poor and forest-dwellers as well as nutritious delicacies to the urban rich. They are a repository of germplasm of many food crops and farm products and a large number of them have potential for domestication and cultivation on commercial basis. Edible NWFPs received notable attention at the United Nations Conference on Environment and Development (UNCED) in Rio in 1992 and thereafter forest managers of several countries have recognized the importance to forest edibles in management of forests. However, there is conspicuous lack of understanding among resource managers and planners on sustainable harvest, value addition, equitable sharing of benefits, marketing, and conservation of these resources.

Forest Measurements

J P Skovsgaard, Royal Veterinary and Agricultural University, Forest & Landscape Denmark, Copenhagen, Denmark

Introduction

The field of forest measurements is concerned with measurement, sampling, analyses, and prediction of properties and characteristics of the forest, including trees as well as other components of the forest ecosystem. In general, the main objective of forest measurement activities is to provide quantitative and qualitative data for forest management, policy-making or research. Forest measurements thus contribute substantially to the basis of forest-related human activities. Often, data acquisition is carried out as part of a forest inventory, at estate, regional, or national level, or in scientific field experiments. Several forest measurement procedures can be used outside of the forest, for example in inventories of trees in urban streets and parks or in the landscape.

Forest Measurements

Historically, science-based forest measurement procedures were developed mainly for aboveground parts of the trees and with the main objective of quantifying the wood resource and its growth potential. Including the planning, performance, and analyses of measurements of tree and stand attributes, this is usually referred to as the discipline of dendrometry (i.e., tree measurement), forest mensuration, or forest biometrics.

In the classical sense, measurements tend to be at the macroscopic level and are often carried out in the field. Exceptions may be, for example, extracted wood cores that are taken to the laboratory for growth analysis, and the use of satellite, aerial, or other photographs for resource assessment. Carried out as part of a forest inventory and combined with land survey data, forest measurements provide information on individual tree properties as well as stand characteristics and overall forest structure for use in subsequent analyses and decision-making.

The Contemporary Context

Due to an increasing diversity of the forest policy agenda and of forest management objectives the field of forest measurements is developing to provide data for a broader range of forest and site characteristics and to adjust and refine measurement procedures accordingly. This includes, for example, assessment of forest operations performance, regeneration abundance and quality, forest health, carbon stock, biodiversity (fauna, flora, and fungi), habitat diversity, range land, water resources, light conditions, crop nutrient balance, soil characteristics, recreation opportunities, and cultural, heritage, and amenity values.

For many of these topics, sampling and measurement procedures have been developed in other branches of science. In the context of forest ecosystem management, the challenge is to combine these procedures cost-effectively with forest measurement practices. Many of the additional ecosystem attributes correlate well with individual tree properties, stand characteristics, or overall forest structure, and traditional forest measurements are often more cost-effective and versatile.

So, regardless of management objectives, the trees of the forest must be quantified for informed decision-making. Consequently, forest measurements maintain a strong focus on the aboveground tree components of the forest ecosystem.

Measurement, Sampling, Analyses, and Prediction

Forest measurement activities generally comprise direct and indirect measurement, sampling, analyses, and prediction. Obviously, mathematics, statistics, and computer science are fundamental to forest measurements, and several measurement techniques are borrowed or adapted from engineering, land surveying, photogrammetry, and other professions.

Due to the forest environment and the size of trees special instruments have been developed for field use. These include calipers to measure tree diameter, relascopes to measure stand basal area, hypsometers to measure tree height, and xylometers to measure wood volume.

In general, due to the huge number of trees present on most forest land, only a sample is measured. Sample values are then expanded appropriately to obtain estimates for the population of interest. General sampling theory provides the foundation, but several sampling techniques have been developed specifically to forest conditions.

Except for the purpose of timber trading, forest measurements are most often based on nondestructive sampling. Consequently, the prediction of quantities, qualities, and events other than those directly measured plays a major role for utilizing the potential of forest measurements. The prediction of stemwood volume is probably the most notable example. A more complex but equally important example is the prediction of forest dynamics in response to management actions. As a general recommendation, models should consider the simultaneous nature of state variables and account for relevant interactions as well as temporal and spatial correlations in data.

Overview

A comprehensive review of all methods used for forest measurements is beyond the scope of this contribution. Here, the focus is on general principles, definitions, variables, instruments, methods, and models that are widely used for the assessment of some basic tree properties and stand characteristics.

Following an introduction to general measurement definitions and principles and a summary of the history of forest measurements, the scope of dendrometry is outlined and forest measurement practices explained for variables age, stem number, diameter, girth and basal area, bark, tree and stand height, stem taper, form factor, and wood volume. More specific approaches and details, including remote sensing measurement techniques and forest modeling based on dendrometric data, are covered elsewhere in this Encyclopedia (*see* **Resource Assessment**: GIS and Remote Sensing. **Mensuration**: Yield Tables, Forecasting, Modeling and Simulation), in forest measurement and modeling textbooks, and in similar texts from other professions and sciences.

General Measurement Definitions and Principles

By facilitating comparison across time and space, consistent and objective measurement principles contribute to an unambiguous interpretation of observations which, in turn, may lead to an extension of human experience and knowledge. Measurements thus contribute to a huge variety of human activities and interactions.

Definition, Scales, and Units

In its broadest sense, measurement can be defined as the rule-based assignment of numerals to physical objects and natural phenomena. Numerical quantities can be assigned under different rules using different kinds of scales and different kinds of measurement procedures. Any scale of measurement may be classified as being a nominal, an ordinal, an interval, or a ratio scale.

A nominal scale is used for numbering or counting objects or phenomena of a certain identity (for example, number of live trees). An ordinal scale is used to express rank or position in a series (for example, numerical codes 0, 1, 2, 3, or 4 for tree sociological classes dead, suppressed, intermediate, codominant, or dominant, respectively). An interval scale includes a series of graduations marked off at uniform intervals from an arbitrary origin (for example, temperature). A ratio scale is similar to an interval scale, but implies an absolute zero of origin (for example, stem diameter, tree height, and wood cubic volume). Ratio scales are the ones most commonly applied in forest measurements.

The analysis and interpretation of observations must take into account the measurement scale. For example, the number and type of legitimate mathematical operations depend on measurement scale. Although different measurement units are used in different parts of the world, numbers generally follow the decimal system, while the SI system offers comparative advantages over possible local units.

Variation, Accuracy, and Precision

Variation caused by uncontrolled factors, both known and unknown, is called error. The main sources of variation include properties intrinsic to the measurement object as well as external factors in sampling, measurement, and analysis of data.

Any measurement is subject to error or, in other words, deviation from a true value which generally remains unknown. It is often useful to identify, estimate, and reduce this source of variation relative to other sources. Errors include systematic and random components and originate in measurements due to measurement object, instrument, procedure, or the imperfection of human senses.

Systematic errors are constant or functionally dependent on their cause. These should be identified and eliminated as far as possible. Random errors are normally and independently distributed with zero mean and common variance. They are due to several possible causes, none of which dominates the measurement process. Random errors account for unexplained variation and are inherent to any measurement.

For any application of measurements, results are only as reliable as the input. So, other things being equal, the measurement error should be minimized for increased accuracy and precision. Accuracy is a measure of reliability as indicated by the difference between the true value and the most probable value derived from a series of measurements. Bias is defined conversely of accuracy. Precision is a measure of repeatability and is the degree of agreement between individual measurements in a series of measurements of the same quantity. In practice, accuracy is often judged from precision although this may lead to misinterpretation.

History of Forest Measurements

Assessment of forest resources, including the production and harvest potentials, has probably been crucial for exploitation by people and land managers ever since trading of natural resource products began and has definitely played a vital role during history for central authorities of societies that depended on forest products. Although timber is useful or even a necessity for the construction of houses, fortifications, bridges, carriages, and ships, the forest also provides firewood, fencing material, berries, fodder, grazing, and a host of other commodities.

Scarcity of resources obviously provides an incentive to initiate forest measurements. It is known that early societies in many parts of the world developed local forest measurement practices and rules to ensure reliable estimates of forest resources. Some of these even took approaches that are very similar to modern scientific methods and principles.

The Scientific Approach

The scientific approach to forest measurements in a modern context began in Central Europe at the introduction of regular and planned forestry in the mid-1700s, coinciding with the advent of forest science and modern natural sciences in general. Early initiatives concentrated on the identification of key variables for estimation of wood volume and prediction of growth, and on measurement procedures (**Figure 1**).

The establishment of the German Federation of Forest Experiment Stations in 1872 furthered a major breakthrough which resulted in a common norm for tree and stand variables in Central Europe. Following the foundation of the International Union of Forest Research Organizations (IUFRO) in 1892 these recommendations have greatly influenced forest measurement developments and practices in other parts of the world. However, no internationally agreed standards have emerged (**Figure 2**), but there

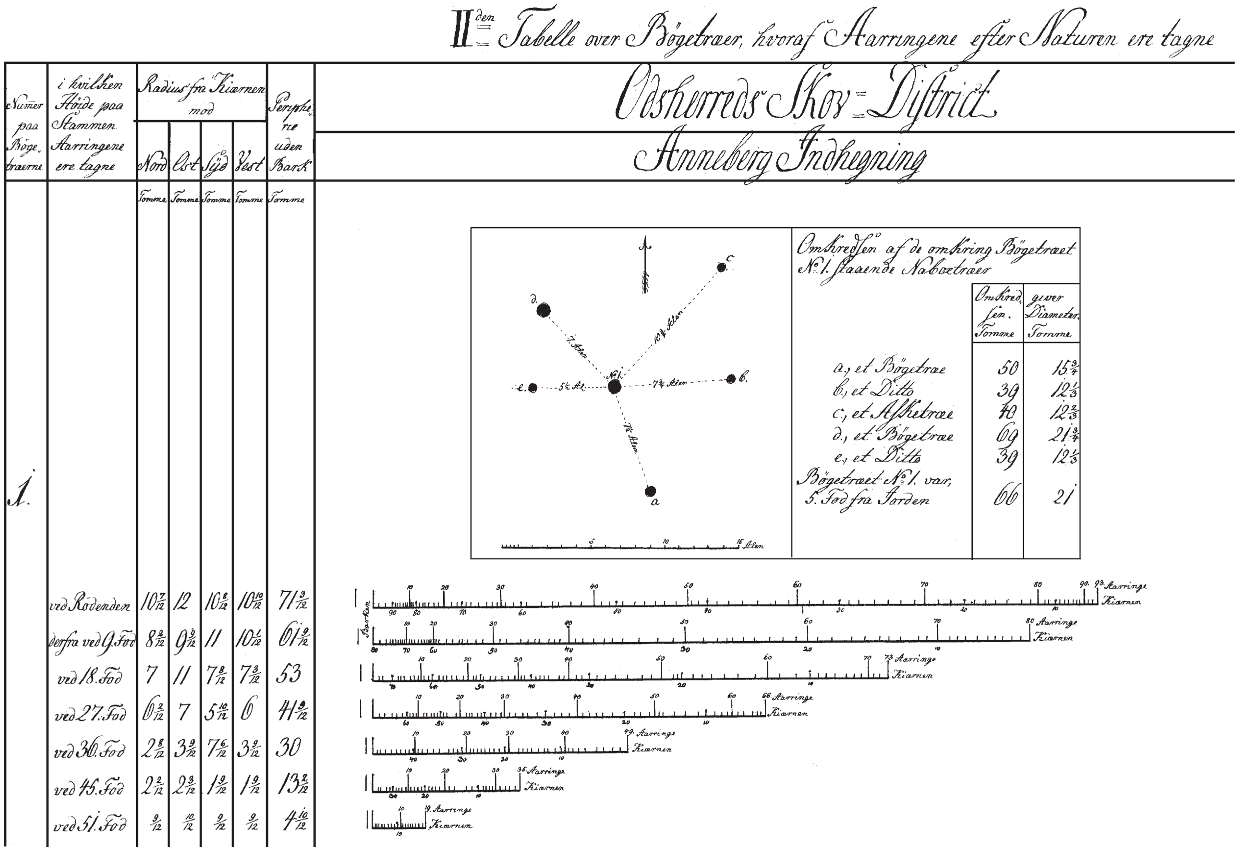

Figure 1 An example of early forest measurements to a modern scientific standard. In 1793, C.D.F. Reventlow initiated dendrometric measurements in stands of oak (*Quercus*) and beech (*Fagus*) in Denmark. Analyzing the size and past growth of trees in relation to the size of neighboring trees, he constructed accurate yield tables and prescribed economically optimal thinning practices that still prevail. Original record sheet for beech tree no. 1 in Anneberg Fenced Forest, Odsherred District. The sketch is a stem map for tree no. 1 and its closest neighbor trees A, B, C, D, and E, recording location, species, and circumference at the butt for each tree. Below to the left, measurements of stem radius (towards north, east, south, and west) and circumference of tree no. 1 at the butt and up the stem at regular intervals. To the right, measurements of annual rings at the same locations in the stem, indicating ring width and age. Number of years is counted from the center (right) as well as from the bark (left). From the archives of the Danish Museum of Hunting and Forestry/Society of Forest History.

appears to be a general consensus on some basic principles and variables. The most notable and universal key variable is diameter (or, alternatively, basal area) at 1.30 metres above ground level, often referred to as diameter at breast height (dbh).

Several of the historical forest measurement variables still prevail, although they were conceived during a period when the science of statistics was only emerging and calculations had to be carried out manually or using a slide rule rather than electronic data processing. Also, market demands for more uniform raw material due to the industrialization promoted a strong focus on timber production. An analytical, more holistic approach to classical dendrometry, unbiased by traditions of the profession and considering the range of issues in forest ecosystem management, would probably result in more comprehensive and statistically rigorous choices and definitions of variables and methods.

Dendrometry

The dendrometric components of a tree depend on measurement objectives and local traditions, but generally include stem, branches, foliage, bark, stump, and roots (**Figure 3**). Each of these may be measured with or without bark, individually or together, split in parts, or taken as a whole. Next, measurements may be carried out for standing trees, dead or alive, or for felled trees or wood products. Supplemented with area-based measurements, for example of sample plot area and stem number, measurement values for individual trees are expanded to obtain estimates at the population or stand level. Instruments for measuring or estimating dimensions of trees or forest products are collectively referred to as dendrometers.

Dendrometric measurements concentrate mainly on wood volume or, more precisely, measurements of

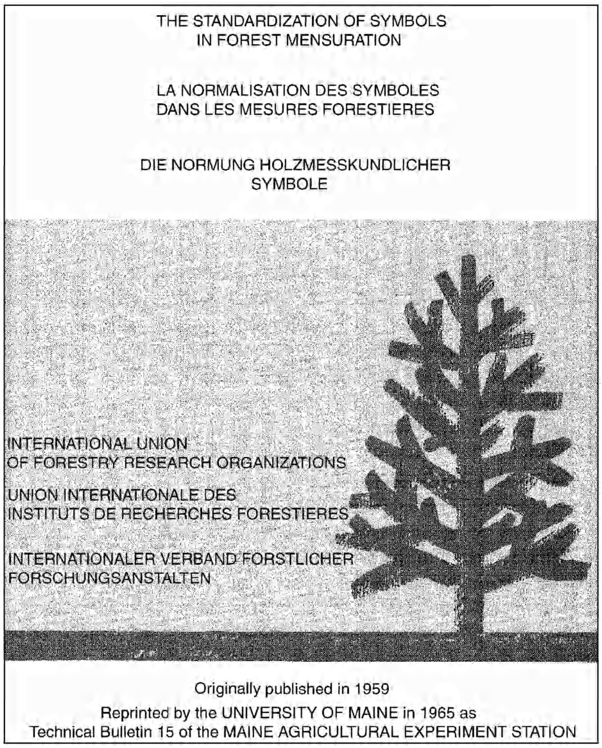

Figure 2 Forest measurement standards. Although seminal initiatives have been taken in Central Europe already in the late 1800s, no internationally agreed standards for forest measurements have emerged. Following approval from member organizations in 1956 IUFRO launched recommendations on the definition of variables and the standardization of symbols in forest mensuration. Although these recommendations were published simultaneously in English, German, and French, their use varies considerably between continents and countries.

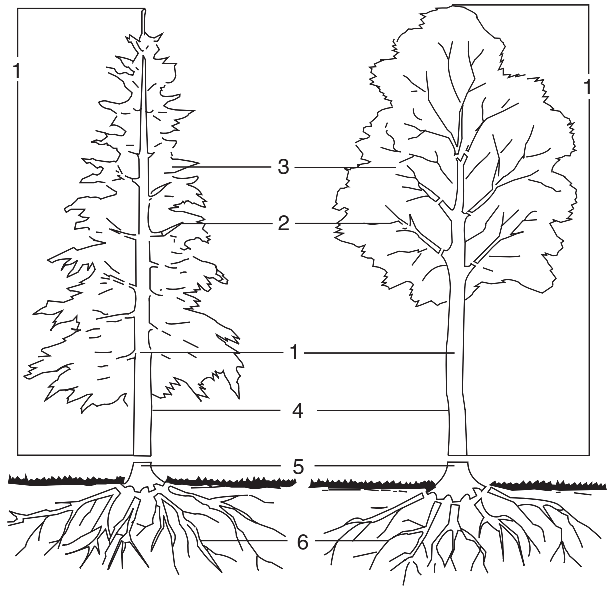

Figure 3 Dendrometric components of a tree: 1, stem; 2, branches; 3, foliage; 4, bark; 5, stump; and 6, roots. Depending on measurement objective and local traditions, measurements may exclude undersized material (size limit usually defined in terms of stem, branch, or root diameter), they may exclude or include bark, or bark may be measured separately. Generally, foliage is not considered except for scientific purposes, for health assessment, or in the case of whole-tree harvesting.

tree and stand attributes from which wood volume can be derived. For commercial purposes the main concern is merchantable volume of the main product, often one or more parts of the stem. Correspondingly, merchantable height (at which stem diameter or exterior wood quality is at its merchantable limit) is assessed directly in the field or derived from models of stem taper or total stem volume.

Due to different growth habits different tree species or species groups generally differ significantly in their dendrometric characteristics. This also holds for age, site, and stand treatment effects. Consequently, the identification of tree species or species group is often needed to capture and model the variation in tree sizes and shapes. However, in most situations, the volume of harvested products can often be assessed using general models that are independent of species or species group.

The most frequently used forest measurement variables include age, stem number, diameter, girth, basal area, bark thickness, height, stem taper, form factor, and volume at tree and stand level. In the following text, symbols for these and other dendrometric variables generally follow recommendations from IUFRO (**Figure 2**). By convention, uppercase symbols are used to denote stand values, whereas lowercase symbols refer to individual trees.

Age

For many practical and scientific purposes chronological time and age are considered fundamental variables for understanding and predicting the dynamics of tree and stand growth and other processes and events in the forest.

Definitions

By definition, the chronological age, t, of an individual tree is calculated from the time of germination of the seed or from the time of budding if the tree originates from a cutting or a sprout. Alternatively, age in a forestry context may be calculated from the time of planting or from the year in which the tree reached a certain reference height, for example 1.30 m above ground level. The latter is often preferred if early growth is hampered by browsing or severe weather such as drought or late frost. For coppiced trees, the age of stems may differ from the age of stools and roots.

In the case of strictly even-aged forest stands where all trees germinated, rooted or sprouted in the same year, stand age, T, is either known from management records or can be determined quite accurately from sampling. Otherwise, if a stand appears even-aged and the age of individual trees ranges within limits, stand age generally refers to some sample average. In the case of uneven-aged forest stands, age is hardly a main concern and is often disregarded.

Considering the longevity of trees, the scale of resolution for age is often 1 year, but any measure of time may be used.

Measurement Principles and Instruments

With distinct annual rings age is easily determined from counting on stumps or radial wood cores. Radial wood cores are extracted using an increment borer, a hollow auger that is screwed into the stem to remove a thin cylinder of wood. The main sources of error include incomplete, partial, and false growth rings, incorrect adjustment for age at the point of sampling, and failure to include the pith in core samples. The most reliable ring counts are made on complete cross-sections.

For some tree species, age may be determined alternatively from counting of branch whorls. In this case, errors may originate due to broken tops. Another important variation of the theme is dating of stumps to determine time and harvest volume of past cuts.

In the absence of seasonal growth rings and other reliable age indicators, age may be derived from observed correlation with other variables of the forest ecosystem. This method is subject to large variation.

Applications

Age determination of trees and stands is essential for even-aged forest management where age or, alternatively, a given period of observation, is often used in the prediction of growth, for site classification and for calculations leading to an optimization of economic return. For uneven-aged forest management age generally remains an inferior variable.

Stem Number

One of the most simple characteristics of a forest stand is the number of trees present, either dead or – more commonly – alive.

Definitions

In a forestry context, stem number is a more operational variable and frequently replaces the number of live trees. Generally, stem number is expressed in count per unit area. Sometimes, stem number refers only to trees above a certain size.

Measurement Principles and Instruments

Stem number at stand level, N, may be derived from stem counts, n, on sample plots or estimated based on counts at representative points in the stand.

For a plot, i, of known area, a_i, $N_i = n_i/a_i$. In the case of multiple plots per stand, the stand average may be weighted by plot area or another relevant factor. The number of plots needed to achieve a reliable stand level estimate depends mainly on the required precision, the stem number level, and its variation across the stand. Obviously, the error in determination of area propagates to stem number at stand level. When trees occur in rows spaced at regular intervals, counting may be carried out in a sample of these, and stem number at stand level derived from row length and sample fraction.

In dense stands, stem number can be pragmatically judged using a string of fixed length. Tied to a randomly located tree, the length of the string equals the radius of a circle of known area. For example, if the string is 3.99 m long, stem number per hectare equals stem count times 20. An alternative, pragmatic method is to measure the distance, k, from a sample point, i, to the nth nearest neighboring tree. Then, $N_i = 10^4(n - 1/2)/(\pi k_i^2)$. The efficiency and choice of these techniques depend on the pattern of variation in the stand and the ease of measurement.

Applications

Combined with other variables such as age or size of the trees, stem number provides an immediate impression of stand density for a given species or forest type. Consequently, stem number is widely used in forestry, for example in thinning decisions or in quality assurance of thinning operations. Stem number is also a significant variable in volumetric calculations.

Diameter, Girth, and Basal Area

Diameter, girth, or cross-sectional area of the stem or other woody parts of the tree is frequently used as an indicator of size, to calculate wood volume, or as a predictor of other tree and stand properties. This text mainly refers to measurement of the stem of standing trees, but similar principles apply to any other measurement of diameter, girth, and cross-sectional area.

Definitions

For standing trees, the most widely used tree and stand characteristic is stem diameter, d, measured outside of the bark at breast height, often referred to as diameter at breast height (dbh). In countries that use the SI system breast height is generally located at 1.30 m above ground level. Alternatively, some other reference height may be used, for example 4 feet 6 inches.

Assuming that stems are circular, stem cross-sectional area or, in the forestry terminology, basal area, g, is calculated as $g = d^2(\pi/4)$. Alternatively, diameter and basal area may be derived from girth or stem circumference, c, as $d = c/\pi$ and $g = c^2/(4\pi)$.

At the tree level, stem diameter, girth, and basal area can be used interchangeably, but generally diameter is the preferred variable because it is easier to visualize. Stand basal area, G, i.e., total basal area per unit area of land, is a specific characteristic of stand density.

Obviously, the stem and other woody parts of a tree are generally not exactly circular in cross-section. Consequently, the objective of any tree diameter measurement is to obtain the diameter of a circle with the same cross-sectional area as the measured part of the tree. The deviation from the circle depends on tree species, terrain, and wind conditions. In the case of substantial and consistent deviations a model to adjust measurements may help provide reliable estimates of basal area.

Another problem is the universal reference level at breast height. This provides an apparently consistent standard and a convenient measurement height, but is biologically not well justified. In practice it is difficult or impossible to determine the exact location of ground level due to natural variations at the base of the tree, and for the individual tree ground level may change over time, for example due to subsidence, erosion, or changes in the amount of organic material. However, definitions such as the highest, lowest, or average point of the ground surface touching the tree are usually considered sufficiently accurate.

Depending on tree species, forest type, terrain, weather, and other conditions a number of irregularities may occur. The most common problems include stem swell, wound callus, forking, lean, and buttressing. Local stem irregularities may be circumvented by measuring above or on either side of the irregularity, and when trees fork below breast height each fork is usually considered an individual stem. Severe and frequent buttressing usually requires an alternative reference level above breast height.

For small trees, and especially those below breast height, another arbitrary reference may be used, for example 10 cm or a level consistent with measurement points for stem taper or form factor. However, measuring the diameter of trees shorter than breast height is generally only considered for scientific purposes.

Measurement Principles and Instruments

The diameter of stems, branches, stumps, and roots is most frequently measured directly using a caliper (**Figure 4**) or indirectly using a tape graduated in π units. Usually 100 cm is the size limit for caliper measurements. Reliable electronic calipers are now available and are widely used.

As an alternative to caliper and tape, indirect measurement may be carried out using a fork or a stick with two arms or sighting lines forming tangents to the stem and a scale graduated according to this geometry. A similar principle is used for remote, optical measurement of diameter. For scientific purposes, diameter and diameter change may be monitored on a continuous basis using a band dendrometer (periodic readings) or a dendrograph (continuous record) encircling the stem or a branch.

In the absence of previous measurements and when growth occurs in a traceable, seasonal, or annual pattern information on past dimensions and growth performance can be obtained from the analyses of growth rings, for example from extracted wood cores, cut trees or stumps (see section 'Age' above). This approach is sometimes used for inventory purposes, in scientific investigations, and for dendrochronological dating (*see* **Mensuration**: Tree-Ring Analysis). A main concern with this method is the representativeness of samples.

Errors in determination of diameter, girth, and basal area are mainly due to measurement object (the tree), instrument, class grouping, or observer. In general, the relative error is small compared to other forest measurements.

Obviously, diameter, girth, and basal area change throughout the growing season and for that reason time of measurement should be chosen consistently and considered in subsequent data analysis. Even in the case of a distinct growing season size during the rest period may fluctuate depending on weather conditions, but generally this does not produce error of any significant magnitude.

For convex as well as concave cross-sections, a calipered diameter is the directly measured distance between parallel tangents to the region of a convex closure, whereas a taped diameter is derived from a parametric measurement of the convex closure. By definition, the diameter of the measured cross-section should equal the average of diameters measured over all possible directions. Consequently,

Figure 4 The caliper is the most common instrument in forest measurements. It is used for direct measurement of diameter of stems, branches, stumps, and roots. The conventional forestry caliper consists of a graduated bar with two parallel arms at right angles; one arm is fixed on the bar, while the other slides on it. Calipers made of metal or carbon fiber are more reliable than those made of wood, because they are sturdy, weather-proof, and easy to clean for resin and dirt. Modern calipers operate electronically with data storage directly in the caliper or data transfer to a portable field computer.

taped measurements are more precise, but result in a slight overestimation of diameter and basal area. In contrast, the caliper is theoretically unbiased for direct distance measurement and the average error may be reduced through the use of random measurement directions.

Instrument error due to a loose caliper arm is likely to result in underestimation, whereas error due to natural fluctuations in the length of a tape is randomly distributed. Each of these can be reduced to a minimum through the use of properly manufactured and well-maintained equipment. For optical instruments the use of a calibrated prism, a magnifier, a split-image, and a tripod improves precision considerably. Generally, alternative instruments are less precise than caliper and tape.

When using an analog instrument diameter is often recorded to size classes. The error due to class grouping depends mainly on class width and the distribution of tree sizes. Except for very thin trees, the error for 1 cm classes is negligible.

Errors due to the observer include failure to identify breast height correctly or consistently, failure to measure perpendicular to the length axis of the tree, and varying or inconsistent contact pressure. The error due to incorrect measurement height may be one- or two-sided and depends mainly on stem taper. In the case of heavy snow cover, floodwater conditions, or similar irregularities, a stick may be used as a probe to locate true ground level. Tilting always results in overestimation of diameter and girth. The problem with contact pressure depends on bark characteristics. Special care should be taken for species with soft, scaly, or otherwise irregular bark.

If successive measurements are taken on the same tree, for example on continuous inventory plots or in scientific experiments, accuracy can be improved considerably by permanently marking the exact location of the breast height reference level. If a caliper is used, accuracy can be further improved by taking two perpendicular measurements and measuring in the same two directions on each measurement occasion (d_1 and d_2). Typically, basal area is then calculated based on the quadratic, arithmetic, or geometric mean diameter, where $\sqrt{(d_1^2 + d_2^2)/2} \geq (d_1 + d_2)/2 \geq \sqrt{d_1 \cdot d_2}$.

As a rule-of-thumb for trees with a "regular" cross-section, individual tree diameter can be measured to within $\pm 2.5\%$ of the true value when using a tape or two perpendicular caliper measurements. Often, diameter is recorded to the nearest 1 cm in forestry practice and to the nearest 1 mm in high-precision scientific investigations. As a rule of thumb stand basal area can be measured to within 1–2% of the true value.

As an alternative to diameter and girth measurements, stand basal area may be estimated directly using a relascope for angle count sampling. The relascope is used to discriminate between trees depending on whether or not the tree subtends an angle equal to or greater than that of the relascope gauge when viewed from the sampling point (**Figure 5a**). Counting from a random point the stems whose diameter at breast height exceeds a certain angle produces an estimate of stand basal area (**Figure 5b**).

A stick equipped with a notched metal plate at one end is an example of a simple relascope. More sophisticated versions include, in order of increasing precision, the wedge prism, the optical mirror relascope, and the telerelascope. In the absence of an instrument, the observer's thumb can be used to obtain a crude estimate of basal area, provided proper 'calibration' at an arm's length to a personal count factor.

Applications

Diameter at breast height provides an immediate impression of the measured object and is the most widely used general characteristic of standing trees and forest ecosystems. Often, diameter at breast height is measured for all trees of a sample, and several other tree and stand characteristics are then modeled based on this quantity. Derived properties commonly include height, stem form, wood volume, volume growth, and branch size. Models for each of these may be improved by including additional variables. For example, upper stem diameters for estimation of stem form and volume.

Full enumeration of individual tree diameters provides substantial information on the sociological structure of a forest stand, including the size class distribution (**Figure 6**). Commonly used stand variables includes arithmetic mean diameter, $\bar{D}$, and quadratic mean diameter, D_g. While the arithmetic

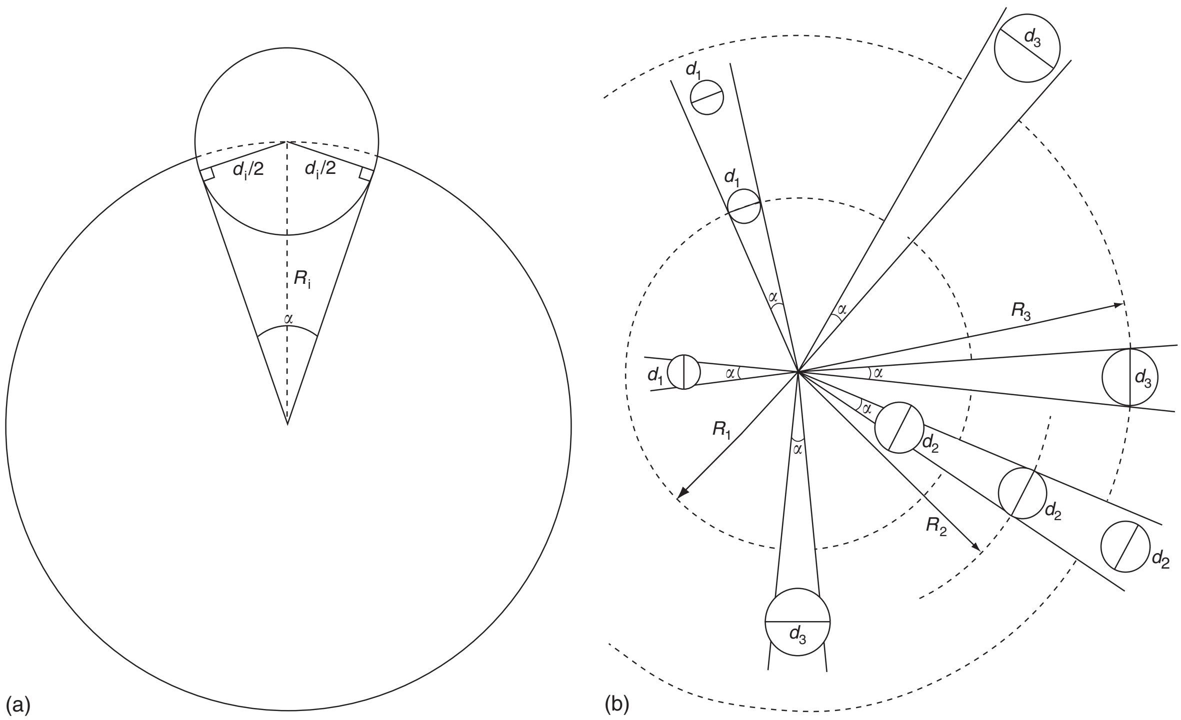

Figure 5 Angle count or point sampling. (a) Given a random point in a stand of trees of varying diameters d such that a particular tree of diameter d_i exactly subtends the relascope angle α when viewed from the random sampling point, the center of this tree is the distance R_i away from the sampling point, where $R_i = d_i/[2 \cdot \sin(\alpha/2)]$. The radius R_i describes a circle or sweep of area πR_i^2. (b) All trees of diameter d_i within this circle subtend an angle greater than or equal to α. The ratio of the basal area of these trees to the area of the circle equals $\sin^2(\alpha/2)$ independently of d_i. Consequently, a count n of all trees subtending an angle greater than or equal to α provides an estimate of the sum of basal area of these trees within each of their circles, i.e., $G\,\text{ha}^{-1} = n \cdot [10^4 \sin(\alpha/2)]$, where $[10^4 \sin(\alpha/2)]$ is called the count or basal area factor. Borderline trees exactly subtending the angle should be counted as $\frac{1}{2}$. For the example in Figure 5b n equals $4\frac{1}{2}$. Count accuracy is considerably improved by choosing an appropriate count factor, using steady instrument support, checking for hidden trees, inspecting the size of leaning and borderline trees, adjusting for slope in line of sight, and avoiding stand edges.

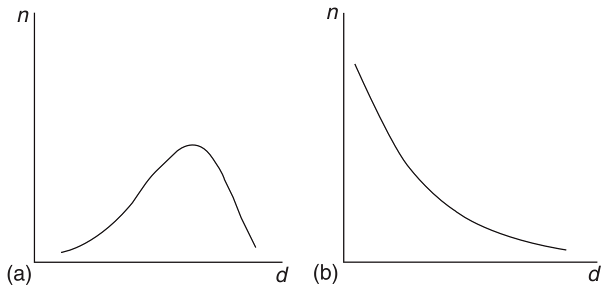

Figure 6 Smoothed diameter distributions (stem number, *n*, vs. diameter, *d*) for two different forest types. (a) An even-aged monospecific stand, and (b) an uneven-aged mixed species forest. The size class distribution is widely used in analyses of the sociological structure and dynamics of tree populations, and is a powerful tool for scenario modeling and decision-making in forest management. Commonly used models include continuous distribution functions as well as discrete functions and matrix models. Models may be univariate, as in this example, or multivariate, taking into account the simultaneous distribution of, for example, diameter and height of individual trees. For prediction and projection purposes parameter values are often recovered or predicted from relatively simple mensurational tree and stand characteristics.

mean relates immediately to the size class distribution, the quadratic mean is equal to the diameter corresponding to mean basal area. In forestry terms, the quadratic mean is often considered more meaningful because of its direct relation to basal area and, in turn, stand volume. Diameter enters quadratically into volume calculations, which are often based on either size class distribution or mean tree dimensions.

Stand basal area is an essential variable for forest management, for example for thinning decisions. In managed forests, individual tree diameter is strongly influenced by thinning practices, and stand mean values thus directly reflect management practices and their effects on growth. For a given forest type management guidelines are often based on an index or decision criterion that combines stand basal area with stand height, stem number (live trees), or mean tree size.

In addition to dendrometric tree and stand properties, diameter also serves as an input variable for harvesting criteria, assortment distributions, stumpage prices, forest valuation, and a range of other uses. Ultimately, through a number of model links, diameter at breast height is *the* key variable for decision-making in forest management, including ecological as well as economic and social aspects.

Bark

Measurement of bark thickness or bark volume may be needed to quantify bark for harvesting or to convert from over bark to under bark dimensions.

Definitions

Mensurationally, the bark comprises all tissues outside of the xylem, including the cambium. Bark thickness is generally defined as the difference in radius of two concentric circles, one defined by the bark surface, the other by the interior wood surface.

Measurement Principles and Instruments

On felled trees bark thickness can be measured at the cut ends or on bark samples that are cut off. On standing trees bark thickness may be measured using a probe or a gauge with a nail or a blade that is pushed through the bark, perpendicular to the stem periphery, to meet the wood surface. The depth of penetration is measured. Alternatively, bark thickness may be measured on extracted cores (see section ‘Age’ above) or on small pieces of bark that are cut off. Often, two or four measurements are made at diagonal points, and often at the points where the tree was calipered.

Measurements of bark thickness are often subject to large variation mainly due to irregular bark, difficulties in penetrating the probe or gauge exactly to the wood surface, slanted boring, and compression of the bark when using the instrument (probe, gauge, or increment borer). In the case of a distinct seasonal growth pattern, measurement accuracy usually deteriorates during the growing season.

When bark is a main commercial product more accurate methods may be needed. This normally implies cutting out samples of bark, for example squares of $20\,\text{cm} \times 20\,\text{cm}$, to determine thickness, volume, or weight. These may also be used for assessment of bark quality. The size and distribution of samples should be optimized based on statistical correlation with harvest quantities.

Bark volume may be derived from thickness or measured directly using a xylometer. Xylometry is also used for direct measurement of wood volume (see section ‘Volume’ below). The bark (or another object) is submerged into water to determine water displacement or buoyancy. If the bark is highly irregular, sample volumes measured by xylometry may underestimate stacked or piled volume.

The weight of bark is easily measured directly. Due to large variation within and between trees and seasonal fluctuations in moisture content, objective measurements require that the bark has been dried to a specified level. For operational purposes, the bark may be allowed to dry in open air for a given period to achieve equilibrium moisture content before being measured.

Applications

Bark thickness varies with tree species, genotype, site conditions, age, stand treatment, tree size, growth rate, health, height above ground, and geographic orientation. For many species, the average volume of bark ranges from 5 to 20% of the over bark volume.

When trees are measured over bark, bark measurements may be needed to estimate diameter, basal area, or volume under bark. This is essential mainly when sale of commercial timber is based on under bark dimensions, or when growth estimates are based on extracted wood cores or stem cross cuts. In the latter case, bark growth should also be considered. Often, bark volume or under bark wood volume is calculated based on the simple model $b_v = ((d_{\text{ob}}^2 - d_{\text{ub}}^2)/d_{\text{ob}}^2) \cdot v_{\text{ob}}$, where b_v is bark volume, d_{ob} is stem diameter over bark, d_{ub} is stem diameter under bark, and v_{ob} is volume over bark.

When bark is a main product, requirements on accuracy of measurements and models obviously relate directly to the commercial value of the bark. Bark is often traded by weight, which may be measured directly or predicted from other dendrometric variables.

Height

The height of individual trees as well as stand height are widely used in volume calculations, in the estimation of site productivity, and for a range of other objectives. Height measurement is more demanding and less precise than measuring the length of felled trees or wood products.

Definitions

The height of a standing tree, *h*, may be defined in different ways, depending on usage and measurement traditions. For total height, two slightly different definitions prevail: the shortest distance either between base and top of the tree, or between ground level and top of the tree. These definitions result in different measures of height only for leaning trees. The first definition may be preferred because it is often compatible with the length of felled trees and a consistent measure for volume calculations, whereas the second definition may be generally more practical. Other height definitions may refer, for example, to merchantable parts of the tree.

Another problem with definition of tree height is the exact location of ground level and of the base and the top of the tree. The principles for location of ground level and tree base is similar to those used to define the location of breast height (see section 'Diameter, girth, and basal area' above). Except for trees with a very distinct tip, it can be difficult to locate the top. This may be due to deliquescent growth, drooping branches, an irregular crown, or crown dieback. Consequently, the top of a standing tree is often defined as its highest growing point.

Measurement Principles and Instruments

Tree height and any other measure of height along the stem may be determined by direct or indirect measurement. Instruments for measuring the height of standing trees are collectively referred to as hypsometers. Several such instruments have been developed specifically for use in the forest.

Due to poor sighting conditions and the time needed for instrument handling it is generally slow work to measure tree height and a much smaller sample is measured than for diameter or basal area. Sampling principles and sample size should be determined based on requirements for end-use precision balanced with measurement costs. As an alternative to measuring standing trees, height estimates may be obtained from the length of felled trees that are sampled for this purpose.

Depending on tree size and stand density direct height measurement may be carried out using a graduated rule, stick, or pole. Extendable poles may be equipped with an engraved or colored scale on the outside or a self-winding tape measure in the inside. Generally, direct measurement is practical only for trees shorter than 10–15 m, and often indirect measurement is used even for these.

Indirect height measurement is based on geometric or trigonometric principles (**Figure 7**). The geometric principle relies on the use of similar triangles, whereas the trigonometric principle makes use of trigonometric functions. In both cases, the accuracy and precision of hypsometers generally depend more on construction details and fine mechanics than on measurement principle. However, with the advent of electronic hypsometers based on high-precision angle measurement combined with acoustic or laser technology for distance measurement, the tendency is that trigonometric hypsometers prevail. This technology has increased reliability of height measurements considerably, but not to a standard similar to that required in land surveying.

In the absence of previous measurements and when height growth occurs in a traceable, seasonal, or annual pattern, information on past height and growth performance can be obtained from measuring back to the terminal bud in previous years (see section 'Age' above). For species without annual whorls, reasonable estimates of height growth can be obtained from counting growth rings at intervals along the stem. If diameter growth is also analyzed

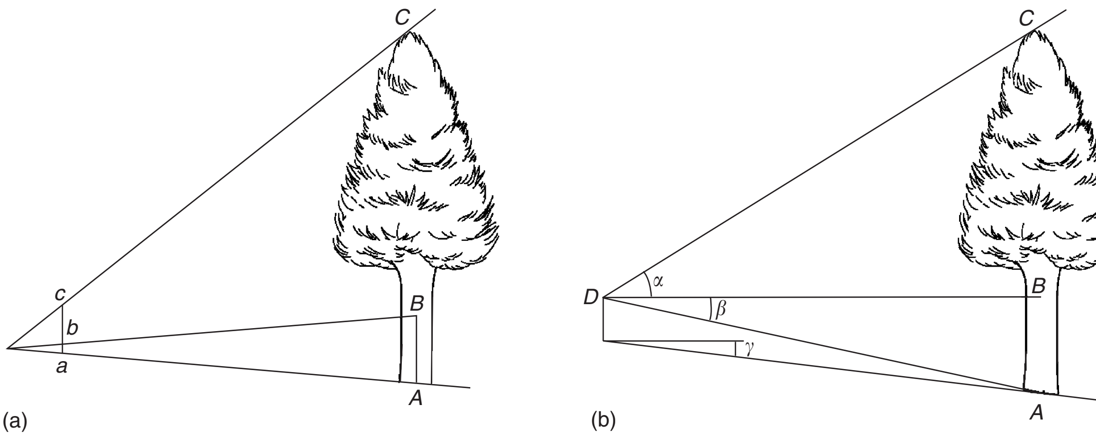

Figure 7 Indirect height measurement based on geometric or trigonometric principles. (a) The geometric principle relies on the use of similar triangles. In this example, a vertical ruler on the hypsometer is adjusted to fit the reference measure $|ab|$ with the length $|AB|$ of a pole at the base of the tree. Next, total tree height $|AC|$ is read directly off a scale which is graduated according to the known proportion between $|ab|$ and $|AB|$, i.e., $|AC| = |ac| \cdot |ab|/|AB|$. (b) The trigonometric principle relies on the use of trigonometric functions. In this example, the angles α and β are measured with the hypsometer, while the horizontal distance $|BD|$ between tree and observer is determined independently. Total tree height $|AC|$ equals $|BD| \cdot (\tan\alpha + \tan\beta)$. If horizontal distance is not measured directly the distance between tree and observer needs adjustment for terrain slope γ by a factor $\cos\gamma$. The angle scale of the hypsometer may be replaced by a nonequidistant tangent or percentage scale, so that tree height is easily calculated directly from hypsometer readings.

this may provide a complete record of past growth. This method is known as stem analysis.

Errors in height measurement are mainly due to measurement object (the tree), instrument, or observer. The most common field problems include leaning trees, parallax error in sighting, and incorrect identification of the tree top. While the latter can be avoided by careful observation, the effect of these problems is essentially similar: sighting is not done to a point located vertically above the geometric center of the base of the tree.

Generally, only a small fraction of trees is measured for height, so trees that lean severely can be avoided. Otherwise, simple geometry and trigonometry can help provide an estimate of tree height that is close to the true value. When parallax error is not due to hypsometer construction this can be avoided by careful observation.

Instrument errors originate in the construction or calibration of hypsometers. Whereas bias in analog hypsometers is often one-sided, more subtle but significant patterns may originate with electronic hypsometers. Outdoor work conditions and the sensitivity of mechanical and electronic components is a critical combination that stresses the need for regular test and calibration.

The random error in height measurement depends highly on tree species, forest type, hypsometer quality, and whether instrument support is used. As a rule of thumb individual tree height can often be measured to within $\pm 2.5\%$ of true height, but measurement errors of up to $\pm 5\%$ or more may occur. Electronic hypsometers and the use of instrument support may help increase precision. Often, individual tree height is recorded to the nearest 10 cm.

Applications

Tree and stand height as well as their distribution and growth provide essential information on forest and stand conditions and are used for a range of different objectives. For example, height is used in the estimation of wood volume, volume growth, stem form, and site and stand productivity, and it is incorporated in more complex models of forest dynamics. Height is also used more directly for management decisions, for example as a criterion for thinning of conifer plantations at a high risk of windthrow.

The potential uses of tree height depend highly on forest type. For even-aged forest individual tree height is often modeled as a static, age and stand specific function of diameter at breast height (**Figure 8a**). For uneven-aged forest interpretation of the relationship between tree height and diameter is less straightforward due to a more complex stand structure, and mathematically more flexible models are needed.

Different indicators of stand height may be derived from the model or directly from sample values. Commonly used indicators of stand height include arithmetic mean height, $\bar{H}$, height corresponding to mean basal area, H_g, mean height weighted by basal

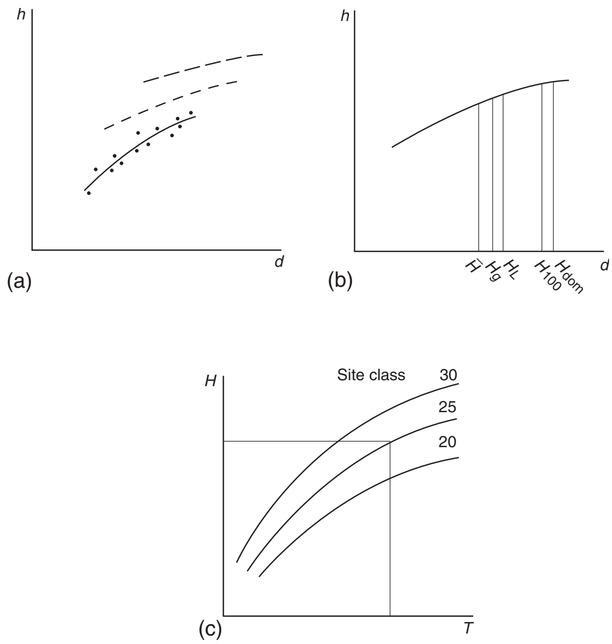

Figure 8 Tree and stand height in an even-aged, monospecific forest. (a) Individual tree height, *h*, as a function of diameter, *d*, at breast height (full line). If remeasurements take place, for example as for continuous forest inventory plots or scientific experiments, a family of curves (dashed line) may be derived that reflects site characteristic height growth for a given stand treatment. In this example there are three remeasurements, with individual observations (•) included only for the first one. (b) The relative position of different indicators of stand height ($\bar{H}$, H_g, H_L, H_{100}, H_{dom}). For readability, labels for stand height appear on the *d*-axis. (c) Classification of site and stand productivity by age, *T*, and stand height, *H*. In this example, the typical height–age development has been shown for three site classes (stand height 20, 25, and 30, respectively, at a given reference age), and a stand has been classified.

area, H_L, top height or average height of 100 thickest trees per hectare, H_{100}, and dominant height or average height of sociologically dominant trees, H_{dom} (**Figure 8b**). Historically based on arguments of computational ease rather than statistical rigor, each of these was conceived for specific purposes, generally aiming to reflect an 'average' property of the forest. Except for stands that are thinned from above the dependence of stand height on stand structure and thinning practices decreases through the progression $\bar{H}$, H_g, H_L, H_{100}, and H_{dom}. Consequently, $\bar{H}$, H_g, and H_L are mostly useful for volume calculations, while H_{100} and H_{dom} are better suited for classification of site and stand productivity (**Figure 8c**).

Volume

Volume is the most widely used measure of wood quantity. For some purposes, however, dry matter production is a more informative variable, but because volume is more easily determined, dry matter content is usually derived from volume estimates. Alternatively, fresh weight may be used to quantify wood or dry matter, with or without adjustment for moisture content and wood density.

Definitions

The wood volume of a tree includes stem, branches, stump, and roots (**Figure 3**). For standing trees, aboveground volume production is generally calculated on stemwood volume for conifers, but may include branch volume for broadleaved tree species. Depending on measurement objectives and local traditions measurements or predictions of wood cubic volume may refer to, for example, total stem volume, v, total tree volume (stem and branches), v_b, or volume above a certain merchantable limit ($d \geq a$), v_a. Volume estimates may exclude or include bark (disregarding the fact that anatomically bark is not a wood component) and, for aboveground estimates, exclude or include stump.

Measurement Principles and Instruments

Wood cubic volume may be determined by direct or indirect measurement. Direct methods are based on the principle of water displacement or pycnometry, while indirect methods are based on geometry. Indirect methods prevail because these are often more practical.

Generally, due to the tedious work, a much smaller sample of trees is measured for volume than for diameter and height. The volume of remaining trees is subsequently derived based on general or stand-specific models. Choice of sampling principles, sample size, and volume function should be based on requirements for end-use precision balanced with measurement costs.

It is relatively easy to sample and measure for stem volume, more tedious for branches, and quite difficult for stumps and roots. Stem volume can be measured on standing as well as felled trees, branch measurements are most often carried out on samples from the crown of cut trees, while stumps and roots that need excavation are only rarely measured. Consequently, and because of the commercial importance, methods and models for volume estimation mainly consider stemwood and other traditionally merchantable wood products.

Direct volume measurement is carried out using a xylometer, which is essentially a water tank in which the wood is submerged. The principle of water displacement requires that the xylometer is equipped or used with a suitably graduated volume scale. The cubic volume of wood equals the volume of water and wood minus the volume of water. Pycnometry requires that the wood is weighed before and during submersion, for example on a scale beam or in a sieve bucket. The cubic volume of wood equals the apparent difference in mass.

In principle, both approaches are accurate, but their precision depends strongly on a suitable graduation of measurement scales (i.e., relative to the size of the piece of wood being measured). Except for very small pieces of wood, measurement error due to air bubbles and the effect of water temperature is negligible. With pycnometry it is important that the water is still.

Direct volume measurement obviously requires destructive sampling. In scientific investigations it may be useful for measuring irregularly shaped parts of the tree and for testing the quality of indirect volume measurements. Often, branch wood is weighed as a substitute for xylometry. Commercially, direct volume measurements are used at some industrial-scale sawmills and plants, for example for scaling of pulpwood.

Indirect volume measurement relies on geometrical models of stem, branches, stump, and roots and may be carried out for felled as well as for standing trees. Due to differences in taper and shape different models are usually required for different parts or segments of the tree. The exact location and number of segments depend on measurement objective, species characteristics, tree size, and local measurement traditions. When felled trees are measured for total (aboveground) volume, for example for the construction of a volume function, the volume of under-cut and back-cut should be included or adjusted for.

In practice, the cubic volume, v_s, of each segment of a sample tree is calculated from the product of its cross-sectional area, g, and length, l_s (**Figure 9a**). Three formulae are commonly used for this purpose: Huber's formula with $v_s = l_s \cdot g_m$, Smalian's formula with $v_s = l_s(g_1 + g_2)/2$, and Newton's formula with $v_s = l_s(g_1 + 4g_m + g_2)/6$, where subscript m refers to the middle and subscripts 1 and 2 to one or the other end of the segment, respectively. The accuracy of each of these formulas depends on the shape of the segment (see section 'Form factor, stem taper, and volume models' below). Huber's formula provides relatively robust volume estimates for long logs and is often used in timber trading.

Most indirect volume measurements on felled trees are carried out using a caliper and a tape measure. Depending on circumstances, an optical caliper and a hypsometer may be better suited for standing trees. The measurement principles that apply to these instruments therefore also apply to the determination

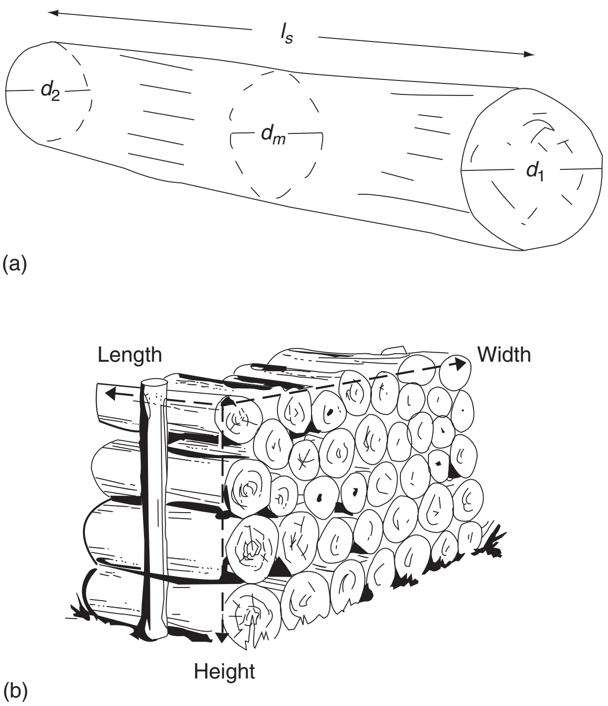

Figure 9 Measuring the cubic volume of wood and wood products. (a) Solid cubic volume is generally derived from measurements of diameter (d_1, d_m, or d_2) and length (l_s) of logs and pieces of wood. (b) Stacked wood is often measured for stacked volume, whether in a regular stack (as here) or in an irregular pile (as for example a heap of wood chips). Stacked volume is the total space occupied by a stack or a pile of wood, as determined by its external dimensions. Solid wood content is calculated using a conversion factor that adjusts for open space in the stack.

of wood volume, and potential measurement errors compound to the calculation of cubic volume. Next, apart from sampling error, error in volume estimates may be due to the models used and, for volume at stand level, error that originates in determination of plot and stand area.

The measurement of trade volume for wood products depends on local customs and trade agreements. The trade volume of logs that are measured individually generally refers to solid wood content. Stacked wood is often sold by stacked volume and solid wood content derived using a conversion factor that adjusts for open space (**Figure 9b**). In both cases, trade customs often prescribe rounding down of measurements. Alternatively, wood products may be traded by weight, with conversion to volume or dry matter based on estimates of moisture content and wood density.

Form Factor, Stem Taper, and Volume Models

The volume of stems, branches, stumps, and roots is modeled in numerous ways, using a range of different predictor variables. Here, three different approaches to modeling stem volume serve as examples.

In its simplest formulation, the classical approach to estimation of volume, v, is based on three volume factors: basal area at breast height (or at another nominated reference level), g, total tree height, h, and a form factor, f (**Figure 10**). The product of basal area and height ($g \cdot h$) yields the volume of the so-called reference cylinder. The form factor is a reduction factor, by which reference cylinder volume is multiplied to obtain the volume of wood. Thus, wood volume is calculated as $v = g \cdot h \cdot f$. Alternatively, diameter or circumference may enter the volume equation directly.

As a second example, volume may be estimated directly from dendrometric variables such as diameter and height. Classical volume models include the so-called combined-variable equation, $v = \alpha + \beta \cdot d^2 h$, and the more general model, $v = \alpha \cdot d^\beta h^\gamma$, where in both cases α, β, and γ are coefficients and other symbols are as usual. The latter model is often used after logarithmic transformation, $\log v = \log \alpha + \beta \log d + \gamma \log h$, where estimates of β often approach 2 while estimates of γ approach 1.

Choice of model may depend on modeling objective, data used in the estimation of coefficients and on error structure. Both models may be expanded to account for effects of, for example, age, site, and stand treatment. Apart from stand variables, the inclusion of an upper stem diameter often improves model performance. As an advantage, variation within stands can be quantified separately from variation between stands, and the accuracy of volume estimates improved. This requires, however, that there is no significant interaction between variables which determine volume level as this could result in ambiguous predictions due to lack of parallel response planes.

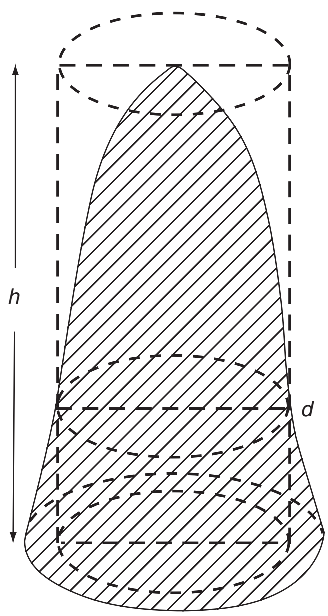

Figure 10 The form factor, f. In one number, the form factor summarizes the volume of a tree relative to its height and its diameter or basal area at breast height, viz. $f = v/(h \cdot d^2 \pi/4)$. Counterintuitively, the form factor is not a characteristic of stem form. The form factor is generally influenced by tree species, age, site, and stand treatment. Because the reference point, for example 1.30 m above ground, is chosen arbitrarily rather than relative to tree size, f is called the artificial form factor. For conifers f usually refers to stemwood, whereas for broadleaved tree species f often includes branches.

The classical form factor and volume equations can be used for individual trees as well as for stand values. Stand values are calculated by summation of individual tree or size class volumes, or a model tree is assumed. The model tree is sometimes referred to as the mean tree. Model tree dimensions reflect an 'average' tree of the stand in question. For example, with diameter corresponding to some stand average and height corresponding to some indicator of stand height. To obtain total stand volume, model tree volume is multiplied by stem number. Interestingly, the sum of individual tree volumes is identical to stand volume according to the mean tree method, when models of the combined-variable equation type are used with quadratic mean diameter, D_g, and stand height weighed by basal area, H_L.

As a third example, stem taper and stem volume may be modeled jointly, resulting in compatible estimates of volume and diameter at any height along the trunk. In the compatible system of stem taper and volume functions, the solid of revolution of the stem taper equation equals the volume according to the stem volume function.

Assuming circular cross-sections (see section 'Diameter, girth, and basal area' above) the cubic volume of the stem or any segment of the tree can be calculated based on the general taper equation $y = k\sqrt{x^r}$, where y is the radius at any point along the length axis x, and k and r defines the rate of taper and the shape of the solid, respectively (**Figure 11**).

In forestry terms, the classic stem taper equation is often expressed as $d_l^2 = 4p(h - l)^r$, where d_l is the diameter at a given height l (above ground), h is total tree height, $p = k^2 > 0$ and $r \geq 0$; r is called the form exponent. The solid of revolution, i.e., the stem volume, is thus

$$\begin{aligned} v &= \pi \int_0^h p(h - l)^r dl = \frac{\pi p}{r + 1} h^{r+1} \\ &= \frac{\pi}{4} d_{1.30}^2 \frac{1}{r + 1} h \left(\frac{h}{h - 1.30} \right)^r \end{aligned}$$

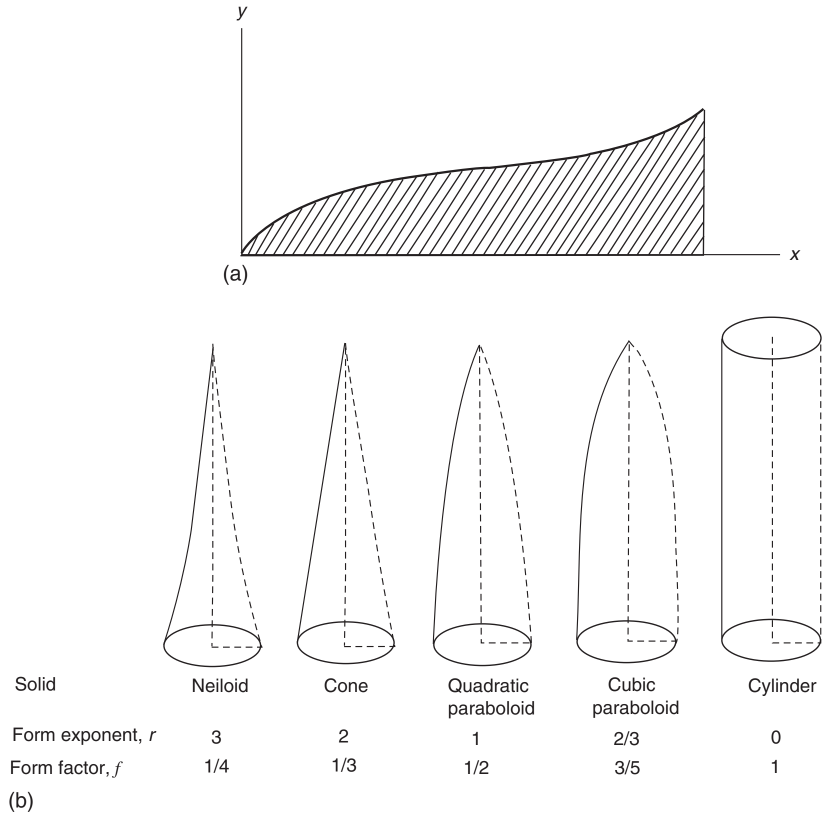

Figure 11 The classic stem taper equation and its solids of revolution. (a) The stem taper equation $y = k\sqrt{x^r}$ provides a general model of radius, y, at any point along the length axis, x. (b) Resulting solids of revolution depending on the form exponent, r. The form factor, f, given for each solid refers to a cylinder of identical diameter at the base.

where v is cubic volume and other symbols are as just described. Combining these equations yields

$$d_l^2 = \frac{4v}{\pi h}(r+1)\left(1 - \frac{l}{h}\right)^r$$

When using the model in practice, some restrictions may be desirable. Apart from compatibility, predicted diameter at breast height should equal the measured diameter, predicted diameters should decrease with increasing height along the stem, no diameter predictions should assume negative values, predicted diameter at the tip of the stem should equal zero, the derivative of the stem taper function with respect to l should equal zero at the tip of the stem, and first derivatives should agree at points of transition along the stem.

With this model the stem volume is explicitly expressed in the stem taper function and it is possible to adjust estimates of the stem taper curve to a specific stand volume level, thereby accounting for the effects of age, silvicultural practice and site on stem taper. Compatible systems may be taper-based or volume-based, depending on which function is derived first.

When the value of r progresses from 0 to 3 the solid of revolution progressively changes from a cylinder ($r=0$) through a cubic (2/3) and a quadratic (1) paraboloid to a cone (2) and a neiloid (3) (**Figure 11b**). Generally, stems approximate the shape of a truncated neiloid at the butt end, one or more truncated paraboloids in the middle, and a paraboloid or a cone towards the tip. Merchantable logs often falls between the frustum of a paraboloid and the frustum of a cone.

Considering the accuracy of indirect volume measurements (see section 'Measurement principles and instruments' above), all three commonly used formulas are accurate when $r=0$ (a cylinder) and when $r=1$, and Newton's formula is unbiased for all of the geometric solids concerned. When $r>1$ Huber's formula overestimates volume, while Smalian's formula underestimates volume; vice versa when $r<1$. In practice, a stem and even a short wood segment may be an irregular composite of different geometric solids whose real shape usually remains unknown. Consequently, the theoretical bias should be interpreted with care.

The volume of branches is often modeled for whole trees at a time (rather than at a more detailed level). Roots generally vary considerably and are very difficult to model.

As a rule of thumb individual stem volume can be estimated to within $\pm 7.5\%$ of the true value and stand volume to within $\pm 5\%$. Often, the volume of individual trees is calculated to the nearest $0.001\,m^3$ ($0.0001\,m^3$ for very small trees) and at stand level to the nearest $0.1\,m^3\,ha^{-1}$ for research plots and $1–10\,m^3\,ha^{-1}$ in operational forestry.

Applications

Quantification of wood volume and volume growth is one of the most important forest measurement activities. The wood volume of a tree or a forest stand is an integral measure of solid substance for a major component of the forest ecosystem and a potential basis for estimates of tree biomass, dry matter production, and carbon storage. Furthermore, trading of wood products is often based on their cubic volume, and standing volume and volume growth are significant decision variables in forest management. Importantly, the magnitude and quality of growing stock is closely correlated with the economic potential of the forest as well as with its biological and social value. At the national level, accurate inventory information on volume, volume growth, and their distribution to owner categories, growth regions, forest types, species groups, etc., is a basic requisite for suitable, well-targeted, and efficient forest policies.

As forest management objectives gradually change over time and may vary considerably from place to place, it is becoming increasingly important that forest measurement variables can be used purposefully for a wide range of different aims. It is easy to invent new and unproven variables, but hard to think of any variables that are more robust and less expensive to measure than those from which wood volume is derived. Although dendrometry rarely provides causal models for science or for forestry, it certainly should continue to provide suitable measurements for the sustainable management of our forests.

Timber and Tree Measurements

C L Brack, Australian National University, Canberra, Australia

Introduction

Trees are complex three-dimensional structures that are very difficult to quantify or measure accurately. To overcome this complexity, the practice of tree measurement is generally to assume that portions of tree resemble simple shapes like cylinders, spheres, etc. A lot is known about these simple or Euclidean shapes, and this knowledge includes relationships between specific variables (e.g., radius of a sphere and the volume or surface area of that sphere). The closeness of the assumed shape to the real shape will partially control the closeness or the errors in estimating the quantity or size of a tree based on measurements of the simple variables. The study of the lengths, areas, and volumes of simple geometric shapes is called *mensuration*.

Forest mensuration is 'the art and science of locating, measuring and calculating the length of lines, areas of planes, and volumes of solids; and the appropriate application of these calculations to trees and forest stands.'

A tree may be divided into various components that may be quantified in various ways. The most appropriate quantification will depend on the reason why the quantification is required.

Definitions

Bole/Trunk

This is the main woody part of a tree, which is the major source of woody products derived from a tree. It is a three-dimensional object with a cross-sectional area that decreases progressively with increasing height. The bole may be quantified by its volume, height/length, or size at a reference height. The number or volume of standard wood products also often quantifies the bole.

Bark

The bark is the outer sheaf of the bole, branches, and twigs. Bark provides protection for the tree and may be harvested for horticultural, agricultural, or medicinal purposes. The thickness of the sheaf varies with height and position, and whether the bark is persistent or deciduous. Volume or thickness at specific positions may quantify this component.

Leaves/Needles/Crown/Branches/Twigs

The branches and twigs of the crown support the display of the leaves or needles to capture radiant energy for photosynthesis. This component may be harvested as fodder or horticultural products. It is also strongly correlated with growth of the tree. Quantification can include measurements of volume or mass, depth/length of the crown along the bole, and size at a reference height.

Roots

Tree roots provide anchorage and storage (large roots) and access to water, minerals, and other elements in the soil (fine roots) and may be harvested for agricultural or medicinal purposes. Quantification is relatively rare, but is normally mass.

The following sections outline the issues and practices involved with measuring these tree components.

Bole/Trunk

Reference Height (Breast Height)

To allow measurements of bole size to be compared, a standard point on the trunk is defined. It is important that this point is at a convenient height near the ground and that it can be reliably located (and relocated) by different measurers. This standard height is termed *breast height*.

The actual location of breast height varies slightly between some countries. In continental Europe, South Africa, Australia, the UK, Canada and some former members of the British Commonwealth, breast height is defined as 1.3 m above the ground. The breast height convention in the USA, New Zealand, Burma, India, Malaysia, and some other countries is measured at 1.4 m (or 4′ 6″) above ground.

Breast height is a convention with a long history of use within forestry practice. However, other standard heights are also used. Some researchers in grazing and agriculture use bole size at 0.3 or 0.7 m above the ground as their standard height. This reference height is used because it has a strong relationship to the grass/crop/tree competition measurements. Researchers studying tree volume have also found very strong relationships between volume and the size of the bole at a relative height (e.g., 5% of the total tree height up from the ground). However, while 5% of a 30-m tall tree is only 1.5 m above the ground and therefore easily within reach, it is difficult to reach the same relative height on a 60-m tall tree.

Measurement at breast height (or other nominated height) may not always represent the appropriate size of a tree. For example, the volume of the tree bole may not be correlated with a measurement at a height that corresponds to a fork in the tree or a fire scar. Typical causes of unrepresentative points include:

- branches or forks
- nodal swellings
- malformations of the trunk due to genetics or disease
- wounds
- insect attacks.

Special rules apply where a tree forks near breast height. For example, if a fork is below breast height, the tree should be treated as double- or multi-stemmed (i.e., more than one tree). If the fork is above breast height, treat the tree as a single stem with multiple leaders. When swelling at breast height occurs due to multiple leaders, the breast height measurement is conventionally taken where the bole diameter is smallest below the swelling.

Special instructions are also necessary where buttressing and fluting are common. Measurement is commonly made above the influence of the buttress or fluting. Where this influence extends well up the bole, an arbitrary height is specified.

When repeat measurements on the bole are expected (e.g., permanent samples), the actual height of measurement should be clearly marked.

The representative size of the bole at a nominated height may be estimated by two common techniques:

1. Take two measurements equally distant above and below the nominated height. If there is little difference between these measurements, take the mean value as the representative size. If the difference in bole diameter at these two heights is relatively large, then a quadratic mean may be more appropriate.
2. Subjectively select a representative point and take measurements at this point. Although quicker than the above method, this approach may lead to bias.

Consistent definition of ground level is essential to maintain precision of measurements. Ground level generally excludes loose leaves and litter that is not incorporated into the soil. Clear this loose material away before taking measurements of height. Sloping ground presents another problem for consistency of measurement. Conventionally, ground level on sloping ground is taken to be the uphill side of a vertical tree, however the mid-point between the uphill and downhill side is used in some countries. If a tree is leaning, imagine which would be the uphill side if the ground were rotated to make the tree vertical. Thus, on flat land, ground level would be defined from the underside of a leaning tree.

Size at a Specified Height

Measurement of a tree bole at a specified height would be easy if the bole corresponded to a simple geometric shape. For example, if we could assume that the bole cross-section was like a circle, then we could measure the radius (r), diameter (d), circumference (c), or area (a). We can calculate all the other variables once we measure any one of them.

$$c = \pi \times d = 2 \times r \times \pi$$

$$d = c/\pi = 2 \times r$$

$$a = \pi \times r^2 = \pi \times d^2/4$$

where $\pi = 3.14159265\ldots$

However, the tree bole is rarely circular (or any other simple geometric shape) and the use of the above equations will only provide approximate estimates. The selection of which parameter to measure will depend on: (1) the use of the measurement; (2) the resources and tools available; (3) tradition; and (4) the acceptable error.

Radius (r): length from the center to the outside of the bole The radius is rarely measured in forestry. Radius cannot be measured on standing trees because the center of the tree needs to be accurately located. Because a bole is not circular, different measurements of radius are possible.

Diameter (d): length from the outside of the bole, through the center, to the opposite side Diameter is commonly measured in forestry. Again, because tree boles are not circular, different measurements of diameter are possible.

Diameter at breast height (dbh) is probably the most common measurement made on a standing tree.

Direct measurement of diameter commonly measures two different axes:

- the diameter of the maximum and minimum axis of the bole on trees that are clearly elliptical
- the diameter of the maximum axis and the axis at 90°
- the diameter of any two axes at 90° to each other.

The two diameter measurements are averaged using an arithmetic mean (most common) or a geometric mean (for highly elliptical boles).

The measurement of diameter on one axis is often acceptable when the data are only being used to group trees into diameter classes for a stand table.

Circumference (c): the length around the outside of the bole Circumference, also known as girth, is commonly measured in forestry, but usually it is then used to estimate bole diameter. If the bole were circular, diameter can be estimated as circumference divided by π. However, if the bole deviates from this ideal shape, then this calculation will overestimate the diameter. The size of this bias is not constant and will vary with the degree and type of deviation. However, this bias is rarely considered significant.

An advantage of measuring the bole girth is that there is no sampling error involved. Unlike diameter measurements, the result does not depend on which axis was selected to measure. This leads to an increase in measurement precision. In addition, if a tree bole changes by 1 cm in diameter, the girth measurement changes by 3.1415... cm (π). Thus, finer readings of the change can be read.

Sectional area (a): the area of the cross-section of the bole This parameter is very important in forestry. The sectional area at breast height is used in many relationships and is called basal area (g).

Sectional area could be directly measured using a planimeter, but this is rarely done. Instead, sectional area is calculated from diameter after assuming that the bole has a circular shape. If the diameter is estimated from a measurement of circumference, then the basal area estimate will be an overestimate (positively biased). If the diameter is estimated from the mean of measurements on one or two axes, then an over- or underestimate of the sectional area is possible. The geometric mean of the maximum and minimum axes is less biased than other approaches.

Height

Total tree height may be defined as the distance along the axis of the bole of the tree from the ground to the uppermost point (tip). In trees with a single, straight stem, this corresponds to the total length of the stem.

The total height (or potential height) of a woody plant is used to distinguish shrubs from trees. For example, a woody plant, usually with a single stem, that is more than 5 m tall may be classified as a tree. Tree height is also well correlated with other important tree and stand parameters.

On leaning trees, height may also be expressed as the:

- vertical component – the vertical distance from the ground to the uppermost point of the tree
- slope or linear component – the length from the base of the tree along the axis of the bole to the uppermost tip of the tree.

The linear component will always be greater than the vertical component for leaning trees. However, unless the lean is severe, the difference is rarely critical. The tree must be leaning by more than 18° off vertical before the difference exceeds 5%. A lean in excess of 15° looks severe.

The vertical component (V) can be calculated from the slope (S) height (and vice versa) if the horizontal distance (H) from the base of the tree to the point directly beneath the tip is known.

$$S = \sqrt{H^2 + V^2}$$

Merchantable height Merchantable height may be defined as the distance from the base of the tree to the first occurrence of either:

- the highest point on the main stem where the stem diameter is not less than some specified value or
- the lowest point on the main stem, above the stump, where branching or other defect limits utilization of the stem.

Merchantable height is used to predict conventionally merchantable woody material. Unfortunately, it is a variable quantity that depends on the specification of the merchantable products at the time of measurement.

Shape (Form)

The diameter of a tree bole generally decreases or tapers from the base to the tip. The way in which this decrease occurs defines the bole form. This taper can occur at different rates and in different ways or shapes. Tree form is complex; however, portions of the tree bole may approximate general geometric shapes like cylinders, conoids, and truncated paraboloids and neiloids. The base of the tree tends to be neiloid while the tip tends to be conoid. The main part of the bole tends to be paraboloid. The points of inflection between these shapes however are not constant. Species and genotype predispose the bole to certain forms, but a wide range of environmental and contextual factors will influence this form.

There is a complex interaction between the bole form and the tree crown. Thus, any factor that influences the crown may also influence the bole form. Different parts of the bole grow at different rates as environmental and other factors affect the crown and the way photosynthates are distributed. The major theories that attempt to explain the shape of the bole may be grouped into three general types:

1. Mechanical: argues that the bole shape corresponds to the most economical shape of a beam of uniform resistance to bending anchored at the base, and functioning as a lever arm. If the tree were firmly anchored, the most economical shape for this beam would be a uniform taper similar to a truncated cubic paraboloid. However, if the tree stem were not firmly anchored to the ground, a quadratic paraboloid shape would be more consistent with the mechanical needs imposed by this assumption.
2. Transportation: based on ideas that deal with the movement of liquids through pipes – tree bole shape is related to the need of the tree to transport water or nutrients within the tree (water-conducting theory and nutritional theory of stem form respectively).
3. Hormonal: growth substances, originating in the crown, are distributed around and down the bole to control the activity of the cambium. These substances would reduce or enhance radial growth

at specific locations on the bole and thus affect bole shape.

Overall or average shape is in some cases quantified as an index of a nominated bole dimension to a reference shape or dimension. Two common indices include:

1. Form factor: the volume of the stem compared to the volume of a standard geometric solid of the same diameter at the base and total height. The most common form factor is the breast height form factor, which is defined as the ratio of the bole volume to a cylinder of the same height as the bole and with a sectional area equal to the sectional area of the stem at breast height. Specific breast height form factors suggest general stem shapes: 0.25 neiloid; 0.33 conoid; 0.50 quadratic paraboloid; 0.60 cubic paraboloid; and 1.00 cylinder.
2. Form quotient (FQ): the ratio of the diameter at some point above breast height to the diameter at breast height. The absolute FQ is used to group trees into form classes. This quotient is calculated by measuring the diameter at a height halfway between breast height and total tree height. This diameter is then divided by the diameter at breast height and expressed as a decimal. Absolute FQs also suggest general stem shapes: 0.325–0.375 (FQ class 35) neiloid; 0.475–0.525 (FQ class 50) conoid; 0.675–0.725 (FQ class 70) quadratic paraboloid; 0.775–0.825 (FQ class 80) cubic paraboloid.

More precise quantification of bole shape is now commonly achieved through the development of mathematical equations that predict the diameter or sectional area of the bole at any height up the tree. These mathematical equations, called taper equations or taper models, use polynomial, exponential, and other types of mathematical structures to relate diameter or sectional area at nominated points up the bole to a reference diameter (diameter at breast height), total tree height, and the relative height where the prediction is required.

Volume

Stem volume is a function of a tree's height, basal area, shape, and, depending on definition, bark thickness. It is therefore one of the most difficult parameters to measure, because an error in the measurement or assumptions for any one of the above factors will propagate to the volume estimate.

Volume is often measured for specific purposes, and the measurement and interpretation of the volume estimate will depend on the units of measurement, standards of use, and other specifications. For example:

- Biological volume is the volume of stem with branches trimmed at the junction with the stem, but usually excluding irregularities not part of the natural growth habit (e.g., malformation due to insects, fungi, fire, and mechanical damage).
- Utilizable or merchantable volume excludes some volume within irregularities of the bole shape caused by normal growth in addition to those irregularities not part of natural growth. For example, the volume contained in the swelling around a branch node may be excluded because this volume could not be utilized (by a nominated user).
- Gross volume estimates would include defective and decayed wood.
- Net volume estimates would exclude defective and decayed wood.

Thus, the type of volume measured must be reported for reliable interpretation. For example, the net merchantable volume of sawlogs in a tree will be significantly different from the gross biological volume.

Calculations of merchantable volume may also be based on true cubic volume or product-oriented volume. Product-oriented volume is the volume of a nominal product that could be cut from the log or stem under specified conditions and assumptions.

Direct and indirect methods for estimating volume are available. The direct methods tend to divide the stem into theoretical or actual sections and measure the volume of these sections:

- Fluid displacement: essentially, the tree stem is cut into manageable sections and immersed in a bath. The amount of water displaced equals the volume of the section. Also called xylometry, this approach most accurately measures gross biological volume.
- Graphical method: measurements of sectional area are made every 1–2 m up the tree bole and then plotted against height (in meters) on a scaled graph. Freehand lines join the plots, and then the area under the curve is equivalent to the cubic volume of the bole.
- Standard sectional method: the main stem, up to merchantable height, is theoretically divided into a number of (mostly) standard length sections. The standard length is normally 3 m (10 ft). The exception to the standard section is the odd log – a section less than the standard length that fits

between the last standard section and the merchantable height. These sections are assumed to be second-degree paraboloids in shape. The bole from the merchantable height to the tip is assumed to be conoid in shape. Equations to predict the volume of second-degree paraboloids and conoids from measurements of length and sectional area are then used to estimate the volume of each section.

The indirect methods include:

- Volume tables: a tree volume table is a statement of the expected volume of a tree of nominated dimensions in a particular stand or population. The number of measurements or dimensions determines the number of entry points or ways into the table. For example, a one-way table normally uses dbh or basal area as the only measurement; a two-way table may use dbh and height; while a three- or more way table would include measurements that correspond to bark thickness or taper.
- Volume equations: volume equations are a mathematical statement of the expected volume of a tree of nominated dimensions in a particular stand or population. The input variables to the equations can also include diameter (at breast height and other heights), height, taper, and interaction terms.
- Integrating taper equations: where a taper function is continuous and able to be integrated, the volume of the bole can be determined by integration. Where this is not feasible, the equation can be used to predict the sectional area at 1- or 2-m intervals up the tree, and volume can be calculated as for the graphical method.
- Variance reduction methods (e.g. importance sampling and centroid sampling): variance reduction methods use the knowledge contained in taper functions to improve the precision and cost of estimating sample tree volume. Essentially, a taper model predicts tree shape and hence sectional area and cumulative volume at any height up the tree. A sample height on the tree is selected and the bole measured. The difference between the measured and predicted size at that height is used to correct the volume estimated from the original taper equation. Various methods differ in the way the sample height is selected and the way the original estimate is corrected.

The volume of wood contained in a tree bole is of primary interest to sawmillers and these millers are interested in the quantity of product they can extract from the bole or logs cut from the bole. Therefore, product-oriented volume definitions rather than the true volume estimates of the three-dimensional shape are of more direct interest. Log rules are a common attempt to estimate volume that is of direct interest to these wood-processing industries.

A log rule is a table or formula showing estimated volume, in standard units, for various log diameters and lengths. During the 1900s, at least 100 log rules were devised. Several sets of these rules are widely adopted throughout the USA, but have not become common in other regions of the world.

The major log rules in the USA predict the production of the board foot. A board foot is equivalent to a plank 1 in. (2.5 cm) thick and 12 in. (1 ft: 30 cm) square; it contains 144 cubic in. (900 cm^3) of wood. However, none of these rules can accurately predict the mill output of boards, except when near-cylindrical logs are sawed according to rigid assumptions on which the rules are based.

Bark

Bark is the outer sheath of the tree. Some trees annually shed bark, while others have persistent bark. The inner bark transports photosynthates from the crown, while the outer bark has a major protective role. The bark protects the bole from insects and damage from physical abrasion. It is also important for fire resistance. Bark thickness normally decreases from the ground to the tree tip. This decrease may be related to the rate of taper of the bole, but there are often irregularities and anomalies. Bark thickness varies with species; genetic constitution; site; tree age, health and size; rate of growth; bark persistence; and position along the bole.

On felled trees and logs, bark thickness can be directly measured at the cut ends. A small chip of bark can also be cut and the thickness measured. However, cutting the chip with an axe may compress the bark and provide biased estimates. Where a ring of bark can be removed, the diameter overbark and diameter underbark can be measured. Bark thickness is one-half of the difference between overbark and underbark diameter.

On standing trees, bark thickness is measured indirectly. A probe is pushed through the bark to meet the wood interface and the length of penetration is measured. Because bark varies around the bole, an average of four measurements (evenly spaced or where the caliper arms contact the bole) is normally required.

Bark sectional area is normally calculated as the difference between overbark and underbark sectional area. Similarly, bark volume is the difference between overbark and underbark volume, where volume is by the standard sectional or other technique. Thus diameter overbark and bark thickness, at a number of heights up the bole, needs to be determined.

Many hardwood trees maintain a reasonably constant ratio of diameter underbark to diameter overbark along the tree bole. Thus diameter underbark at any point along the tree may be calculated by multiplying overbark diameter by the ratio of under- to overbark diameter at breast height.

For many other tree species, particularly conifers, the under- to overbark diameter ratio increases with increasing height along the bole. That is, the relative bark thickness decreases. A few rare species have a decreasing ratio of under- to overbark diameter.

Where the ratio of under- to overbark diameter is not constant, statistical equations may be developed to predict bark thickness from measurements at ground level.

Leaves/Needles/Crown/Branches/Twigs

Crown Diameter

The width of a crown can be measured by projecting the edges of the crown to the ground and measuring the length along one axis from edge to edge through the crown center. Unless the crown has a regular shape, the width measured will depend on the axis selected for measurement. If the crown width is being used to estimate sectional area (used in crown surface area and volume calculations), two axes are normally selected and averaged.

Crown Depth (Length)

Crown depth is the length along the main axis from the tree tip to the base of the crown, where the base of the crown is defined by:

- the lowest complete branch whorl or major branch that forms part of the canopy (used in calculating upper crown length) or
- the lowest live branch, excluding epicormics or water shoots (used in calculating lower crown length).

The depth of the crown is often expressed as:

- crown length ratio (crown length divided by total tree height)
- green crown percent (crown length ratio expressed as a percentage of total tree height).

Crown Surface Area

Crown surface area is a surrogate for the area available for leaves to capture radiant energy from the sun or atmospheric gases and pollution. As the most actively photosynthetic leaves are the young leaves near the crown periphery, crown surface area is a useful index of growth. Crown surface area is calculated by assuming the crown is a solid geometric shape (e.g., conoid, paraboloid, or hemisphere) with a measured crown depth and crown width.

Crown Volume

Crown volume is calculated in a similar way to crown surface area. It is normally estimated from the crown width and crown depth after assuming a regular geometric shape.

Crown Mass

The only direct way to determine crown mass is to fell the tree. Once felled, the leaves, twigs, and branches are separated into discrete pools and the fresh or green weight of these components is determined. The dry weight (and mineral content if required) of a subsample of components is also determined. The ratio of dry-to-fresh weight is used to estimate the original crown's total mass. A variety of sampling approaches has been designed to estimate an unbiased ratio of dry-to-fresh weight.

Indirect approaches to estimating crown mass include the development of statistical equations of the correlation between the expected mass of a tree crown or branch of nominated dimensions in a particular stand or population.

Roots

The measurement of mature tree roots is difficult and rare. The mass of smaller, pot-grown roots is determined by washing away the potting material and direct measurement. The mass of the large roots for mature trees may be estimated by digging a trench around the tree and then pushing the tree over. Many of the major roots will stay attached to the pushed bole. These roots can then be detached and weighed.

Indirect approaches to estimating root mass include the use of estimated root : shoot ratios and the development of statistical equations of the correlation between the expected mass of the roots and dbh or basal area.

Growth and Yield

R Matthews and E Mackie, Forest Research, Farnham, UK

The Purpose of Forest Mensuration

Forest mensuration (the study of measurement) is the research discipline that develops and evaluates both the theoretical basis and practical application of systems for assessing the growth and yield of trees and forest stands. Originally subjective assessments and qualitative systems were used for characterizing the productivity of forest stands; however, methods of mensuration developed over the past 200 years have allowed the adoption of a strictly quantitative approach.

Forest inventory techniques are underpinned by a substantial body of research on measurement methods, and on approaches for the processing of measurements to derive summary results that provide an indication of current and potential future yield. Often the term mensuration is also used to describe the conventions adopted in standardized procedures used by forest industries for quantifying forest resources and as part of production forecasting.

A comprehensive forest mensuration research program involves developing and evaluating:

- measurement instruments and conventions for their use
- procedures for quantifying the structure and yield of forest stands
- descriptions and analyses of tree and stand growth patterns
- relationships between potential stand yield and site factors
- mathematical models of forest structure, growth and yield.

Measurement Variables, Instruments, and Conventions

The essential endeavour of mensuration involves working out how to measure variables relevant to the growth of trees and forest stands. Traditionally measurements are taken of external physical characteristics of a tree or sample of trees that are easy to measure and obviously related to growth. Notable examples of tree growth variables include:

- total height
- stem diameter, circumference, or cross-sectional area
- stem volume
- gross dimensions of the crown.

Sometimes more complex measurements are included as part of mensuration procedures, for example involving detailed assessments of tree and stand architecture. A variety of methods exists for measuring and describing the architecture of individual trees or stands, such as based on:

- the shape and size of crown(s)
- the detailed disposition of branches, foliage, and roots
- the distribution of tree species and size classes in a stand.

A wide range of instruments has been applied to the measurement of growth variables of trees as illustrated in **Table 1**.

Conventions and standards for the measurement of growth and yield variables are very important in order to ensure consistency. These need to cover not only the typical trees in a population but also give clear rules for the measurement of unusual trees (**Figure 1**). Conventions are also required for the measurement of felled trees and any cut produce such as roundwood. Consistency is important if measurements and derived results are to be repeatable. This is essential in the forest industries when buying and selling of quantities of wood. It is also important in a research context when the growth of trees or stands needs to be monitored over time, for example to find out if production is consistent with growth.

An important function of measurement conventions is to prescribe levels of accuracy for measurement. For

Table 1 Examples of tree growth variables and instruments used for their measurement. Common units of measurements are also indicated for each variable

Variable	*Examples of measurement instruments*	*Units*
Tree height	Graduated poles (on smaller trees)	
	Simple hypsometer (geometric principles)	m
	Clinometer (trigonometric principles)	
	Ultrasonic or laser-based combined range-finder and hypsometer	
Tree diameter	Tape measures (which may be calibrated in terms of diameter of an equivalent circle)	cm
	Pair of calipers (which may include digital recorder)	
	Optical dendrometer (for out-of-reach diameters)	
	Laser-based, optical scanning systems (under development)	
Tree basal area	Calculated from diameter assuming circular cross-section	m^2
Stand basal area	Sum of cross-sectional areas based on diameters of individual trees	$m^2\,ha^{-1}$
	Relascope (optical device which may include digital recorder)	
Tree stem volume	Sum of volumes of short sections of tree stem calculated from the measured lengths and diameters of sections	m^3
Stand volume	Measurement of a sample of tree volumes as above; establishment of correlation between tree stem volume and diameter; sum of individual tree stem volumes based on correlation with tree diameters	$m^3\,ha^{-1}$

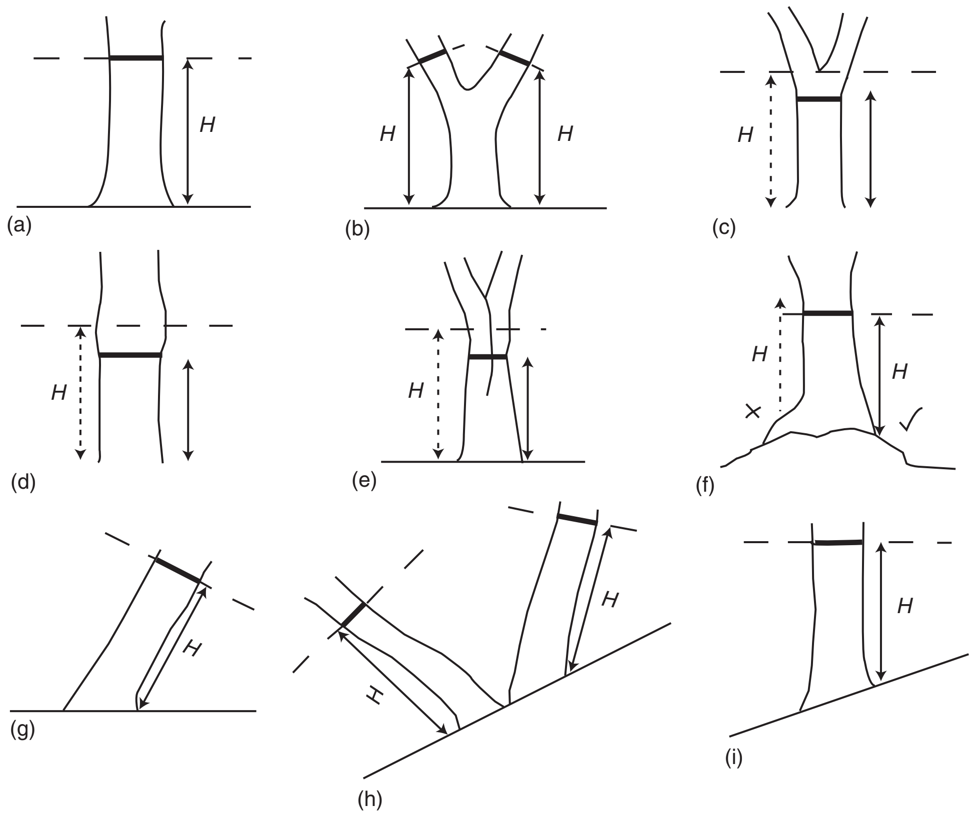

Figure 1 Illustration of conventions that may be adopted to determine a point above ground level (*H*) for measuring tree diameter. (a) Measurement of upright stem on flat ground; (b) stem forked below *H* – measure both diameters; (c) stem forked at *H* – measure diameter at smallest point below fork; (d) swelling at *H* – measure diameter at smallest point below swelling; (e) forks have fused up to and above *H* – measure diameter at smallest point below; (f) planted on plowed or uneven ground – measure from base of stem, not root buttress; (g, h) on leaning stems – measure diameter at *H* on underside of stem with smallest angle to the ground, diameter should be measured perpendicular to long axis of stem; (i) on sloping ground measure diameter at *H* on upslope side of stem.

example, a convention may require the height of a tree to be rounded down to the nearest 0.1 m to reflect the accuracy of the measurement instruments in general use.

Quantifying Stand Structure and Yield

One important aspect of mensuration methods is the requirement for efficient and cost-effective methods of measurement. For example, one of the most important variables used in describing forest growth and yield is tree stem volume which is time-consuming and expensive to measure directly. In particular, inventory systems rely on relatively quick, cheap, and reliable methods for assessment of stand structure and potential volume yield. The forest industry also uses a suite of simple mensurational methods for deciding if, when, and how to carry out thinning or harvesting of stands, as a basis for sale of timber, for planning forest operations, and ultimately as part of the development of forest design plans. These methods are thus essential tools for supporting and demonstrating the sustainable management of forest estates.

Mensuration researchers develop protocols for the assessment of stands that aim to minimize the intensity and complexity of measurements needed to obtain yield estimates of different levels of precision. Where stand structure and volume need to be quantified to high accuracy, an intensive procedure may be specified involving for example:

- counting all the trees in the stand
- measurement of a large sample of tree stem diameters
- measurement of a smaller sample of tree stem volumes.

Tree stem volumes may be measured by climbing or felling trees, or using an optical instrument such as a dendrometer.

Standardized statistical computations can be specified for processing measurements into estimates of numbers of trees, tree size class distribution, and potential volume yield (**Figure 2**). It is also possible to use statistical theory to provide guidance on the size of samples of trees measured for diameter and volume needed to achieve a required level of precision.

Often forest inventories require relatively low resolution estimates of stand structure and yield over an entire forest estate formed of hundreds (sometimes millions) of hectares. In such situations, mensuration protocols are needed that are much

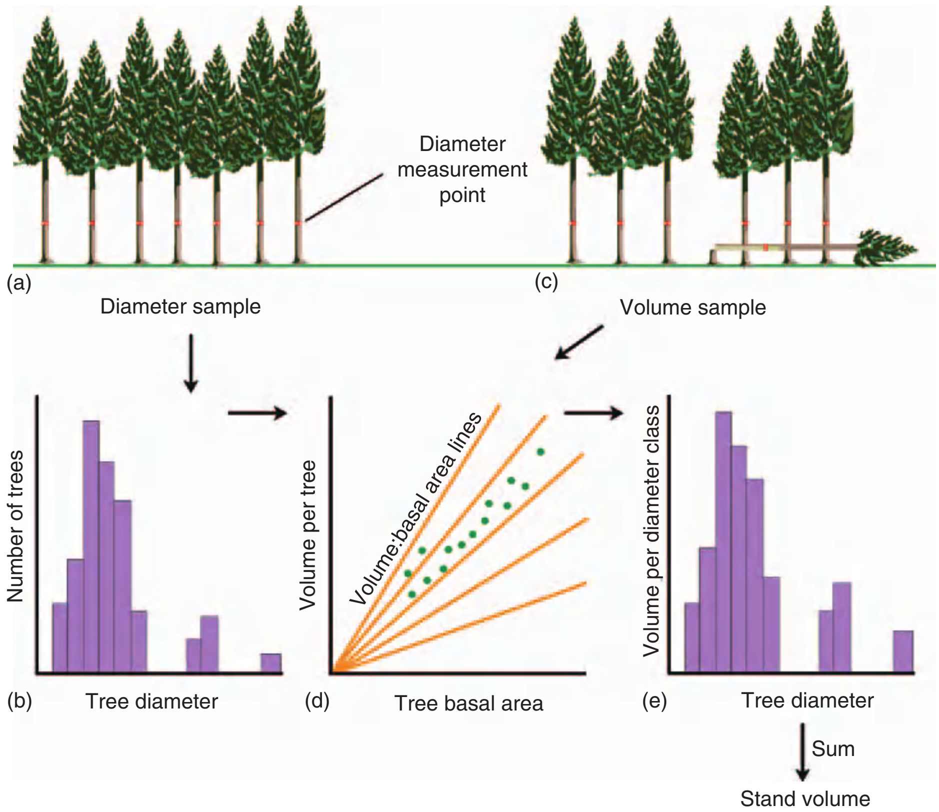

Figure 2 Illustration of intensive forest stand inventory procedure. (a) Count of all trees and diameter measurement of large sample of trees. (b) Construction of diameter frequency distribution based on diameter sample measurements and tree count. (c) Measurement of diameter and stem volume of small sample of trees (in this case by felling). (d) Measurements on volume sample trees are plotted as a scatter diagram of volume versus basal area (calculated from diameters). These are compared against a set of standard charts to determine a specific volume : basal area relationship for the stand. (e) The diameter frequency distribution is combined with the volume : basal area relationship to infer the stand volume in each diameter class, which can be summed to give total stand volume.

cheaper and more rapid to carry out than the sort illustrated in **Figure 2**. A diversity of such 'abbreviated' methods have been developed. The most obvious way is to restrict measurements (including tree counts) to small plots of known area rather than covering the whole stand. The plot level results are then scaled up to give a stand level estimate. Statistical theory can be used as the basis for guidance on the numbers of plots required to provide estimates of stand density, structure, and yield with target levels of precision.

The simplest and cheapest assessment methods dispense with plots, relying instead on 'point measurements' for example of basal area per hectare taken with an optical instrument such as a relascope. Alternatively stand density may be inferred from measurements of a limited number of measurements of distances between trees in the stand.

Simple mensuration protocols usually avoid involving intensive measurements of tree or stand stem volume. Instead these are estimated from measurements of basal area per hectare, individual tree diameters, or height by reference to standard tables or mathematical equations. Estimates may also be derived from yield tables or growth models.

As part of both simple and intensive protocols it may be necessary to estimate quantities of stemwood falling into different categories such as large diameter material suitable for sawlogs, small roundwood, and branches. Alternatively information about stand structure may need to be predicted from more simple measurement; for example, the distribution of tree diameters in a stand might be inferred using a table or statistical distribution function, selected by reference to measured stand mean diameter and assumptions about silvicultural practice. The development of reliable systems for deriving detailed estimates from more easily obtained summary measurements is one of the major tasks of mensuration research.

In all cases, the reliability of estimates derived from mensuration protocols depends crucially on the assumption that assessments are taken in a stand that is distinct in terms of area and uniform in terms of structure. The process of identifying distinct and uniform forest stands comprising a forest estate is known as stratification. Robust mensuration protocols include unambiguous rules for stratifying areas of forest.

Describing and Analyzing Growth

A significant aspect of the work of mensuration researchers involves describing and analyzing the patterns of growth exhibited by different tree species grown on different sites and according to different systems of silviculture.

Analysis of Growth Trajectories

Graphical analysis is a fundamental and frequently used technique which involves plotting sequences of measurements of selected growth variables (**Figure 3**). The sequential measurements, taken on the same tree or sample of trees over time, may be collected at intervals of less than a year or over several years, depending on the rate of growth and on the frequency of perturbations due to environment or management.

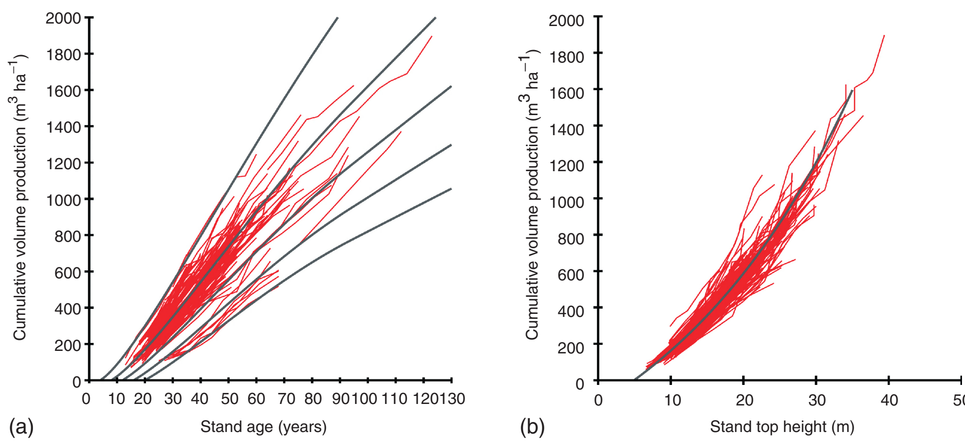

Figure 3 Examples of investigations of growth patterns by plotting trajectories. The graphs are based on assessments taken on stands of Corsican pine (*Pinus nigra* var. *maritima*) in Britain. (a) Cumulative volume production plotted against stand age. The red trajectories show sequences from different stands. The gray lines represent examples from a family of model curves describing the pattern of growth for different levels of productivity. (b) The same cumulative volume production data as in (a) but plotted against stand dominant or top height. Cumulative volume is observed to be more closely correlated with stand top height than with stand age. The gray line shows how the development of cumulative volume production might be described by a single curve with respect to top height. Mensuration researchers use results such as this to simplify the task of building growth models and yield tables.

A graph formed of lines joining the successive measurements of a given variable plotted against age is often referred to as a graph of trajectories. Trajectories may also be formed by plotting measurements of one tree or stand variable against another, in order to explore correlation between different growth variables. Tree level variables may be analyzed in this way but it is more common for growth patterns to be characterized graphically at the stand level. A range of variables may be analyzed, typically including:

- dominant or top height (the average height of dominant trees in a stand)
- mean height
- numbers of trees per hectare
- quadratic mean diameter (the diameter equivalent to a tree with average basal area in a stand)
- standing basal area per hectare
- standing (stem) volume per hectare
- cumulative basal area production
- cumulative volume production.

Traditionally, variables describing aspects of cumulative production, notably cumulative volume, are regarded as important, fundamental measures of growth performance. For an even-aged stand of trees, cumulative volume production is defined as the standing stem volume per hectare observed at a specified stand age plus the sum of all per-hectare volumes harvested as thinnings up to and including that age. Cumulative production has an obvious definition in even-aged stands but there is no widely accepted definition for application to uneven-age stands. Strictly speaking, cumulative volume production does not have any significance as a meaningful physical or biological variable, although it might be regarded as a rough indicator of ecosystem net primary production. The main applications of cumulative volume production are in economic analysis and in support of practical forest management. It has also proved useful in the theoretical development and practical construction of some types of yield models. In essence cumulative volume production represents the outturn of commercial stem volume from a stand up to a given year in the stand's development.

Construction of Growth Curves

Graphs of trajectories are used to construct curves describing the characteristic patterns of growth for the tree species, site types, and silvicultural regimes of interest. In certain circumstances, the shapes of these curves may be established directly by visual inspection of the data and by drawing curves freehand over the trajectories.

However, in the past 40 years mathematical expressions have been formulated for describing tree and stand growth patterns. Sophisticated statistical analysis techniques have also been developed which, when combined with computer software, can be used to calibrate mathematical growth curves based on data collected from trees or stands for the variables of interest.

Parameters of growth curves, estimated for different tree species and growing conditions, may be used as summary statistics indicating the potential growth and yield of different stands. The most common of these is a parameter generally known as the site index, which is usually based on curves describing patterns of height growth in dominant trees in stands (**Figure 4**). Dominant height (sometimes known as top height) growth is often favored as a variable for indicating the influence of site on stand productivity. This is based on the assumption that the growth of dominant trees is relatively unaffected by competition within the stand and not usually influenced by silvicultural interventions,

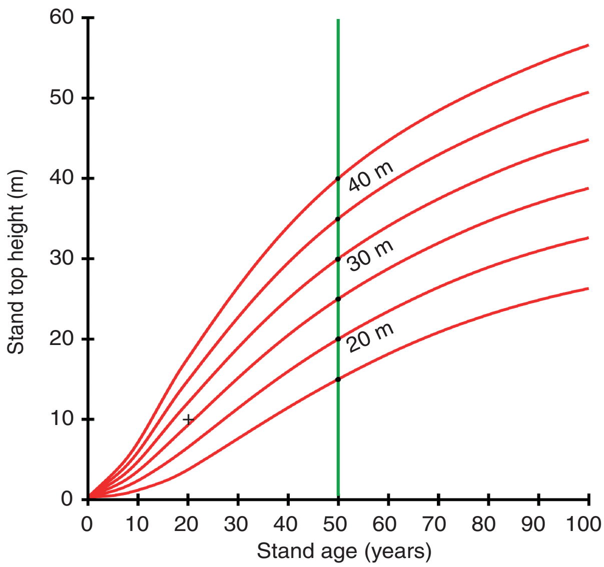

Figure 4 An example of a set of site index curves used for classifying the productivity of even-aged forest stands. The curves are based on observations of top height development with age in stands of Sitka spruce (*Picea sitchensis*) in Britain. Individual curves have been chosen to pass through specific values of top height at a 'reference' or 'base' age of 50 years. Each curve is separated at age 50 years by an interval of 5 m and the height attained at this age is referred to as the site index, for example the curve passing through 20 m represents site index 20. Measurements taken in stands of trees at varying stand ages can be compared to these curves to assess potential productivity. For example, suppose a stand of trees of age 22 years was measured and found to have a top height of 11 m, as illustrated by the black cross. This point is observed to be closest to the curve for site index 25; this curve could be used to forecast future growth potential of the stand.

notably thinning. Furthermore, the height growth of trees and stands has been observed to be much less dependent on stand density than variables such as diameter, basal area, and volume. It follows that height growth, in particular that of dominant trees, should be most strongly determined by the particular growth potential of the tree species comprising the stand in combination with site and other environmental factors.

Analysis of Increment

Mensuration researchers place emphasis on investigating increments of growth variables, indeed increments are among the most explicit representations of growth. They can be calculated for any variable of interest but cumulative volume production is often the focus of attention. Increments can be defined in different ways and three common measures are:

- current annual increment (cai)
- periodic annual increment (pai)
- mean annual increment (mai).

Current annual increment is the actual annual rate of growth of the variable of interest at a specified time. It is sometimes calculated as the difference of two values taken by a variable measured 1 year apart. Occasionally the slope of a curve fitted to a sequence of measurements over time is used to estimate cai. Alternatively periodic annual increment may be used as a surrogate. Records of cai may be used in the investigation of short-term growth trends, for example with respect to management interventions, fluctuations in climate, or episodes of pest infestation.

Periodic annual increment is the annualized growth rate of a variable over a period, typically 5 or 10 years. Measurements of pai are sometimes used in the analysis of forestry experiments for quantifying the growth response due to different experimental treatments.

Mean annual increment is probably the most important of the increment variables and is usually most relevant to the analysis of cumulative volume production. This may be defined as the average rate of cumulative volume production up to a given year. The development of mai follows a characteristic pattern with respect to stand age (**Figure 5**). In the early years of stand development, mai rises steadily from zero to a maximum value. From this point on mai declines steadily, although the rate of decline may be slight in the years immediately following

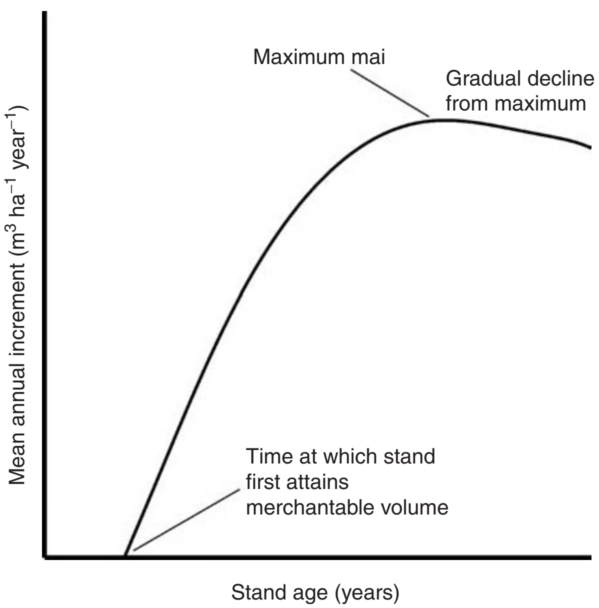

Figure 5 Illustration of the characteristic pattern of development of mean annual increment of cumulative volume production with respect to stand age in even-aged forest stands.

Figure 6 Measurements being taken in a mensuration permanent sample plot. Painted numbers identify the trees in the plot and allow successive measurements to be compared. The horizontal bands on the trees indicate the reference height at which diameter measurements should be taken. Sample plots have been a vital source of data on the structure, growth, and yield of forests. Courtesy of Forest Research Photo Library.

attainment of maximum mai. The existence of a stand age for which mai takes a maximum value may be regarded as being of great commercial significance in the management of even-aged stands particularly if the aim is to maximize sustainable volume production. Specifically, if the maximum value of mai occurs at a predictable stand age then a forest manager may choose to clear-fell the stand at this age. The average rate of volume production over the rotation period will then be equal to the maximum. The forest manager can then replant or regenerate a new stand on the clear-felled site. If this new stand is also grown over the same rotation period then average rate of volume production of the new stand will again be maximal, provided that the fertility of the site has not been depleted and environmental conditions have not changed. Clearly, managing a stand on this site using any other rotation period will result in a lower average rate of volume production.

Applications of Trajectory and Increment Analyses

Analyses of growth trajectories can be applied in some circumstances without further interpretation. For example, suites of curves describing cumulative production and the development of other growth

Figure 7 Illustration of the types of measurements taken in mensuration sample plots and how they can be summarized. Standard protocols for measurement and calculation procedures are very important to ensure consistency and quality of data. (a) The sample plot is marked out on the ground with clear boundaries and protected by a marked surround of protecting trees. All trees in the plot are checked, and classified (for example for dominance or form), and diameter is measured. Standard forms or computer programs are used for collecting the assessments. (b) A sample of trees removed as thinnings is measured for diameter and stem volume. (c) A sample of trees remaining in the stand is measured for diameter, height, and stem volume. Measurements of crown architecture may also be collected. (d) The detailed measurements on sample trees are recorded in a standard format. (e) A sample of dominant trees (which may be used for establishing stand top height) is measured for diameter and height. (f) The measurements on the top height sample are recorded in standard format. (g) The detailed measurements of thinnings and standing trees are analyzed to establish correlations between key tree variables specific for the current assessment of the sample plot. For example, the correlation between tree stem volume and diameter is established separately for the standing trees and any thinnings. (h) The full diameter assessment and analyses of sample trees are combined in the calculation of summary estimates of key variables for the sample plot. Measurements taken at different stand ages can be displayed in a standard format and compared.

variables can be used to construct a range of simple yield tables for direct application to forest management. Summary parameters from these analyses, such as site index, can be used for classifying yield potential of real stands, either as part of stand management and production forecasting or as part of a more general inventory system. Sometimes, individual curves and equations developed to characterize particular growth variables are used to support inventory systems, for example in the form of volume tables or equations. Supplementary analyses may also be carried out that extend beyond direct assessment of stands, for example measurements of site index in stands may be analyzed with respect to site and environmental variables so that the potential growth of trees can be predicted for unplanted sites.

Models of increment are useful in a commercial context for very short-term forecasting. However, the main application of increment studies is in a research context, for example, for understanding relationships between tree and stand dynamics and environmental and management factors. As such, the study of increment has in effect developed into the science of dynamic growth modelling.

Sample Plots

Mensuration research depends on high-quality, comprehensive data on the growth and yield of forest stands. Internationally there has been considerable effort over the past 150 years to collect such data either as isolated assessments or through the long-term monitoring of research plots (**Figure 6**). Such research plots are generally known as 'mensuration sample plots' and are categorized as either temporary (one-off measurement) or permanent (repeated, long-term measurements). The data obtained from sample plots have been vital to the understanding of forest growth dynamics, for mensuration research and for development of models of stand structure and yield (**Figure 7**).

Future Developments in Mensuration Research

Although now a well established discipline, mensuration remains an important, arguably fundamental, element of forest research. Research will continue on development of inventory methods and growth and yield models but this is likely to be carried out in a more integrated context. For example, significant scope exists for integrating networks of mensuration sample plots with other forest monitoring networks addressing subjects such as forest condition, biodiversity, or carbon balance. Extension of the research to cover such integration would require the development of a more comprehensive range of measurement protocols and supporting equations and models. Rapid developments in the fields of geographic information systems (GIS) and remote sensing offer opportunities for combining traditional, intensive mensurational assessments with extensive, state of the art technologies such as satellite imagery.

Yield Tables, Forecasting, Modeling and Simulation

A Kangas, University of Helsinki, Helsinki, Finland
J Kangas, Finnish Forest Research Institute, Joensuu, Finland

Introduction

Growth is usually defined as the net periodic annual increments of forest variables and the yield is their summation. Yield tables typically present the amount of forest variables from a given site, under certain prerequisities during a specific period. The period is usually the rotation, and the variables considered are basic forest parameters such as (mean) diameter, mean or dominant height, basal area, number of stems, and volume. Current and mean annual increment are also shown in a typical yield table, as well as yields obtained from thinnings, so that they should actually be called growth and yield tables. An example of a yield table is presented in **Table 1**.

Growth and yield predictions under different management options are a prerequisite in any forest management and planning task. The main purpose for developing the yield tables and yield equations has been to produce accurate predictions of forest yield to enhance decision-making. These models are typically empirical, based on observed development. Thus, although the object of all growth and yield studies is the past growth, their value lies in predicting the future development.

In this article, the historical development from first growth and yield tables to modern single-tree and projection models is briefly presented.

Predicting Forest Growth and Yield

Growth and Yield Tables

The very first growth and yield tables for pure stands were created in the late eighteenth and nineteenth century. In Germany, the number of publications about yield tables reached 1000 by 1880. An important type of table was the so-called normal yield table. In them, the yields of natural, fully stocked stands were shown. As most of the stands are not normal, they were utilized in yield predictions assuming that the relative density of the stand, compared to the normal stand, would remain the same. However, already in the 1930s this assumption was proved incorrect: the relative density was shown to approach that of the normal stands.

Empirical yield tables, on the other hand, presented the mean development of the stands with respect to age in cross-sectional (inventory) data for a large area. The measured stands were not required to be normal. In this way, the tables represent the development of average stands in the area. The tables were produced using graphical smoothing. They were not yet useful for planning the management of the stands, as they represented averages for different areas, sites, and treatment levels.

Later, site-specific yield tables were constructed from long-term experiments by grouping the observations according to site (**Figure 1**). However, site classification is a problematic field in itself. Climatic and soil properties are not easy to classify, and therefore, the observed yields are used as a measure of site quality. In early applications, quality classes based on mean height of the stands were commonly used.

Table 1 Example of yield table of Scots pine

T	H	N	G	V	$\bar{v}$	p_v	I_v	Y_v/T
20	5.6	1800	6.3	19.0	11	24.6		0.95

Nevertheless, other approaches, for example, based on mean annual increment were also applied. In recent years, the dominant or top height has been the most commonly used variable in quality classification (**Figure 2**). This is because it is assumed to be the stand characteristic least affected by thinning in the stands. In mixed and uneven-aged stands this might be a dubious assumption. For such cases, classification based on basal area index has also been proposed. In some countries, for instance in Finland, site classification based on ground vegetation has been used.

These provisional yield tables were density-free, meaning that an average intensity of thinning was assumed for all stands. Such tables could be used to compare managed and unmanaged stands, but for more detailed planning they were not very useful. In multiple yield tables, there might be two or three different management options, the yields of which could be compared.

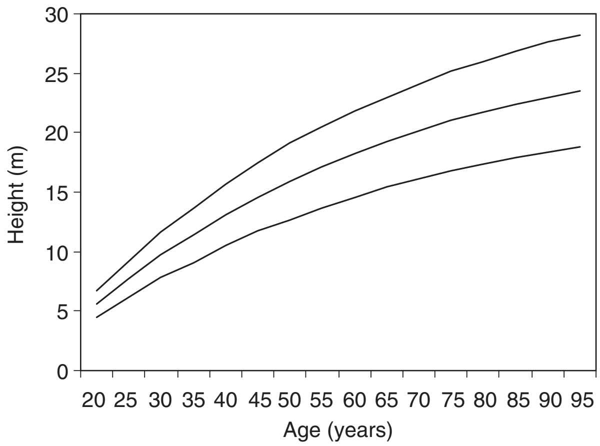

Figure 1 Example of height–age models for site classification.

Even these multiple yield tables are problematic in forest management planning, as they are restricted to the few specific management options. Therefore, variable-density yield tables were needed. These tables are based on statistical models that can simulate the development of the stand under different conditions. Another approach, used particularly in north America, was explicitly to model the change in relative stand density, and to use this information together with normal yield tables to produce growth and yield predictions.

The development of yield tables was quite straightforward as long as pure stands were considered. Such yield tables have been used until recently in most countries, and in tropical countries they are still used. However, mixed stands have always been a problem for both yield tables and equations. The yield tables and equations can only represent a restricted number of different conditions. Therefore, in order to utilize the stand level models, a huge number of parameterizations would be required for different species mixtures, making the practical usefulness of the yield tables for mixed stands very limited. However, examples of such tables can be found.

Growth and Yield Equations

For modeling the growth of stands, two types of models can be separated with respect to the time period considered. The first possibility is to predict the increment of basal area or volume in a period of a certain length, typically 5 years. The development is then calculated by summing subsequent predictions. This type is frequently used in Finland, for instance. Another possibility is to project the development of the desired variables, such as dominant height or basal area, for a desired time. These models, which

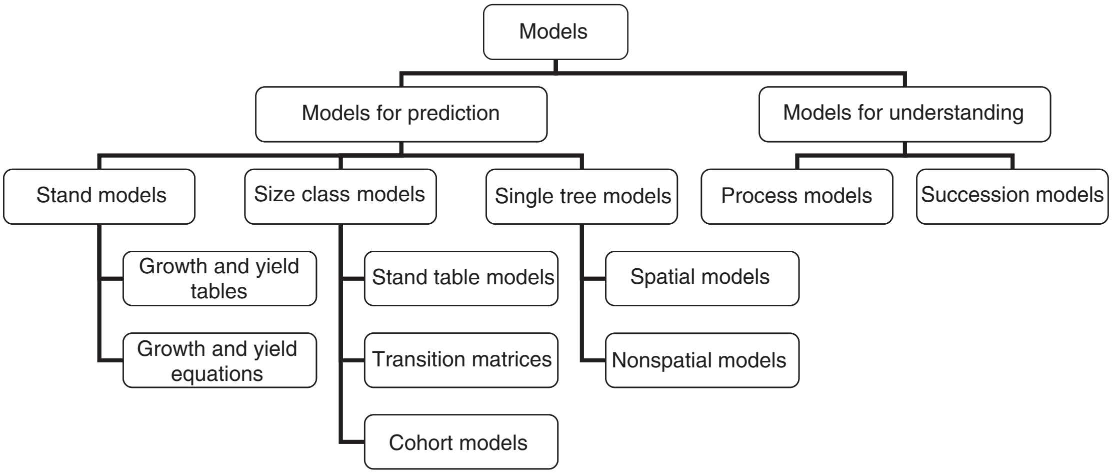

Figure 2 The model classification. Simplified from Porté A and Bartelink HH (2002) Modelling mixed forest growth: a review of models for forest management. *Ecological Modelling* 150: 141–148, with permission from Elsevier.

are called projection models, are commonly used in north America and in tropical forestry.

At the beginning, equations were mainly used to construct yield tables. The first models typically predicted yield as a function of age. Assuming that the parameters of yield models depend on site index and stand density, their effect could be accounted for in the model. Uneven-aged or mixed stands were analyzed, for example, by classifying the data according to species composition and silvicultural history, and by estimating a different parameter set for each group.

Nevertheless, yield equations always assume a certain management regime throughout the projection, but growth equations allow treatments to be defined as desired. The models published by Vuokila for Scots pine (*Pinus sylvestris*), for example, predicted the growth percentage of basal area, dominant height, and volume as a function of stand age, dominant height, basal area, percentage of basal area removed in thinning, and mean diameter. The growth percentage was defined for growth between two successive thinnings.

In those early days, growth and yield models were constructed independently of each other. Therefore, summing up the growths might not produce the predicted yield. To obtain compatible growth and yield estimates many forms of differential equations have been used. Such growth function can be integrated to obtain the yield and growth function can be obtained as a derivative of the yield function. An example of such models is the famous Chapman–Richards equation where growth is described by the equation:

$$\frac{\mathrm{d}x}{\mathrm{d}y} = k\left(\frac{A-y}{A}\right)y$$

and the yield by the equation:

$$y = B(1-\mathrm{e}^{-kx})^{1/1-m}$$

where k, A, B, and m are parameters. In this model type, only one independent variable can be included, typically the stand age.

Obtaining compatible growth and yield equations for several variables from multiple regression models was a challenge that has been tackled from the early 1960s. For example, the equation system proposed by Clutter is:

$$\begin{aligned} E[\ln(V_1)] &= \beta_0 + \beta_1 S + \beta_2 A_1^{-1} + \beta_3 \ln(B_1) \\ E[\ln(V_2)] &= \beta_0 + \beta_1 S + \beta_2 A_2^{-1} + \beta_3 \ln(B_2) \\ E[\ln(B_2)] &= (A_1/A_2)\ln(B_1) + \alpha_1(1 - A_1/A_2) \\ &\quad + \alpha_2(1 - A_1/A_2)S \end{aligned}$$

where V, B, A, and S denote volume, basal area, age and site index, respectively, and β and α are parameters. The subscript in stand variables denotes the time.

In order to obtain compatibility, the system of equations was solved so that $\ln(B_2)$ was substituted with $E[\ln(B_2)]$ in the function of $E[\ln(V_2)]$. Therefore, parameters for projecting the basal area could be solved from parameters of the volume functions. The volume equation can be differentiated to produce a growth function:

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \beta_2(V/B)\left(\frac{\mathrm{d}B}{\mathrm{d}t}\right) - \beta_3 V/A^2$$

This formulation led to compatible equations for standing volume, basal area growth, volume growth, predicted basal area, and predicted stand volume.

This approach is heavily based on stand age as an independent variable. Therefore, it is not suitable for uneven-aged stands, where the definition of stand age is at best ambiguous. For uneven-aged stands, a formulation based on stand density (defined by basal area) was introduced. A following system of equations, also providing compatible estimates, was used:

$$\begin{aligned} V &= \beta_0 B^{\beta_1} \\ \left(\frac{\mathrm{d}V}{\mathrm{d}t}\right) &= \beta_1 V B^{-1}\left(\frac{\mathrm{d}B}{\mathrm{d}t}\right) \\ \left(\frac{\mathrm{d}B}{\mathrm{d}t}\right) &= nB^m - kB \end{aligned}$$

In this approach, the parameter estimates are inefficient in statistical respect, i.e., estimates with better statistical quality could be derived. Therefore, in later applications, simultaneous estimation methods such as two- and three-stage least-squares and seemingly unrelated regression have been used. With these methods, compatibility can be achieved between the prediction and projection models in the system of equations.

Utilizing Size Class Models

Current yield Later, the growth and yield equations were used to construct stand growth simulators for computers. After that it was possible to compute yield tables for any desired management schedules that were computable. These first stand simulators, however, could not produce enough information for modern forest management. There was a growing demand for single-tree information. For example, the timber assortments and value of the stand are difficult to predict with stand information.

Therefore, information concerning the frequencies in different diameter classes, i.e., diameter distribution, was strived for. The current yield is often predicted using probability density functions such as normal, log-normal, beta, gamma, Johnson's S_B or Weibull. For Weibull, an analytical cumulative distribution is available. It describes the probability of values smaller than x. It is of the form:

$$F(x) = 1 - \exp\left[-\left(\frac{x-a}{b}\right)^c\right]$$

The proportion of trees in any diameter class $[d_1, d_2]$ can be calculated from the distribution function F as $F(d_2) - F(d_1)$. The diameter distribution can also be formulated with respect to basal area. Then, the distribution gives the proportion of stand basal area in desired diameter classes. It is a weighted version of diameter distribution, which gives more emphasis to the most valuable trees in the stand.

For predicting the distribution, two main methods have been applied, namely the parameter prediction method (PPM) and the parameter recovery method (PRM). In PPM, the parameters of some distribution function, for example the Weibull distribution, are predicted with regression models from measured stand characteristics. In this approach, site index and age may be quite poor predictors of the parameters, but mean (or median) diameter usually gives a fairly good fit. In PRM, the parameters of the distribution function are solved from a system of equations, equating (measured or predicted) stand attributes to their analytical counterparts. The characteristics can be, for example, percentiles or moments of diameter distribution. In some cases, some of the parameters are predicted and others are solved using a parameter recovery approach.

Another possibility is to use a percentile-based diameter distribution method. In this method, a number of percentiles (of frequency or basal area) across the range of diameters are defined. Usually 12 or more percentiles are used. The distribution is obtained either by linear interpolation (i.e., assuming a uniform distribution of frequencies between adjacent percentiles) or any other monotony-preserving interpolation method. Recently, the distributions have also been predicted using nonparametric approaches. Then, the tree list is obtained as a weighted mean of tree lists from measured stands similar to a target stand.

The predicted diameter distribution is usually scaled to the measured number of stems, so the stem number obtained from the distribution corresponds to the known characteristic. Using the parameter prediction method or nonparametric approach, there is no guarantee that other stand characteristics obtained from the predicted diameter distribution correspond to the measured stand characteristics. With PRM, the compatibility of predicted and measured stand characteristics can be guaranteed for the characteristics used for solving the parameters of the diameter distribution function. Recently, calibration or adjusting techniques have been proposed for such situations.

Future yield When growth of a stand is predicted via size class models, both the current and future stand table are predicted, and the growth is calculated implicitly from the differences between the yields obtained from these tables. A simple way to accomplish such predictions is to predict the parameters of a probability distribution as a function of age and site for desired time points. Another possibility is (simultaneously) to project variables such as number of stems, basal area, and dominant height, and to predict the distribution in the future based on these variables. Then, however, the diameter distributions at different time points are not necessarily compatible.

To obtain a logical development of the distribution, the changes in the diameter distribution are directly predicted. This can be done, for example, by projecting the development of the parameters of the used probability distribution (PPM) or the development of percentiles of diameter distribution for a given time. In the latter case, the future distribution is obtained by analytically solving the parameters of the probability distribution from these percentiles (PRM) or by interpolating between the predicted percentiles (percentile-based method).

It is also possible to project the stand table directly. Then, the whole tree list is assumed to be known. The development of the list is based on an assumption that the relationship between the basal area of a tree and the average basal area follows a certain function. The stand table is constrained so that the projected number of stems and the basal area are consistent with the whole stand estimates. A mortality function is an important part of this system. Such models are already approaching modern single-tree models.

In the matrix approach, the stand is also described with the aid of size classes. These models, however, are stochastic. The model predicts the development of the stand via the probability that a tree will grow up to the next size class, die, or remain in its current class. Therefore, matrix models implicitly include models for recruitment and mortality. The probabilities are usually assumed to depend only on the current size of the trees. The results of these models are the frequencies of trees in different size classes.

The matrix models used are referred to as Usher, Lefkovitsch, or Leslie matrices depending on their characteristics: Leslie used age classes for animal populations, Lefkovitsch used development classes for insects, and Usher used diameter classes for forests. If the probabilities of movements are expressed as a matrix **M**, and the initial and final state of the stand with vectors $\mathbf{V}_0$ and $\mathbf{V}_1$, the prediction for one period is obtained as

$$\mathbf{V}_1 = \mathbf{M}\mathbf{V}_0$$

and for n periods as

$$\mathbf{V}_1 = \mathbf{M}^n\mathbf{V}_0$$

It has been argued that the maximum exploitation of the stand and the stable stand structure can be revealed from the first eigenvalue and eigenvector of matrix **M**. However, they cannot be used to evaluate the optimal density of the stand.

One obstacle in using matrix models for growth prediction is that the basic models do not allow for probabilities to change in time, e.g., as a function of stand density or structure. This problem can be avoided, however, by estimating a new matrix for each iteration using equations.

Assessing the Accuracy of Predicted Forest Development

Models need to be evaluated before they are used in real-life applications. Evaluating growth and yield models requires both qualitative and quantitative analysis. The qualitative analysis of the logics and biological consistency are as important as quantitative analysis of statistical properties. However, the models cannot be proved correct in evaluation: they can only be validated with respect to their usefulness in the applications for which they are meant.

The accuracy of different growth and yield models has been assessed with empirical validation studies. The simpler the models are, the more often they are also validated. The stand level models have generally performed better in these tests than the tree level models, due to the cumulating errors in the tree level. This concerns the short-term predictions — in the long term there are very few validation studies. Consequently, the long-term results may be much worse than expected.

The empirical accuracy assessments based on validation studies are, however, calculated for certain past time periods and for a certain area. To anticipate the precision and accuracy of future predictions, a model-based approach is required. It is possible to model directly the observed past errors of interesting variables predicted using the simulator.

There are also methods for assessing the accuracy of predictions which are not based on empirical validation studies. For instance, the precision of long-term predictions has been assessed through Monte Carlo simulation or Taylor series approximations, where the total prediction error is composed of several error sources. These methods can be applied in producing error budgets for simulators. Such budgets give the contribution of each and every error source in the results. On the other hand, it is difficult to take all sources of error into account. For example, the errors in the model structure, causing biased predictions, are difficult to incorporate into these methods. Yet, in the long term, the model misspecifications may be the most important source of error.

Data for Growth and Yield Modeling

For standwise growth and yield tables, data not identifying individual trees are sufficient. The simplest estimate for growth is the difference between the volumes from two points of time. However, accounting for mortality and recruitment requires more information. Net growth can be defined as:

$$\Delta V = V_2 - V_1 + V_c$$

where V_c is the harvested volume. Gross growth is obtained by adding mortality V_m to the net growth. The growth of the trees observed at both time points is defined as survivor growth.

Permanent, temporary, and semitemporary plots have been used for estimating yield tables and equations. The first tables were based on temporary plots, but permanent plots have later been used in most countries. The obvious explanation for this is that temporary plots do not provide a good basis for analyzing the effect of different management options. However, at the time the first permanent experiments were established, statistical principles such as replications were not known. This somewhat reduces the value of the experiments.

If a retrospective analysis of the development of the stands can be accomplished, temporary plots may, however, be a fairly good option. Temporary plots are cheap and fast to measure, in contrast to permanent plots. In temporary plots the measurement personnel, equipment, and calculation techniques do not vary in the data. Furthermore, the studied treatments are not restricted to a few possibilities, and they can be chosen to be up-to-date options. In temporary plots, natural damages do not affect the studies. Nevertheless, the treatments carried out before the measurements are difficult to define afterwards.

Semitemporary data remeasured at fixed intervals may be a suitable compromise for most occasions. However, the remeasurements should cover a sufficient period in order to include the whole range of variation due to weather conditions. It is also important to cover the extreme densities and treatments in the data. The remeasurement intervals also need to be long enough to ensure that growth can be detected from noise introduced by measurement errors.

Final Remarks

Forest simulators have been developed from simple standwise yield tables and models to increasingly complex single-tree models. The new models are more flexible and suitable for many applications, for mixed stands and even for changing management practices. The causal relationships governing the growth of forests are easier to account for in single-tree models than is a stand model. However, the accuracy of the predictions has not been improved likewise. On the contrary, the more complex a simulator is, the more uncertain the predictions may be.

All in all, it is important to study the contribution of different sources of uncertainty (i.e., to formulate error budgets) to concentrate research efforts where they are most needed. It may well be that the main source of uncertainty is not the growth simulator at all, but the quality of initial data, for example. It would also be useful to separate the inherent randomness of growth from pure ignorance.

Tree-Ring Analysis

M Worbes, University of Göttingen, Göttingen, Germany

Introduction

Tree-ring analysis or dendrochronology is both an old and a modern science. Just counting tree rings sounds simple, but in the context of forest dynamics tree age is an important and valuable parameter. The pattern of tree-ring width, wood density, element content, and other features store information on past growth conditions. Biomonitoring is the reflection of growth factors by biological organisms and their change in time. Tree-ring analysis extends the monitoring period considerably into the past and could be considered as retrospective biomonitoring.

For a long time dendrochronology (from Greek: dendros, tree; chronos, time, and logos, science) was associated with the dating of old houses, paintings, and archaeological samples. In recent decades however it has become a science with a broad range of applications such as global climate change, canopy process decline, the carbon cycle, and many others. Due to its manifold applications for other branches of science dendrochronology is sometimes considered as just a tool for archaeology, art history, biology, climatology, forestry, glaciology, etc. The development of techniques like X-ray densitometry, isotope analysis, special statistical analysis for tree ring interpretation, etc., together with new aspects in the theory of tree-ring formation mean that tree-ring analysis should be considered as an independent branch of earth science.

History of Dendrochronology

Leonardo da Vinci, who in the sixteenth century realized the relation between climate and widths of tree rings, is considered the father of dendrochronology. The beginning of broad scientific knowledge of wood formation, tree rings and climate, however, can be dated to the middle of the nineteenth century, when Theodor Hartig and others postulated their theory of tree-ring formation as a consequence of low temperature in winter. Additional milestones reflect the progress in dendrochronology during the last 150 years.

- 1927: Ch. Coster, a Dutch forester, proved the existence of annual tree rings in the tropics for many species on Java and explained the climatic background.
- 1935: First age dating of a wood sample by cross-dating the tree ring patterns of a construction beam by A. E. Douglass (Pueblo Bonito).
- 1954: E. Schulmann found the oldest living tree in the white mountains of California (bristlecone pine (*Pinus longaeva*): 4798 years).
- 1976: Hal C. Fritts introduced statistical methods to analyze climate signals in tree ring sequences as the base for climate reconstruction using tree rings.
- 1983: Fritz H. Schweingruber established modern dendro-ecology and developed X-ray densitometry.
- 1993: B. Becker developed the longest oak chronology with 11 800 years of tree rings in southern Germany.

Wood Anatomy and the Ecological Background of Tree-Ring Analysis

It is still widely assumed that tree rings occur only in the temperate and boreal zones. The gradual deceleration of growth until cambial dormancy as a consequence of low temperature results in the formation of latewood, which differs structurally from the earlywood of the previous growing season.

In general three different types of climatic seasonality affect annual tree growth (**Figure 1**):

1. Variation of annual temperature with temperature near or below the freezing point in winter.
2. Annual flooding of the great river systems in the tropics (e.g., the River Amazon) rising up to 5 m above the forest floor for 6 or more months per year causes anoxic conditions in the soil. Root respiration and water uptake is hindered; many species shed their leaves and have a cambial dormancy. This is reflected by annual rings in the wood.
3. Variation of precipitation between rainy season and dry season. This climate type covers the major part of the tropics.

Tree rings are bound to the process of secondary radial growth of the xylem. This is the case in gymnosperms and dicotyledonous angiosperms. Woody monocotyledons never form tree rings due to the absence of secondary xylem. In general, growth zones can be classified into four basic anatomical types according to the features at the ring boundaries (**Figure 2**). Many species combine several of the four growth zone features.

Type 1

Density variations occurring in gymnosperms as a unique feature and in broadleaved trees together with one or more of the following features: cell wall thickness becomes greater and the cell lumen becomes smaller from earlywood to latewood (all coniferous species, Annonaceae, Verbenaceae, Lauraceae, and many other families).

Type 2

Marginal parenchyma bands run around the entire cross-section and consist usually of one or few cell rows (Annonaceae, Bignoniaceae, Leguminosae, Meliaceae).

Type 3

This is the tissue pattern type. The most complicated and frequently misinterpreted structure is to be found in Euphorbiaceae, Moraceae, Sapotaceae,

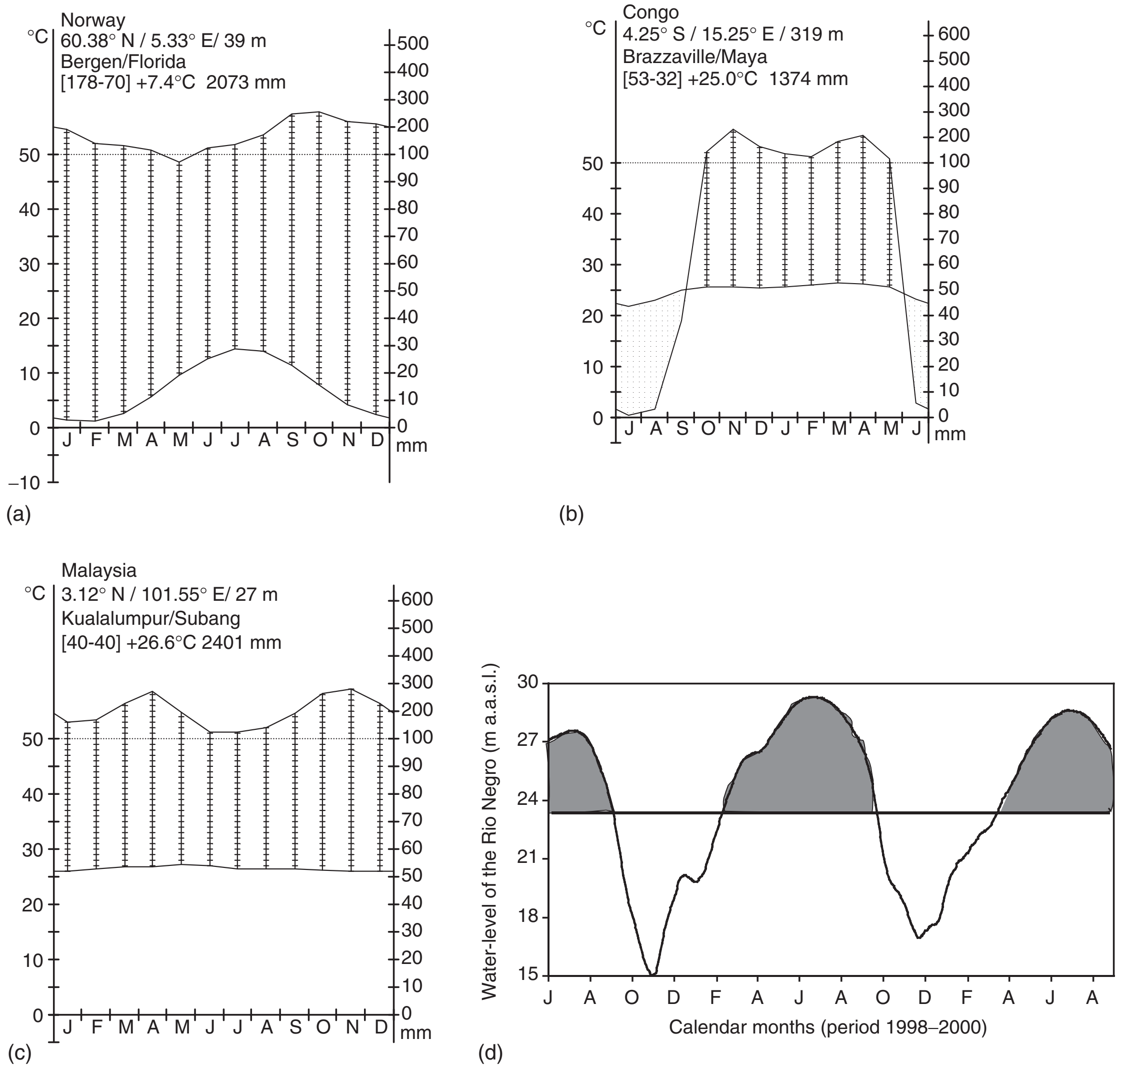

Figure 1 Typical climate diagrams from (a) the temperate zone, the tropics ((b) seasonal and (c) everwet), and (d) the flooding regime of the Amazon river. Seasonality is expressed in high latitudes through temperature variation, in low latitudes through variation in precipitation in the course of the year.

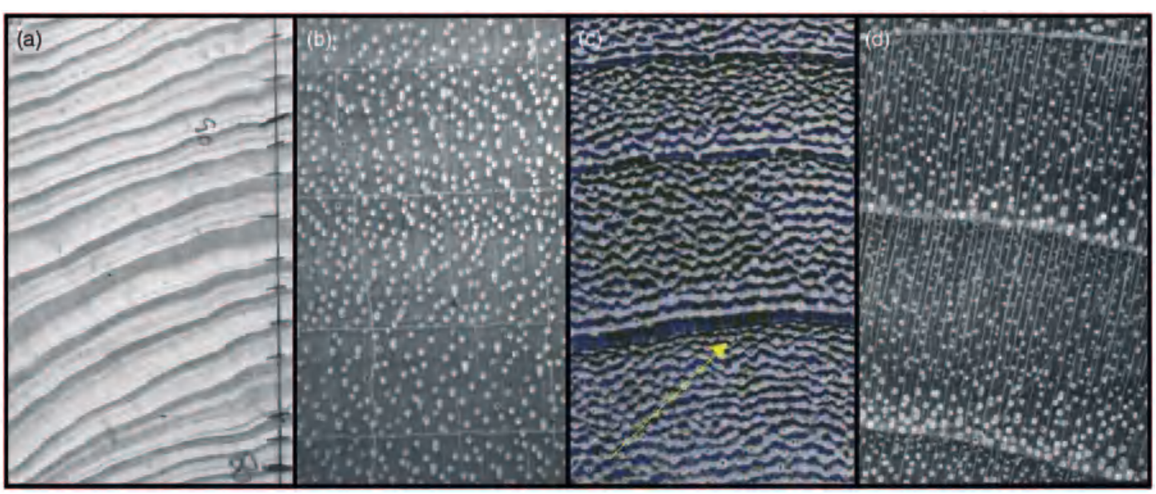

Figure 2 Wood structure of (a) *Pinus caribaea* (São Paulo, Type 1), (b) *Tetraberlinia bifoliolata* (Cameroon, Type 2), (c) *Piranhea trifoliata* (Brazil, Type 3), and (d) *Tectona grandis* (historical wood sample from India, Type 4).

Bignoniaceae, in *Ulmus* spp., *Fraxinus* spp., and many others. Rings are characterized by periodical patterns of parenchyma and fiber tissue. The bands usually become narrower towards the end of a growth zone.

Type 4

This type has vessel distribution in the growth zone. Ring porousness is widely distributed in the temperate zones (e.g., *Quercus*) but occurs in only a few examples in the tropics (e.g., *Tectona grandis*, and some Meliaceae).

Basic Principles of Dendrochronology

One of the most important dendrochronological techniques is the comparison of tree-ring time series of different trees. This is based on ecological principles.

Variation of Tree-Ring Features from Year to Year Based on the Influence of Growth Factors, Mainly on Climate Variations

This is a specification of the ecological rule of limiting factors, especially temperature, radiation, and precipitation which vary from one year to the other. This variation is the reason for the existence of unique tree-ring patterns and makes possible the identification of certain growth time periods. Site conditions influence the intensity of reaction to these factors. Sensitive species usually show great variations in ring width from one year to the other while complacent trees react little.

Since the Climate Influences All Trees on a Given Stand Equally, Tree-Ring Patterns Are Similar between Individuals of a Stand

The degree of similarity depends on the distance between growing sites, the climatic variability in a region and the ecological range of a tree species. As an example oak tree-ring chronologies from sites in the flat plains of northern Central Europe have a high degree of similarity and are even comparable with chronologies from Ireland, both being influenced by an oceanic climate type. Chronologies from spruce (*Picea* spp.), however, may differ over a short distance when the trees grow at different elevations.

Every Ring Can Be Dated to a Certain Growing Period or to a Calendar Year

Tree-ring patterns are the mirror of the growth conditions of a tree. The rings and their features represent an archive of growth conditions during a tree's life.

Methods

Sample Collection and Preparation

One advantage of dendrochronological investigations is the low impact on the living tree when samples are taken with an increment corer. For yield estimations stem disks are chosen from breast height. In dendrochronologically unknown or seldom used species it is helpful to start with the investigation of a cross-section. The structure of the growth zones and the occurrence of matching and wedging rings can be more easily identified on a stem disk than on a small core beam.

The core samples must be glued in wooden supports. Careful preparation of the sample surface is essential for a successful analysis. This can be carried out by polishing the sample with sandpaper of increasing gradation.

Data Measurements

Douglass built chronologies to date the Pueblo Bonito group by estimating and classifying the ring widths in three classes ('skeleton plots'). This method is based on the concept of 'pointer years,' which are substantially smaller or wider than the neighboring rings (**Figure 3**). This system was further developed by Schweingruber and extended to 'abrupt growth changes' (**Figure 4**). In most cases ring widths will be measured by means of a typical measuring device usually with a precision to the nearest 0.01 mm.

Besides ring width several additional features of tree rings were tested in the past for climatological or ecological signals. One of the most important is wood density. A thin sample is irradiated with X-rays, thus developing an image of its density on a film. A densitometer measures the darkness of the film indicating the variations in density (**Figure 5**). The results provide several kinds of information. It is obvious that the latewood of coniferous trees from high elevations and high latitudes carries a strong

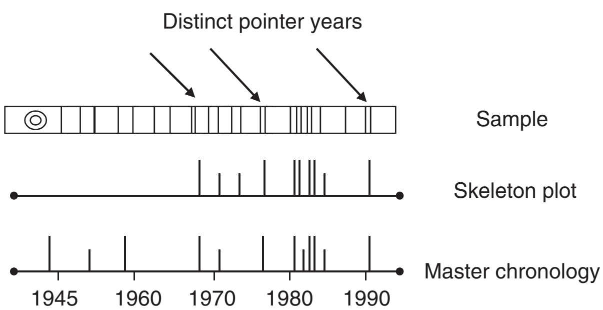

Figure 3 Translation of ring width variation into a skeleton plot and the comparison with a master chronology (below). Small rings are indicated by a bar of different length corresponding to the intensity of growth reduction.

climate signal, i.e., the temperature of the late summer. Recently image analysis has played an increasing role in dendrochronology in the search for additional relevant signals of climate. Time series of tree-ring features such as vessel size and vessel area may help to clarify the relation between tree growth and rainfall patterns (**Figure 6**).

The content of chemical elements and isotopes in tree rings has been tested in different situations. The best results can be expected from elements and isotopes which are bound to the cell wall structure. Some other elements tend to be mobile within the stem. The content of these elements can serve for the detection of environmental stress. Stable isotopes, especially those which are part of the cellulose molecule (D, ^{13}C, ^{18}O) have recently been used to test for climatological signals.

Radioactive isotopes, especially radiocarbon, play an important role in dendrochronology. The analysis of exactly dated oak and bristlecone pine wood samples have served to calibrate the radiocarbon concentration curve for the past 12 000 years. This was necessary since the concentration of CO_2 in the atmosphere has varied considerably in the past and one radiocarbon date could be linked to more than one calendar age (**Figure 7**). The calibration was the precondition for a much higher precision of radiocarbon dating of archaeological samples. Furthermore ^{14}C estimations can be used to test the existence of annual rings in tropical trees. Based on the atomic weapon effect (the ^{14}C content in the atmosphere almost doubled between 1950 and 1964 because of 404 atomic bomb explosions in the atmosphere) single isolated growth zones can be dated by comparing their radiocarbon content with that of the atmosphere (**Figure 8**).

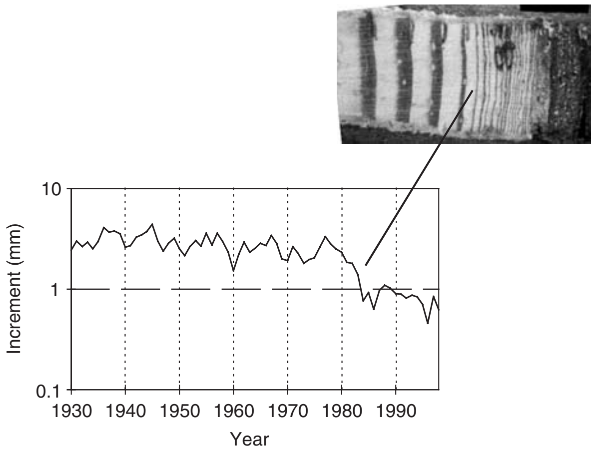

Figure 4 Example of an abrupt growth reduction in Scots pine (*Pinus sylvestris*) and the corresponding ring curve.

Cross-Dating of Ring Curves

The second principle of dendrochronology, the comparison of tree-ring patterns of different individuals, requires tools and limits for matching ring curves. Typical statistical methods are correlation, Student's *t*-test, which combines correlation and length of the compared time series, and the

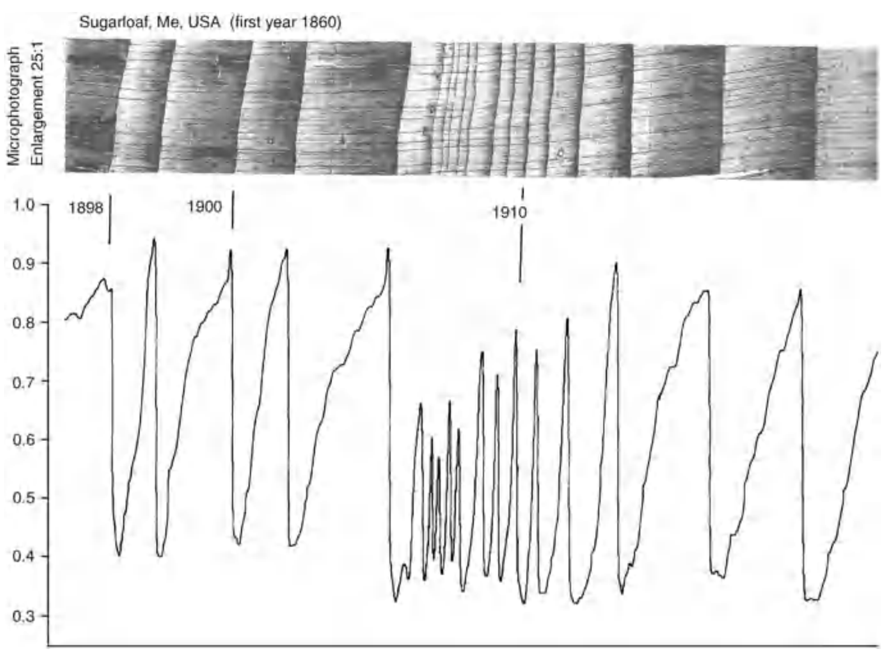

Figure 5 Microsection and corresponding densitogram of pine (*Pinus sylvestris*) derived from X-ray densitometry. Note the variation within one ring and also year by year. 1951 has a considerably lower maximum density than the previous year.

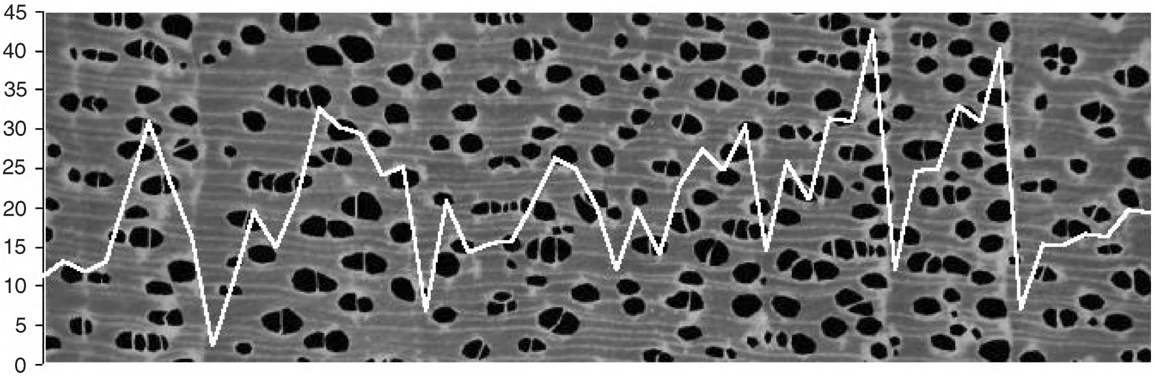

Figure 6 Image analysis of *Terminalia sericea*. In the digitized photograph different features like the vessels can be highlighted, and their dimensions will be measured automatically. The line shows the intra-annual change of vessel area as a percentage of the entire cross-section.

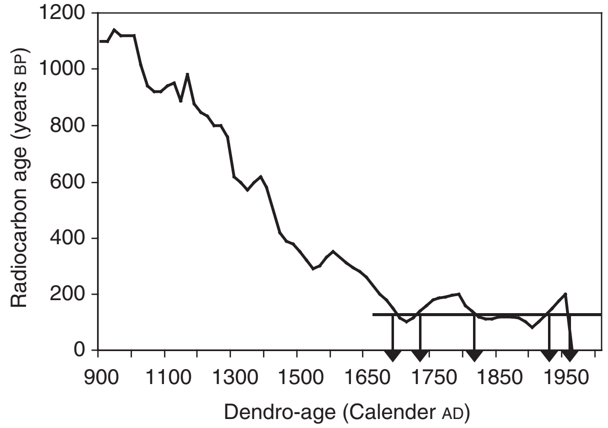

Figure 7 Calibration curve for radiocarbon values to (real) dendro-ages. The curve is derived by analysing tree rings from exactly dated bristlecone pine and European oak. It shows the fluctuation of past ^{14}C content in the atmosphere. The variations between 1650 and 1950 impede the age dating of wood samples from this period, since one radiocarbon age has several possible dendro-ages.

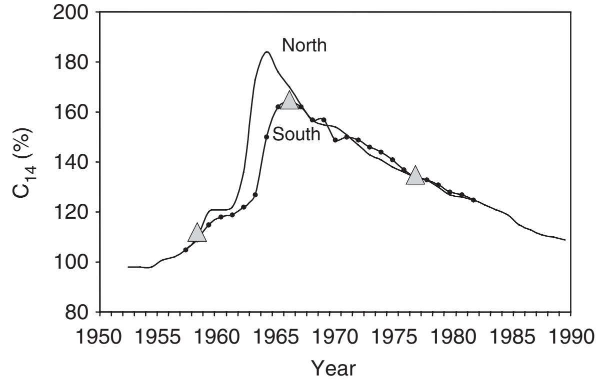

Figure 8 Radiocarbon content of the atmosphere in the northern and the southern hemispheres since 1952. In 1963 the test ban treaty stopped the majority of atmospheric atomic bomb explosions. The ^{14}C content in the atmosphere has declined continuously from that time. The variation makes possible the exact age dating of individual growth zone using two or three samples on different angles of the curve as it is indicated by the triangles.

'Gleichläufigkeit.' The latter means the percentage of parallel trend changes (**Figure 9**). Only those individual curves that match other curves can be included in the chronology.

Data Processing and Transformation

Tree-ring sequences and patterns store various information including the age of the tree, short-term climatic oscillation, and long-term trends. Year by year variation can be traced back to climate variability, but other biotic factors (e.g., pests) or abiotic factors (e.g., air pollution damage by storms, or severe floods) also may cause abrupt growth changes from one year to the next (**Figure 10**). Long-term trends in tree-ring curves can be traced back to long-term environmental changes, mainly processes

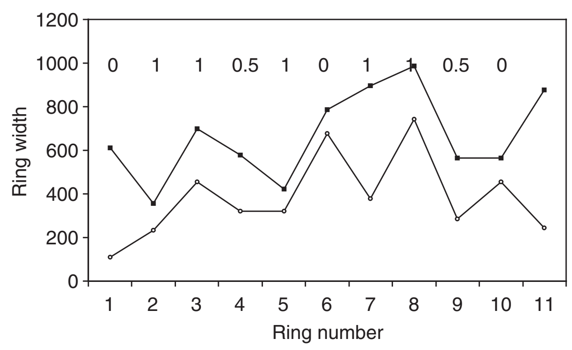

Figure 9 'Gleichläufigkeit' is an important measure for the similarity of tree-ring curves from different trees. It measures the concurring number of trend changes from one year to another. In this example every parallel trend change counts 1. When one curve does not change its direction the value 0.5 is given. The calculated Gleichläufigkeit is 60%.

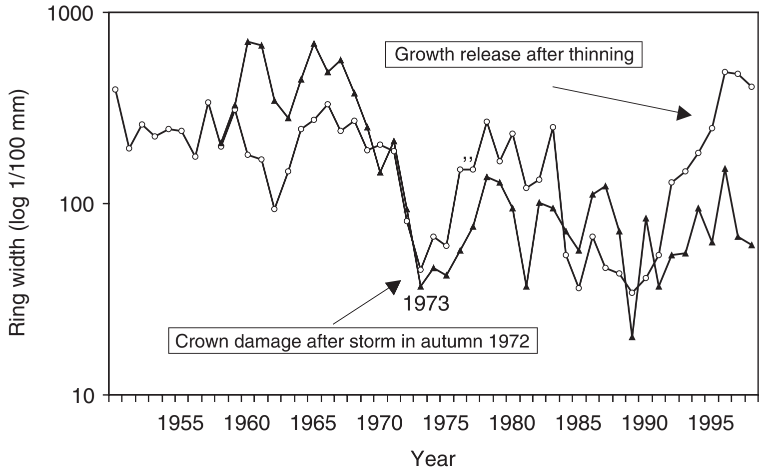

Figure 10 Tree-ring curves of trees exposed to crown damage after a catastrophic storm. One tree released after a couple of years, the other remained on a very low increment level. Note that the scale on the *y*-axis is logarithmic. This presentation points to the minima of a curve and helps to identify 'pointer years.'

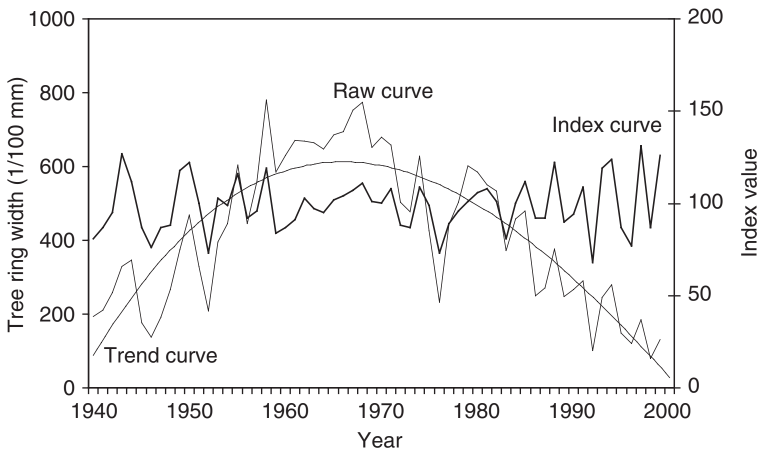

Figure 11 Detrending of an original raw ring curve. For the raw curve a trend is calculated, so that different smoothing functions are possible. The individual raw data and the related data points of the end curve were divided by each other. The resulting residuals form the detrended index curve.

such as increased competition or sudden loss of competition when gaps are opened through tree fall or human activities.

The influence of climate on tree growth can be shown by statistical analyses of tree-ring time series. After cross-dating the calculated mean curve must be detrended to differentiate between short-term oscillation and long-term trend. This procedure is called indexing and starts with the calculation of a trend curve. Various algorithms may be used such as Hugershof or moving average (**Figure 11**). The detrended curve consists of the residuals of raw curve values divided by the values of the trend curve. The residuals vary around a mean and show a normal distribution, a precondition for the calculation of a correlation with climate data.

Applications

Old Trees and Long Chronologies

The maximum age of a tree species is genetically fixed to a certain degree. The oldest living being is a bristlecone pine (*Pinus longaeva*) in the White Mountains in Arizona, USA at 4767 years. *Pinus longaeva* and *P. aristata* grow very slowly due to poor site conditions at the timberline at 3400 m with precipitation of about 100 mm per year. *Fitzroya cupressoides* (3600 years) and *Sequoia sempervirens* (2200 years) reach their ages at lower elevations and higher precipitation. All these species with a longevity over 1000 years are gymnosperms. Angiosperm trees are always much younger. The oldest dendrochronological confirmed ages are known from

Quercus spp. in North America and northern Europe (600–700 years) and for *Weinmannia trichosperma*, an emergent broadleaf tree from Chile (about 730 years). For tropical trees only a few dendrochronological confirmed ages have been published. The oldest trees are *Hymenolobium mesoamericanum* in a Costa Rican forest and *Piranhea trifoliata* from the Amazonian floodplain forests, with ages of between 550 and 600 years, respectively.

A driving force of dendrochronological progress is the construction of ever longer chronologies. Their construction starts with coring living trees to construct a first master chronology. This will be extended to the past by additional samples from already felled and old timber. This is possible when the innermost part of the recent sample shows overlapping parts with the outermost part of old samples. Both parts can be cross-dated and linked (**Figure 12**). In some cases beams of a location can not be dated immediately. Then a floating chronology will be build and dated preliminary by means of radiocarbon analysis. Later the floating and the master chronology might be connected with a 'missing link.'

The longest times series, consisting of thousands of individual samples is the 11 800 years long chronology of oak from southern Germany. A longer chronology is under construction for *Pinus sylvestris* stems, which have been found in alluvial sediments in the southern French Alps. Additional chronologies from other parts of the world are listed in **Table 1**.

Dating of Buildings, Works of Art, and Archaeological Samples

The existence of described chronologies has made possible substantial progress in many historical scientific applications, such as archaeology and the history of art and of buildings.

Many paintings in the late sixteenth and the seventeenth century were made on oak panels; these can be dated and differentiated from later copies. Expensive violins, e.g., from Stradivari, have also been tested for their originality. In some cases the wood of violins labeled from the beginning of the eighteenth century has proved to have been cut in the late nineteenth century, about 100 years after Stradivari's death (**Figure 13**).

Table 1 Chronologies with long timespans and their origin

Species	*Timespan (years BP)*	*Location*
Quercus spp. (oak)	11 800	Southern Germany
Pinus longaeva (bristlecone pine)	8 400	Arizona, USA
Pinus sylvestris (Scots pine)	7 500	Finnish Lapland
Picea, Larix spp. (spruce, larch)	6 000	Alps
Lagarostrobos franklinii (Huon pine)	4 000	Tasmania, Australia
Larix sibirica (Siberian larch)	4 000	Western Siberia
Fitzroya cupressoides (alerce)	3 600	Southern Chile
Tectona grandis (teak)	415	Java

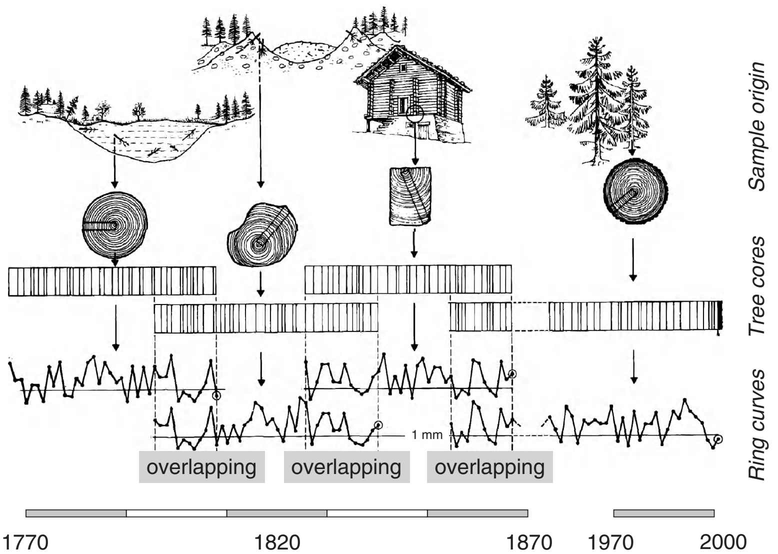

Figure 12 Scheme of the construction of a tree-ring chronology starting with samples from a living tree (right-hand side) and then including stepwise construction wood and subfossil samples. The diagram shows the ring-width patterns of the samples, their transformation into curves, and the overlapping sequences which match the individual curves together.

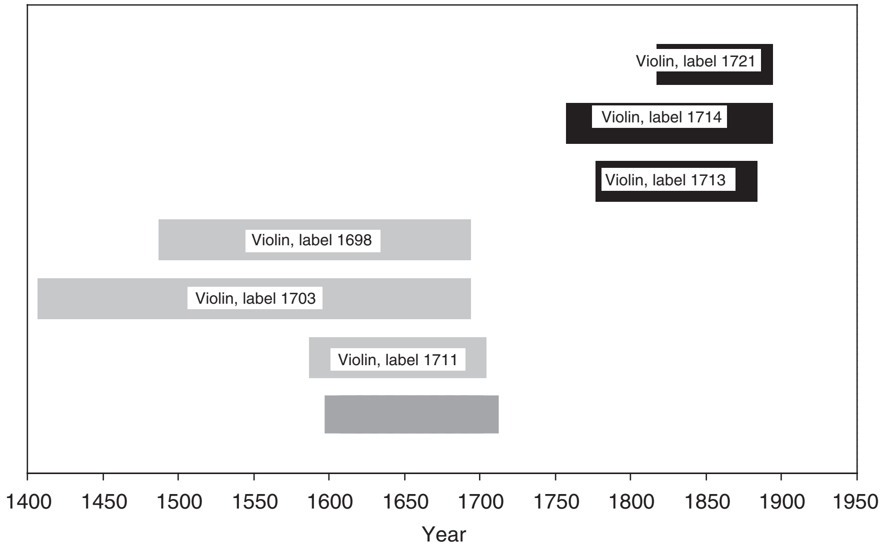

Figure 13 Tree-ring sequences of dendrochronologically dated violins which mostly were labeled as 'Stradivari.' The left-hand group probably were built by the famous master, while the wood of the right-hand group was still growing in the forest after his death.

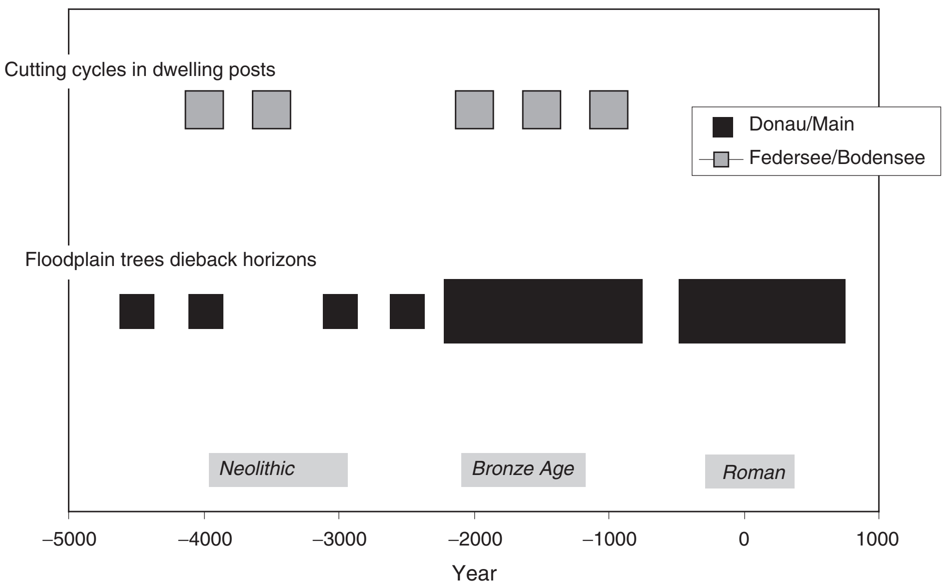

Figure 14 Dieback horizons of oak in southern German floodplain sediments and felling intensity around Bronze Age and Early Iron Age villages. Increasing clearing of the landscape and agricultural use led to an increase in erosion followed by sedimentation in river valleys. The intense dynamic probably led to the dieback of oaks in the floodplain forest.

Dendrochronology also contributed extensively to the knowledge of prehistory of human settlements. In southern Germany, the British Islands, and Switzerland, detailed information on prehistory since the Neolithic and the Bronze Age is known from excavation of dendrochronologically datable wood. During the building phases the surrounding areas of the villages were deforested for agricultural purposes, construction, and fuelwood. Since the early farmers settled on the best and deepest soils, erosion started and rivers changed their courses due to increasing sedimentation. This is visible in the ages at death of oaks excavated from alluvial soils in the floodplains. Several 'dieback horizons' are visible. The last and most distinct appeared during the Roman empire in southern Germany (**Figure 14**).

Climate Reconstruction

One of the most important applications of tree-ring analysis is the reconstruction of past climate. Most reliable climate records start in the second half of the nineteenth century. This is not long enough to judge whether the present global warming has natural correspondences in previous centuries.

As a first step it is necessary to understand the relation between climate and growth in different species. The main problem is that the two variables, temperature and precipitation, act in a complicated and often contradictory way: in the temperate zone high precipitation is related to a relatively cold summer and high temperature to a dry summer. One attempt at solving this problem is the use of samples from sites where one of the two factors is limiting such as temperature in high altitudes. In the tropics, however, the temperature is constant and only rainfall varies.

Analysis of pointer years or discontinuous time series Strong stress-related events like abnormal frosts in spring, exceptionally dry summers, prolonged flooding, insect attacks, and others are usually visible in tree-ring patterns as a 'pointer year.' One example can be traced back to the eruption of the volcano Katmai in Alaska, which occurred on 6 June 1912. The dust particles in the stratosphere then reduced solar radiation. The following August and September in some regions of the northern hemisphere were the coldest in 120 years of temperature records. Coniferous trees at higher altitudes stopped growth abruptly and could not develop typical latewood. In consequence the latewood density in 1912 is much lower than in the neighboring rings.

Analysis of tree-ring sequences or continuous time series The existence of at least two climate variables influencing tree growth requires multiple correlation analyses; the most common is the response function. **Figure 15** gives an example of the regression between ring width and climate at higher elevations. Precipitation and temperature are differentiated monthly back to June of the previous year. This is based on the assumption that climate conditions of the preceding year influence storage of carbohydrates and thereby affect the increment of the current year. Values of the previous year shift between positive and negative influence from one month to another. The results for temperature of the current year follow a clear and interpretable trend with strong positive correlation in June and July.

Reconstruction of climate The relation between late summer temperature and density of latewood allows the reconstruction of pre-instrumental climate history. Time series of density and/or ring width can be used as climate 'proxies' and show events such as the 'Little Ice Age' at the beginning of the seventeenth century and the 'Medieval Warm Period' in the northern hemisphere. One of the longest and probably most reliable climate-sensitive chronologies gives hints of an unusually cool period in the ninth century. This may be one cause of climatic catastrophes in that period and the stepwise extinction of the Maya culture in Central America (**Figure 16**).

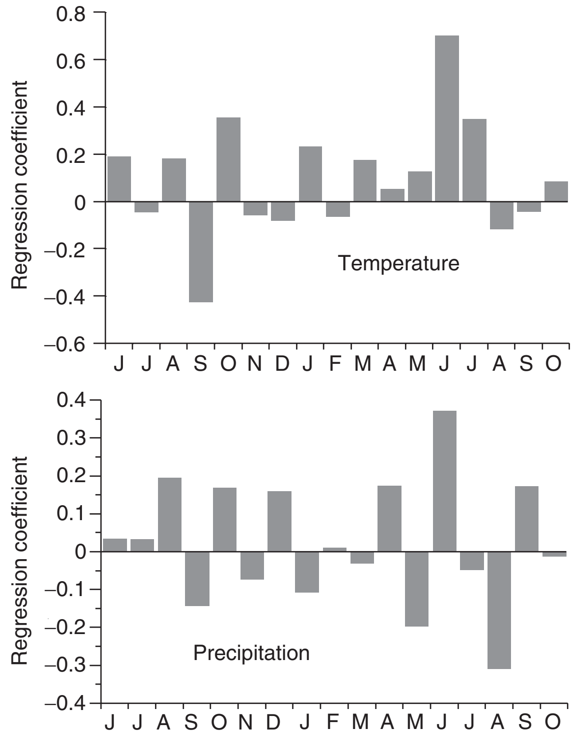

Figure 15 Multivariate analysis of the relation between tree-ring width of high-altitude (about 700 m) spruce trees (*Picea* spp.) and the climate variables precipitation and temperature. Each variable is split into monthly subvariables from June of the previous year (before formation of the tree ring) to October of the current year.

Tree-ring series in the tropics reflect variation in precipitation. One important periodical climate event in the tropical Pacific region is the Southern Oscillation-El Niño Effect. The occurrence of this weather effect was described in 1931 by analyzing a teak tree-ring chronology from Java (**Figure 17**). A recent investigation of tree rings from a floodplain tree species shows the influence of El Niño on precipitation anomalies in the Amazon basin. It seems that its strength increased and its period decreased slightly from the nineteenth to the twentieth century.

Landscape Ecology and Geomorphology

One of the simplest features of a tree-ring sequence, the age of the tree, is most valuable for the detection and interpretation of the movement of glaciers and

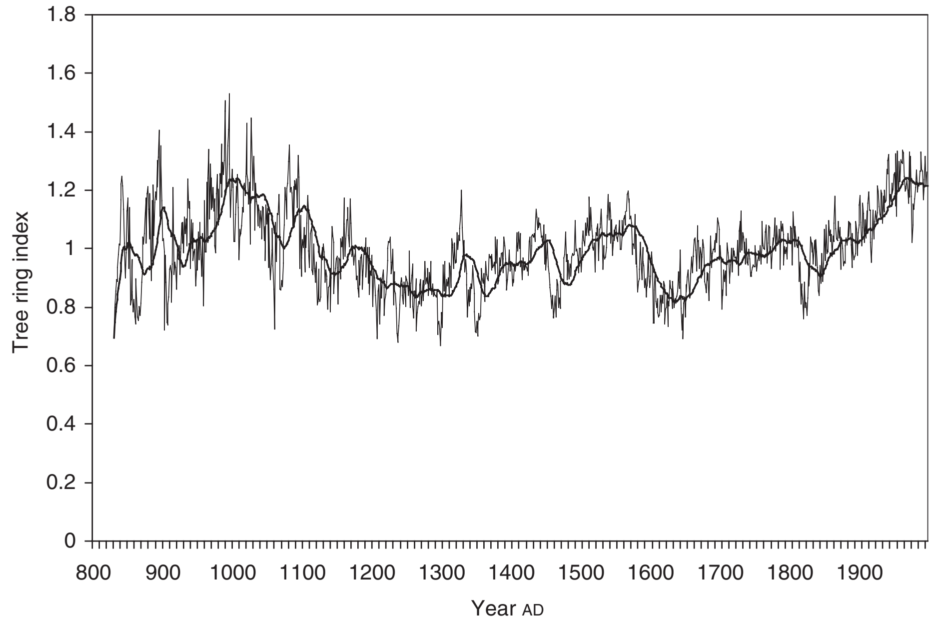

Figure 16 Temperature-sensitive chronology from the northern hemisphere. The chronology is constructed of 1205 individual tree ring series from different species (genera *Picea*, *Pinus*, *Larix*, and *Abies*). Trees origin from 14 high-elevation or high-latitude sites and from the entire Northern hemisphere. The 'Medieval Warm Period' and the 'Little Ice Age' as well as recent global warming are clearly shown.

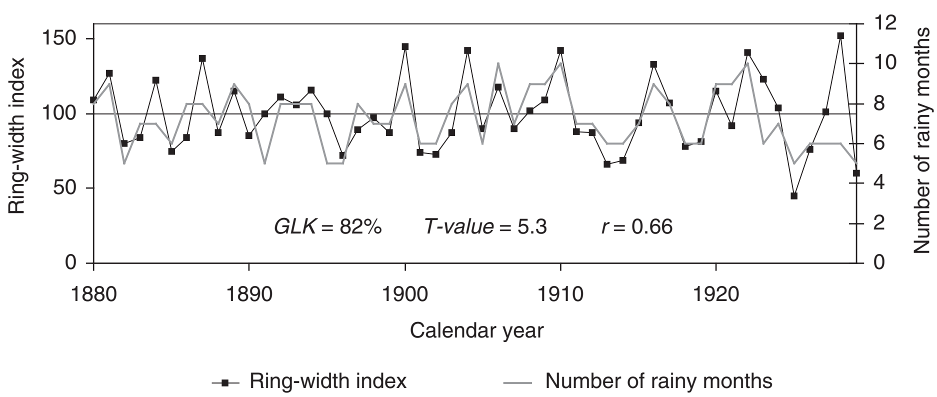

Figure 17 The Java teak (*Tectona grandis*) chronology of Berlage from 1931 shows the concurrence between tree-ring width and precipitation, which is expressed as duration of the monsoon. The tree-ring curve is detrended. The periodical pattern of recurring minima and maxima reflects the influence of the El Niño-Southern Oscillation effect. Berlage was the first to detect the influence of El Niño in tree rings. The graph only shows the latest period of the chronology, which goes back to 1514. GLK, Gleichläufigkeit.

the dynamics of rivers. In the case of glacier dynamics the age of the pioneer trees that follow its retreat can be estimated easily. Information on the course and frequency of avalanches, landslides, mudflows, and stonefalls can also be gained from trees surviving with datable damage to crowns or stems. This information provides estimates of the degree of danger for newly constructed roads and buildings in mountain areas.

Forest Dynamics, Ecology, and Management

Information on forest growth is important for sustainable forest management. Changing environmental influences such as the increasing acid emissions in the twentieth century, fertilization through increasing N deposition, temperature, and damage due to pests and storms require a tool for fast measurement of growth reactions to these factors. In the tropics the current state of knowledge on growth rates and forest dynamics is extremely poor due to the lack of reliable yield tables and the assumed absence of tree rings.

Forest dynamics European forests have been managed intensively for centuries. The network of monitoring and documentation often is dense. However yield tables are based on means and undisturbed situations. Changes of site and environmental conditions are usually not considered. Thinning and

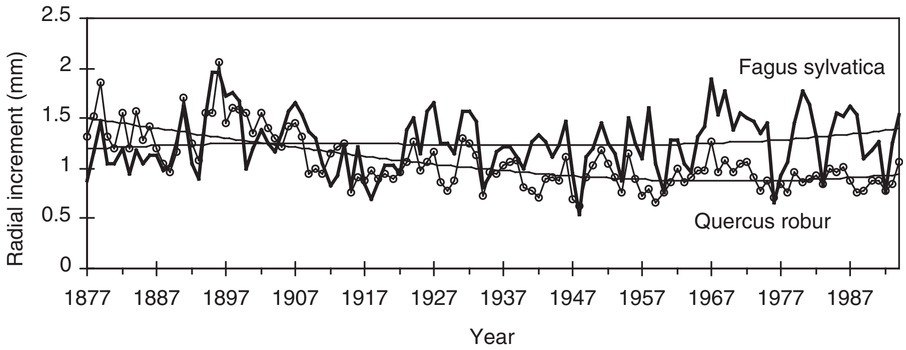

Figure 18 Ring-width curves: raw data and long-term trends of oak (*Quercus robur*) and beech (*Fagus sylvatica*) trees growing at dry sites on steep slopes and shallow soils. Beech outcompetes oak from the beginning of the 1930s. Presently their crowns are at least 3–5 m higher than oak.

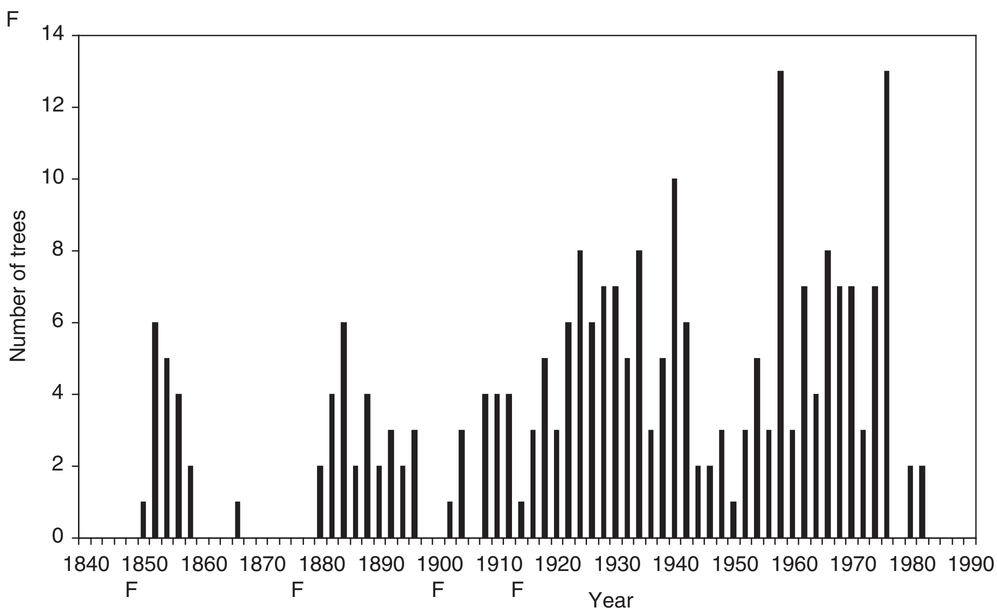

Figure 19 Age structure for *Pinus banksiana* from a boreal site in Canada affected by forest fires. The fire years are identified by age dating of fire scars and abrupt changes in radial increment.

spacing have the effect of increasing the growth of the remaining individuals, whereas growth reductions take place after storms, when trees are partially damaged but survive, and when pests like budworms effect a recurring pattern of pointer years. Competition between species can be described by interpreting long-term trend curves. The example in **Figure 18** explains the predominant growth of beech (*Fagus sylvatica*) in comparison with neighboring oaks, even on the driest sites, where recent ecological knowledge had postulated the opposite.

In certain ecosystems frequent catastrophic events trigger the regeneration of the forest. This is the case after hurricanes, after erosion and sedimentation in floodplains, and after intensive forest fires. These are necessary for regeneration in some temperate and boreal coniferous forest ecosystems. Fire scars in the wood help to identify the fire frequency (**Figure 19**).

Tree decline In the late 1970s in Europe and North America the sudden devastation of entire forest stands, mainly of coniferous tree species, forced an intensive search for its causes and for the basis of prediction of future development. It soon became clear that the deposition of acid rain on unbuffered soils was one of the major causes. In this context tree-ring analysis was the best tool for the comparison of growth trends before and after the intense influence of acid rain. Tree rings show clearly the decrease of increments in heavily polluted areas.

The percentage of trees with increment losses declined with decreasing altitude, and on calcareous

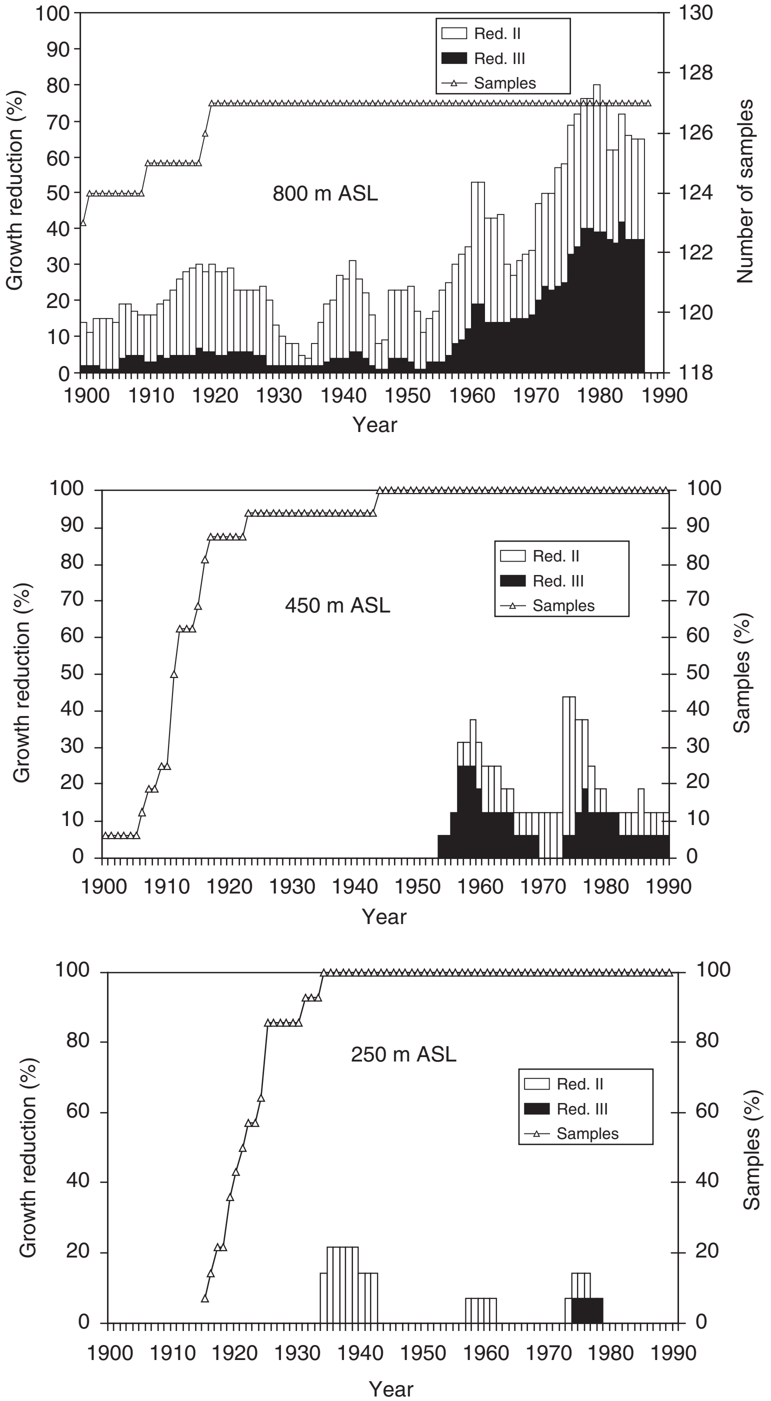

Figure 20 Number of spruce trees (*Picea* spp.) with growth reduction in relation to total sample from different elevations in Northern Germany. Trees from high elevations (ASL, above sea level) show partially letal growth decline since the beginning of the 1960s. Sites were mainly orientated on western slopes of the mountains, where emissions from the Rhine/Ruhr industries are transported on the prevailing wind.

soils in the lowlands the problem was clearly not existent (**Figure 20**). The main agent of damage was sulfur dioxide. Based on tree-ring studies Switzerland enacted new laws aimed at reducing emissions of sulfur dioxide. The reduction was followed by a slight increase of tree growth.

Sustainable forest management in the tropics Many tropical forests are managed intensively, but one way to avoid overexploitation is to support sustainable management systems. Many key factors for timber certification have been developed, but it is still unclear how fast trees grow. However, the existence

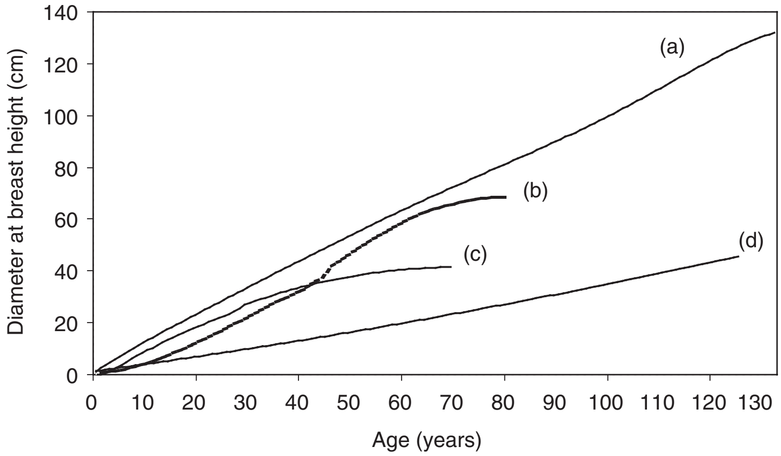

Figure 21 Mean cumulative diameter increments of the softwood species (a) *Triplochiton scleroxylon* from Cameroon and (b) *Macolobium acaciifolium* from the Amazonian floodplains. The growth of the hardwood species *Tabebuia barbata* varies according to origin: (c) from a natural secondary forest and (d) a mature forest, indicated by distinct differences in the shape of the long-term trends. Each curve is a mean curve of 5–20 individuals.

of distinctive annual rings, e.g., in the main West African timber species, has been known for more than 30 years. One of the faster-growing species there is *Triplochiton scleroxylon*, which needs 70 years to reach the minimum logging diameter. In Amazonian floodplain forests, trees of different wood densities and growing environment need different time to reach the cutting diameter (**Figure 21**). A species-specific management system would help to establish more economical use than the recent system with identical measures for all species.

Conclusions and Outlook

'For 70 years dendrochronology was a purely academic science; today certain aspects have become accepted in the sphere of applied sciences.' This statement of Fritz Schweingruber from 1986 is even truer today. Progress can be traced back to the personal dedication of some promoters of tree-ring science, writing textbooks, organizing conferences, teaching students, and running internet sites. However, the main cause of dendrochronological success is the scientific work on modern themes leading to accepted studies in most of the abovementioned fields of research.

Energy from Wood

J I Zerbe, USDA Forest Products Laboratory, Madison, WI, USA

Introduction

In most developing countries wood and charcoal are the predominant fuels for preparation of food to maintain the quality of life that encompasses the majority of citizens. In many developing countries wood fuels are also important for small and medium-size industries.

Moreover, energy from wood continues to be important in industrial countries. In the USA biomass including waste wood and alcohol from corn provided about 3.3% of total energy consumption in 2000. This was more than was provided by conventional hydroelectric power and more than other forms of renewable energy. Wood energy is consumed in a variety of forms that include fireplace lengths, chunkwood, chips, sawdust and shavings, black liquor from pulp manufacture, pellets, fireplace logs, briquettes, charcoal, gasified wood fuel, and liquefied wood fuel. Wood provides warmth and comfort to homes through burning in fireplaces and automated heating systems. And even in industrial countries wood is used for cooking where it is burned in specially designed stoves for convenience or on grilles to bring out special flavors.

Wood fuel is important to commercial wood manufacturing facilities where waste wood can be disposed and used profitably for energy at the same time. In areas where wood from logging and manufacturing is abundant, other industries such as brickmaking and cement manufacture also benefit from sales of wood fuel. In some South American countries wood charcoal provides the fuel for smelters in manufacturing steel.

Some major considerations in using wood for fuel are environmental impact, economics, convenience, reliability, and simplicity. On balance, wood is an environmentally benign fuel. It tends to be more economic than some other fuels, but may be less convenient.

How Wood Is Used for Energy

Solid Wood

Fireplace lengths The most common way of using wood for fuel is to burn pieces about 40–50 cm long that are split from logs. We burn much of such wood in our fireplaces today, and, formerly, such firewood provided the main fuel source for home heating, domestic hot water, and food preparation. Wood is still used for heating some homes in industrial countries. Usually heat is not produced efficiently in fireplaces, but some fireplaces are designed to use blowers to be more effective. Stoves and furnaces burn firewood more efficiently. However, for many applications, wood is converted to other forms of fuel that are more convenient, waste less energy, and are less prone to emit undesirable particulates and other pollutants to the air.

Chunkwood A few manufacturers make machines that can produce fairly uniform particles about the size of an average fist. Such fuel is called chunkwood. Chunkwood can be readily dried since there are openings for air to circulate when it is piled for storage. Drying green wood to lower moisture contents makes it easier to burn with less smoldering and smoking and gives the wood a higher heating value. Transfer of creosote residues to chimneys is of lesser impact. Chunkwood is rarely used now, but it will probably become more popular in the future.

Chips and sawdust Chips and sawdust are more common types of particulate wood fuel. There are some special combustors that can burn green (unseasoned) sawdust, but it is usually necessary that chips and sawdust be fairly dry. Chips are dried in special dryers that may use wood or fossil fuels to generate heat. Sometimes dry sawdust and chips are available at secondary wood manufacturing plants such as furniture plants. Dry sawdust can be a very desirable fuel for use in special combustors that burn particles in suspension. In such cases grates are not necessary. Chips are advantageous for handling and storing. They can be used effectively in automated stoker applications.

Shavings Shavings are produced when lumber is planed or molded or spun off from logs that are peeled. Since shavings are usually produced in the processing of dry lumber they make good fuel. Green shavings from applications such as rounding logs for log home construction may be further processed by chipping and drying.

Pellets

Wood pellets are becoming increasingly popular. They are made by compression milling small wood particles such as sawdust. When pellets are made from clean wood with little bark, the ash content is low. Pellets are sold at retail outlets in 18 kg (40 pound) sacks. They handle and store easily. They should be kept dry to prevent disintegration, and to avoid risk of mold and decay. Sometimes pellets for cooking are made from woods with special flavors that can be used in barbecuing, directly or with charcoal or gas, for conveying this flavoring to meat or poultry.

However, the most common use of pellet fuel is for heating with modern and convenient pellet stoves. Some of these stoves burn pellets with 85% efficiency and have automatic ignition, feed, and control systems.

Manufactured Fireplace Logs and Briquettes

Manufactured fireplace logs (firelogs) are made from waste wood to provide open-hearth warmth and ambience with clean fuel. Wood briquettes are similar products of smaller length that are used as barbecue fuel or industrial stoker fuel.

There are two types of firelogs or fuel logs; one type is made with the addition of around 50% wax. The other type is all wood. In the USA wax-type logs are more popular, but the all-wood type is more popular throughout the rest of the world. Wax-type logs burn with fewer gaseous emissions to the air, but they do emit carbon compounds from nonrenewable fuel that lead to an increased greenhouse effect. All-wood logs do not emit nonrecyclable carbon.

All-wood logs are made in machines that apply pressure with screws or pistons. The heat developed in the process is sufficient to cause the lignin in the wood to flow and act as a binder for the particulate wood waste. Many machines to make fireplace logs are designed to take advantage of the heat generated by high pressure and do not use supplementary heat. Other machines have extrusion cylinders that are externally heated to temperatures between 180°C and 300°C. Electrical resistance coils provide heating, and after the manufacturing process starts a temperature control setting permits operation at an optimum temperature level. The heating process slightly carbonizes the surfaces of the logs or briquettes and gives them a dark brown color. Heating may also contribute to better particle adhesion and less friction in the extrusion process.

Briquettes are made in the same ways as all-wood logs, but the log lengths from the machines are cut into thin disks. In developing countries brickmaking presses have been adapted for briquetteing. In these cases pressures are lower and inexpensive adhesives are used as binders.

The wax-sawdust firelog manufacturing process is not used for producing briquettes, only for fireplace logs. Wax-sawdust logs are composed of about 40–60% wax with the remaining portion being sawdust. The heat content of wax-sawdust logs is higher than all-wood logs. Compared to wood, which has a high heating value of about 20 MJ kg^{-1} (8500 Btu lb^{-1}), wax-sawdust logs have a heat content of 36.4 MJ kg^{-1} (15 700 Btu lb^{-1}).

Charcoal

In industrialized countries wood charcoal is often used as a cooking fuel, particularly in barbecuing or grilling. But consumption for such use is minor. In developing countries charcoal is much more commonly used as a fuel. This is an advance from use of solid wood fuel for use in domestic or light institutional or industrial (e.g., baking) applications. Charcoal is more easily stored and transported than wood, and it is more durable in the presence of moisture.

In developing countries primitive earth or pit kilns are still used in charcoal manufacture. In industrialized countries, various types of improved kilns are used. They may be of brick, concrete or cinder block, or steel construction. Kilns are designed to char the wood without burning it. This is accomplished, after the charge of wood has been ignited and preliminarily heated, by regulating the amount of air entering the kiln so that only ‘glowing’ and not combustion takes place.

Gaseous Fuel

Charcoal is only one of several different forms of advanced products that may be obtained through pyrolyzing wood in the presence of insufficient oxygen to cause complete combustion. Depending on pyrolysis temperature there may be different proportions of char, tar, liquids, and gases. With high temperatures and proportionately low oxygenation, mostly gas is formed. Wood gasification results in gaseous products composed of mainly hydrogen and carbon monoxide and some hydrocarbons that include methane.

Wood gasifiers are of different types that include updraft, downdraft, side draft, and fluidized bed. Most experience in using wood gasifiers has been with the downdraft type. Downdraft gasifiers produce cleaner gases that have less tar. These gases may be filtered further so that they are clean enough to use as fuel in internal combustion engines without causing severe carbon deposits in the pistons and heads of the engines in short periods of time. The gasifiers and engines are most often used in combination with electrical power generators or transmission drive mechanisms for powering automobiles or other modes of transportation. Such combinations are known as gasogens. Wood gas may also be combusted directly. However, unless it is refined it has much lower heating value than natural gas.

Gasogens were used in many countries to power automotive transportation during World War II, but were abandoned after the war because of higher maintenance costs. Today there are better filters for removing tars from the gases before they enter the internal combustion engines so maintenance costs are less. Today gasogens are becoming increasingly popular for power generation, especially in locations where electrical demand is low and power from the electrical grid distribution network is not readily available.

There are also efforts to use gases generated through pyrolysis of wood with insufficient oxygen for complete combustion in turbine generators, but for use with turbines gases must be even cleaner than for use with internal combustion engines. Combustion gases have also been tried in turbines, but in this case corrosive ash that might get through to the turbine is a greater problem.

Liquid Fuels

Alcohols Previously wood distillation through heating in a retort without introducing oxygen was popular in the USA, and the process is still applied in some countries of the world today. This process can produce methanol for fuel along with other chemicals and charcoal.

However, for producing methanol from wood it is more efficient to use a synthesis process similar to that used for making methanol from natural gas. In the synthesis process wood is first gasified. Then it is compressed for removal of carbon dioxide, nitrogen, and hydrocarbons. This is followed by a shift reaction to obtain a gas with two parts hydrogen and one part carbon monoxide. This gas is subjected to high pressure and conversion to methanol results.

There is much more effort to produce ethyl alcohol or ethanol for fuel. In the process for making ethanol wood is first separated into its main constituents of cellulose (about 50%), hemicellulose (about 25%), and lignin (about 25%). The cellulose is then hydrolyzed to glucose and the glucose is fermented to ethanol. Previously this was the extent of the process. But, more recently, ways have been found to ferment xylose. Now xylose can be liberated from hemicellulose and fermented to ethanol.

Little alcohol fuel is made from wood today, but the promise for the future, with continuous development of cost-lowering technology, appears better.

Black liquor The kraft paper manufacturing process is popular throughout the world. It can produce high-quality paper with less pollution than with the sulfite process. In the kraft process recovery of papermaking chemicals is important. These chemicals are contained in the large amounts of liquid waste known as ‘black liquor’ from the process. Therefore the overall process includes a large recovery boiler that produces much energy in using the black liquor as fuel. In 1992 in the USA 32.5 million tonnes or 26.5% of the energy obtained from wood came from black liquor (**Figure 1**).

Where Wood Is Used for Energy

Home Heating

Throughout industrialized countries wood for home heating is a minor, though increasingly important, application. In developing countries wood is a major source of fuel, but there is little need for domestic heat, because of warm tropical temperatures.

Nonetheless flaming wood is appreciated as a source of warmth and center for socializing. In industrialized countries, also, wood for home heating is often used in fireplaces for the warmth and ambience of the hearth, although fireplaces are relatively inefficient means of producing heat.

But, there are also efficient ways of using wood for home heating. One traditionally effective and efficient example is the masonry stove commonly used in Europe. These unique heaters are sometimes known as Russian stoves, German tiled stoves, Finnish masonry stoves, or Finnish contraflow fireplaces. Such stoves may be constructed in place by masons, but there are also fully fabricated wood-fired masonry heaters that may be purchased for simpler installation.

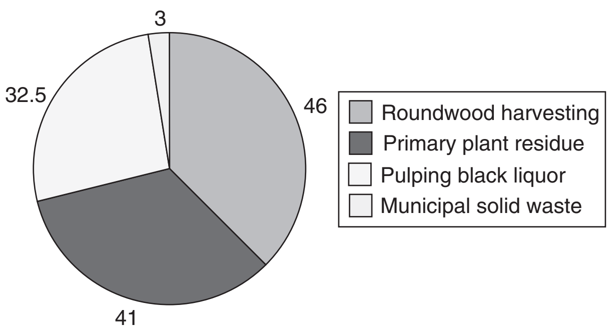

Figure 1 Source of fuels derived from wood in the USA in 1992 (in million tonnes).

Other improved stoves and furnaces for handling wood or wood-derived fuels supplement traditional firewood stoves and furnaces. The more recent technologically advanced stoves and combustors operate with wood chips and pellets.

In the USA wood was an important fuel from the beginning of European settlement. First wood was used mainly for domestic heating, but charcoal fired furnaces for making iron became important during the eighteenth century, and by 1870 when consumption of wood fuel reached a maximum, use in steam engines such as in locomotives and for riverboat propulsion was significant (**Figure 2**).

Industrial Plants

Industrial use of wood fuels today is a typical practice in primary and secondary forest products manufacturing plants. Unseasoned wood and bark fuel is typically used in sawmills and plywood and particleboard manufacturing plants. Pulp and paper mills burn green manufacturing waste, and, sometimes, forest harvesting waste. The black liquor that pulp mills use is a high percentage of total overall wood fuel usage. Furniture plants often have premium dry wood fuels available.

Outside the forest industry, wood fuels are often used in brickmaking, lime kilns, and cement manufacture throughout the world. In countries including Brazil and Argentina wood charcoal is used extensively in the manufacture of steel.

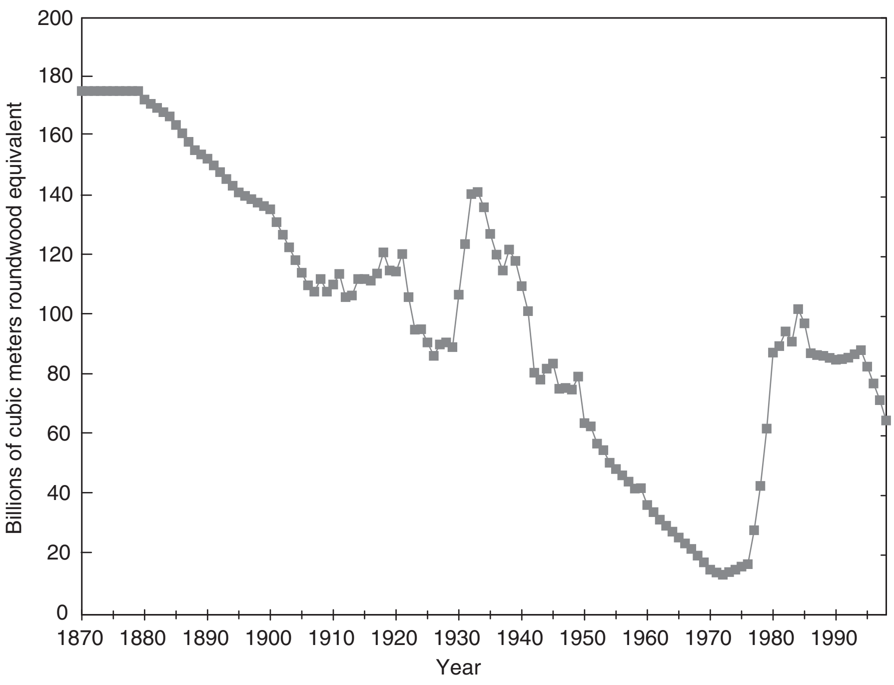

Figure 2 Trend line for wood fuel consumption in the USA from 1870 to 1998.

Institutional Wood Fuel Usage

In the US Midwest and New England and in Canada wood fuel is an important base for providing heat for schools during moderately severe winters. On several campuses district heating is employed. Many other schools have individual heating units in separate buildings. Other wood fuel applications provide heat for hospitals, prisons, government administrative offices, and small businesses. In another application wood is used to provide fuel for both heating and air conditioning in a large Midwest US conference center.

Power Plants

Electricity generation in wood-fueled power plants in the USA became significant with the passage, in 1978, of legislation favorable to small producers who would generate less than 80 MW of electricity. More recently competition for smaller generating plants has become more critical, and some plants have shut down. However, besides the stand-alone generating plants, the majority of the existing capacity is operated in combined heat and power (CHP) facilities in the industrial sector, primarily in pulp and paper mills and paperboard plants. Other countries that have wood-fueled generating plants include Sweden, Finland, and Brazil.

In addition to larger power plants to provide electricity to a distribution grid, there are opportunities to generate electricity at smaller capacities at locations away from grid supply, or at locations where electricity from the grid is very high cost. Often such locations are dependent on diesel engine generators for electricity. Wood gas fueled generators may be competitive in these cases. Examples are a coconut plantation in the Philippines and an Indian reservation in the USA.

Importance of Wood Fuel in Developing Countries

Energy use in developing countries is much more dependent on wood than in industrial countries. As a typical example in 1992 nearly 70% of the final energy consumption in the Southern African Development community countries was derived from wood biomass. In the household sector, wood fuel accounted for 97% of the energy consumed. This consumes significant amounts of wood from developing country forests, but use of wood in more refined form, mainly charcoal, causes an even greater demand.

In many cities in developing countries charcoal is the major cooking fuel. For example, in Abidjan, Côte d'Ivoire, to satisfy the household supply of charcoal the annual demand is about 300 000 tonnes, produced from 5 million tonnes of wood.

Besides household use the demand of wood fuel and charcoal for industry use is also great. Fuelwood is the dominant source of energy for many rural industries in Malaysia. In 2000 almost 85% of the energy source for numerous medium-scale industries such as smoking of rubbersheets, curing of tobacco leaves, firing of bricks, and the drying of foodstuffs came from fuelwood.

Figures 3 and **4** show charts of the sharp difference between the developing world and the industrialized world in relative use of wood for fuel and for roundwood. In the developing world the relative use of wood for fuel is much higher.

Vehicles

Since automotive vehicles consume such a large portion of the world petroleum resources, they present a market opportunity for wood-derived fuels. Today small quantities of ethanol derived from wood are used, but the potential for greater future use of wood converted to liquid fuel is good.

Co-Firing Wood with Other Fuels

Coal

Wood fuel is fired together with coal in some power plants where the primary coal fuel has high sulfur content. Wood is low in sulfur so that the mixture of coal and wood facilitates meeting sulfur emission requirements.

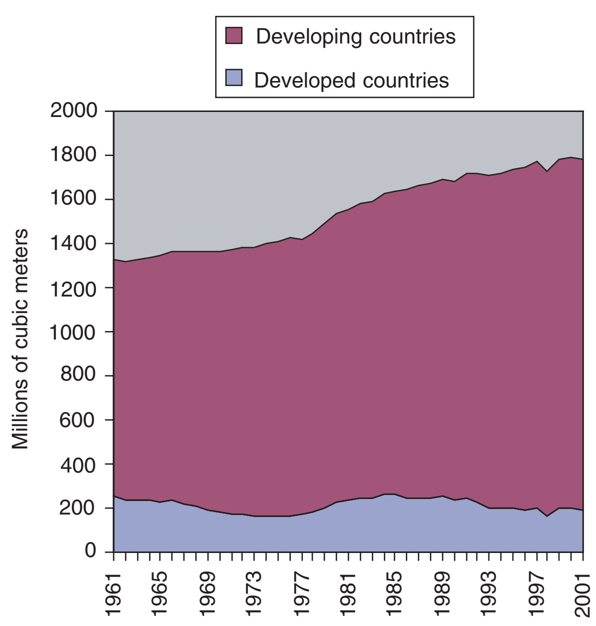

Figure 3 Annual fuelwood consumption in millions of cubic meters for developing and developed countries. Estimated data from Food and Agriculture Organization.

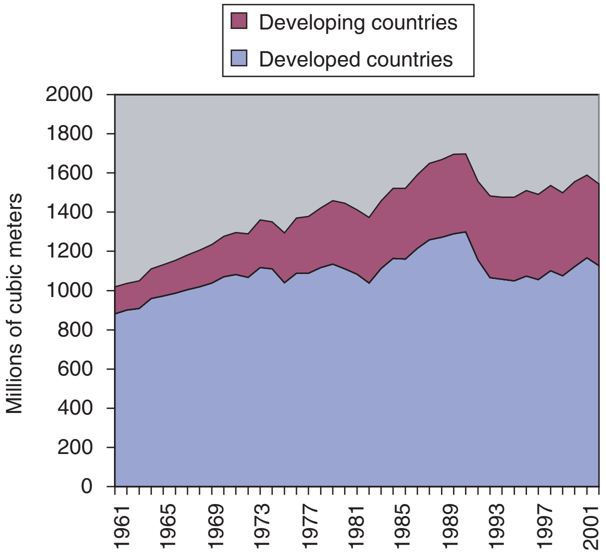

Figure 4 Annual roundwood production in millions of cubic meters for developing and developed countries. Data from Food and Agriculture Organization.

Gas

Gas is co-fired with wood to overcome difficulties when wood is at a higher moisture content than that at which it can readily be combusted. With co-firing gas it is fired through one or more burners mounted above wood fuel feeders. The gas burners can also be fired to maintain up to 100% of the heat delivery load for start-up and as a back-up during fuel supply shortages.

Wood Energy and the Environment

Carbon Dioxide

The increasing accumulation of carbon dioxide and other greenhouse gases in the atmosphere is generally considered to be a threat to future stability of the earth's climate, and, though there are disagreements, climate change could be unsettling to our modus operandi and quality of life. There can be no doubt that our vast use of fossil fuels is the major contributor to increased atmospheric carbon. The renewability of wood and other biomass fuels makes them a desirable alternative to fossil fuels to prevent or retard increasing retention of carbon dioxide emissions. In wood fuels when new trees are grown to replace the wood that was the source of the fuel, carbon is constantly used and regenerated in the growth cycle. The carbon that is emitted to the atmosphere is absorbed by photosynthesis in new growth.

Sulfur

Sulfur emissions to the atmosphere are undesirable because they can precipitate and cause harmful acidic conditions in soil and water. Wood contains little sulfur, but some coal and some oil contain substantially more. Therefore sulfur emissions from wood are more easily controlled than those from their fossil fuel counterparts.

Oxides of Nitrogen

Oxides of nitrogen emissions tend to be lower with wood fuel than with fossil fuels. On the other hand, a major source of nitrous oxide, a greenhouse gas, in the atmosphere is forest fires. Higher oxides of nitrogen emissions usually accompany combustions at higher temperatures. New technology stoves designed to be more efficient have higher oxides of nitrogen emissions than conventional stoves.

Particulates

Emission of particulates is the most common cause for concern in meeting environmental requirements with the burning of wood fuel. In the USA in some municipalities and under some atmospheric conditions, particularly air inversions, there are periods when wood burning in fireplaces and stoves is not permitted. Catalytic stoves can help in attaining lower emission rates.

Chemicals from Wood

T Elder, USDA – Forest Service, Pineville, LA, USA

Introduction

A wide array of both commodity and specialty chemicals can be derived from wood, either as a primary product or by-product of another process. The technologies in which chemicals are the primary products include thermal degradation, hydrolysis/fermentation, direct collection, and extraction methods. Chemicals collected as by-products generally come from fiber-producing processes, including pulp and paper and steam explosion. While cellulose, lignin, and derivatives thereof could be classified as chemicals derived from wood, the current review will be limited to low-molecular-weight chemicals from wood. The synthesis and utilization of various chemicals from renewable resources have received considerable recent attention through research efforts in green chemistry.

Extractives

Perhaps the oldest of the chemicals produced from wood are those derived from the extractives. The term 'naval stores' provides a clue to the waterproofing applications for which these chemicals were originally used. The extractives can broadly be divided into terpenes, resin acids, and fatty acids.

Terpenes

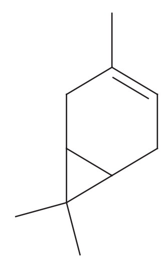
Terpenes are relatively volatile hydrocarbons based on isoprene (2-methyl-butadiene) units, and are the major components of turpentine. Turpentine was once produced largely by tapping trees and collecting the exudates, which after processing are called 'wood naval stores.' Currently, most turpentine comes from the sulfate pulping process, in which the volatile materials are removed by the action of heat and pressure in the digestion step. The volatiles consist mainly of the monoterpenes, α-pinene, β-pinene, and Δ^3-carene, depending on the wood species (**Figure 1**). While turpentine was once used extensively as an industrial solvent, the monoterpenes are now modified into much more valuable products, used in perfumery, flavorings, and to some extent insecticides and disinfectants. Although most terpenes are now produced as a by-product of the pulping industry, the exception to this generalization is natural rubber production. Natural rubber (*cis*-1,4-polyisoprene) comes from *Hevea brasiliensis*, and is still collected by tapping living trees and collecting the latex sap.

Resin Acids

The resin acids, the main components of rosin, are diterpenoids such as abietic acid, neoabietic acid, palustric acid, pimaric acid, and isopimaric acid (**Figure 2**). Rosins can be isolated from directly collected oleoresins, but are now more commonly separated from tall oil as a by-product of the kraft, black liquor recovery process. Metallic salts and esters of resin acids are used as additives to printing inks to improve gloss, mechanical stability and resistance to chemicals. Rosins are also extensively used in paper sizing and in rubber manufacture as emulsifiers and tackifiers.

Fatty Acids

In addition to the resin acids, tall oil also contains fatty acids. Given the acidic character of both of these components and the very high pH in kraft black liquor, during the recovery process, the acids are converted to insoluble salts, referred to as soaps, that are skimmed from the concentrated black liquor. The skimmings are acidified to release the acids resulting in crude tall oil (CTO). Resin acids, fatty acids, and any unsaponifiable neutral compounds are separated by vacuum distillation. Among the fatty acids are oleic and linoleic acid. The fatty acids find applications in ore separation, metal working, rubber, as detergents, and as drying agents in finishes.



α-pinene β-pinene Δ^3-carene

Figure 1 Monoterpenes.

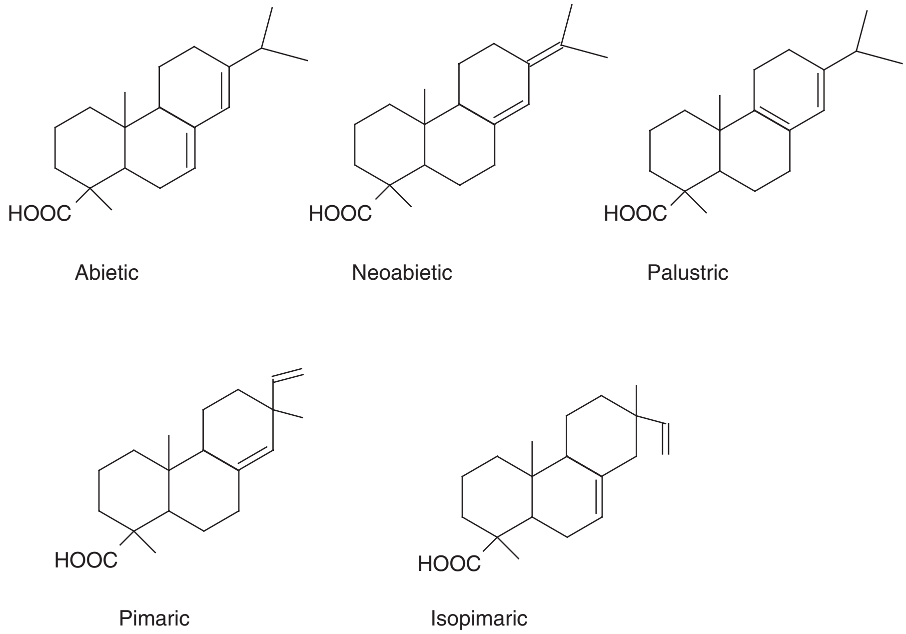


Figure 2 Resin acids.

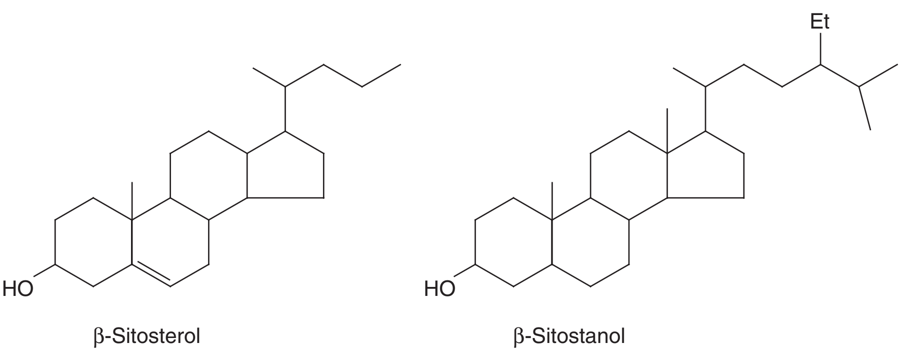

Figure 3 Triterpenes.

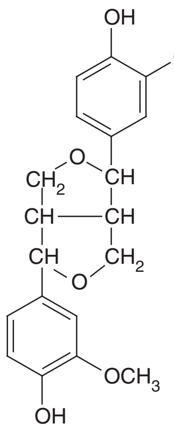
The neutral fraction of the tall oil is made up of triterpenoid β-sitosterol, β-sitostanol, and lignoceryl acohol (**Figure 3**). Given the structure of the former compounds, these have been of interest in the synthesis of other steroids that may have biological applications. The butter/margarine substitute Benecol that reduces low-density lipoprotein cholesterol contains sitostanol.

Phenolics

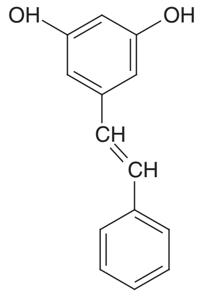
Among the other extractives that are present in wood are a number of phenolics (**Figure 4**). These include the lignans that occur through coupling of C_6C_3 groups, and the stilbenes, made up of 1,2 diphenyl ethylenes. In addition are the flavonoids, and their derivatives, with $C_6C_3C_6$ skeletons. These may be antifungal, can repel insects, act as antioxidants, and are responsible for the colors in flowers. Tannins, originally used as leather tanning agents, due to their ability to bind to proteins, are represented by the condensed tannins, which are oligomeric flavonoids, and the hydrolyzable tannins that are polymers attached to sugars through ester linkages, which yield gallic and ellagic acid upon hydrolysis. More current applications of the tannins have been as adhesives, antioxidants, and viscosity control agents.

Pharmaceuticals

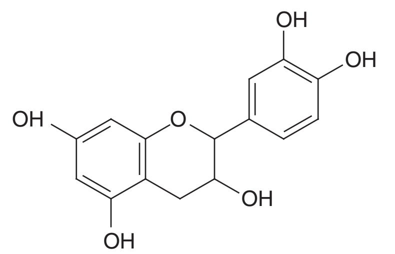
The extractives from wood and bark have had both a long history and recent success with respect to the isolation of important drugs (**Figure 5**). Perhaps the oldest and best known of these applications is the alkaloid quinine, present in the bark of *Cinchona calisaya*, *C. cussiruba*, *C. legeriana*, and *C. officinalis*.



Pinoresinol
(a lignan)

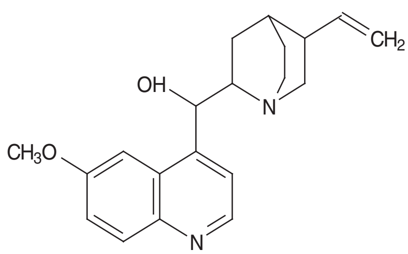


Pinosylvin
(a stilbene)

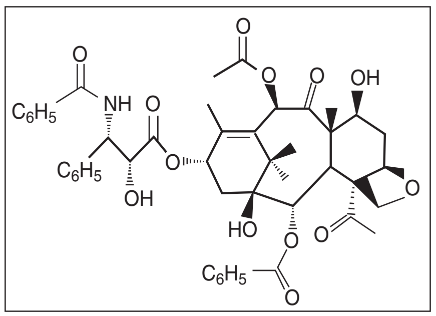


Catechin
(a flavonoid)

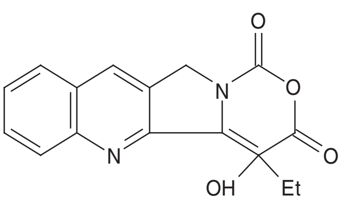
Figure 4 Other extractives.



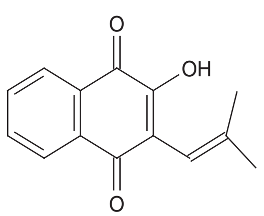
Quinine



Taxol



Camptothecin



Lapachol

Figure 5 Biologically active extractives from wood and bark.

These trees are native to the Andes and the bark may contain up to 15% quinine. Natives of South America used the bark as medicinal, but it appears that Jesuit missionaries first found that the powdered bark had antimalarial properties. The bark from both the tree and branches is used in a powdered form, and usually taken as an infusion.

A more recent development, of course, is the case of taxol, a diterpene originally isolated from the bark of *Taxus brevifolia*. An extract of pacific yew bark was first found to be effective against rodent cancers in 1962, in 1966 taxol was identified as the active compound, and in 1971 the structure was published. Taxol is active against leukemias, breast, ovarian, brain, and lung cancers. Limitations in its use have been encountered due to the slow growth, environmental restrictions, and low concentrations of taxol in the bark of Pacific yew. It has been reported that six 100 year-old trees would be required to treat one patient. Recently, several semisynthetic analogs of taxol have been produced from other species of yew.

Camptothecin, an alkaloid isolated from *Camptotheca acuminata* and its analogs topotecan and irinotecan, has been used in the treatment of ovarian and colorectal cancers. Topotecan has been found to be as effective or more so than taxol in such applications. The tree *C. acuminata*, a member of the Nyssaceae, is native to China and Tibet, where it is known as xi shu ('happy tree'). Harvesting for medicinal purposes caused a rapid decline in the availability, leading to restrictions of cutting and seed exportation. Prior to the exportation bans, plantings were established in the USA, but yields of camptothecin were low. In the meantime, another species, *C. lowreyana*, which is a shrub, has been planted with some degree of success.

Several species of *Tabebuia* (Pau d'Arco), from the rainforests of Central and South America, have been examined as a source of the compound lapachol that has been reported to be effective against some tumor cells. Severe toxicity problems have been reported, however, and to date this compound is not used in cancer therapies.

Polysaccharides

In addition to extractives, polysaccharides have been examined as possible therapeutic agents. A 4-O-methylglucuronoxylan has been isolated from *Fagus crenata* and tested in mice. Cancers in the peritoneal cavity were suppressed, as were the growth rates of tumors. Arabinogalactan, a highly branched, water-soluble hemicellulose with very high molecular weights, that can be isolated from larch heartwood and echinacea, has also received attention from the health care community. This polysaccharide has found use as dietary fiber, for which it is approved, and may have efficacy in immune system responses and as a supplement in cancer treatments. As a dietary supplement, the polysaccharide is rapidly fermented in the intestine, producing short-chain fatty acids that are used by cells in the colon as an energy source. These fatty acids also protect the intestine from diseases and carcinogens. In animal studies, arabinogalactan has been reported to reduce the colonization of the liver by tumor cells.

Lignin

Other by-products from pulping processes are the lignin that is removed during sulfite or sulfate pulping. While most of the sulfate (or kraft) lignin is burned for energy, and as an integral part of the recovery process, the sulfur-containing fractions can be utilized to produce dimethyl sulfoxide (DMSO), dimethyl sulfide, and methyl mercaptan. Methyl mercapatan and dimethyl sulfide are used as odorants in natural gas, while DMSO, due to its solvation properties, is used as a carrier for drugs and agricultural chemicals. Sulfite lignin, or lignosulfonates, have also been used in chemical applications. Under alkaline hydrolysis or oxidation conditions lignosulfonates will produce vanillin. Vanillin is used as a flavoring agent, upon derivatization can be used in sunscreens and fibers, and is an intermediate in the synthesis of the antiparkinson's drug L-dopamine. Lignosulfonates are also used as viscosity control agents in oil well drilling muds, dust suppressants in paving materials, dispersants, and adhesives.

Hydrolysis and Fermentation

The saccharification of wood for the production of monomeric sugars can be accomplished by several methods, including concentrated acid hydrolysis, dilute acid hydrolysis, and enzymatic hydrolysis. Concentrated acid hydrolysis employs mineral acids (mainly hydrochloric or sulfuric acid) at percentages as high as 80%, such that relatively low reaction temperatures (20–25°C) can be used. The drawbacks to this process involve corrosion of equipment due to the acidic environment, neutralization of the product stream, and recovery of the acid. In the dilute acid process, a two-step reaction is used to maximize the sugar recovery from both cellulose and the hemicelluloses. In the first step, a dilute acid pretreatment is performed (0.7% sulfuric acid, 190°C, 3 min), followed by a hydrolysis step at 0.4% sulfuric acid, 215°C for 3 min. The disadvantage of this method lies in the dilute nature of the product. In order to overcome this limitation, a great deal of engineering work has been reported on varying reactor designs. Enzymatic hydrolysis originally used cellulase enzymes as a substitute for the mineral acid, converting the polysaccharides to simple sugars that would be fermented in a separate step. Subsequently, simultaneous saccharification and fermentation (SSF) methods were developed, in which the cellulase and fermenting microorganisms are combined. The enzymes used in both of these processes have largely been isolated from *Trichoderma reesei*, and can be subdivided into endoglucanases that react randomly along the cellulose chain, exoglucanases that react endwise to produce glucose and cellobiose (a glucose dimer), and β-glucosidases that convert cellobiose to glucose.

Upon hydrolysis, the monosaccharides can be converted to a large number of chemicals via either fermentations or chemical processes. The most familiar of the fermentation methods is the conversion of glucose to ethanol by the action of *Saccharomyces cerevisiae*. More recently pentose sugars, which had been problematic in this regard, have been fermented to ethanol by recombinant strains of *Zygomonas mobilis*, *Escherichia coli* and *S. cerevisiae*. Acetic acid can be produced by fermentation with *Acetobacter*, or *Clostridium thermoaceticum*, while lactic acid is fermented from glucose by *Lactobacillus*. An acetone–butanol–ethanol blend can be made with an anaerobic *Clostridium*. Acetaldehye can be produced as a secondary product of ethanol by *Candida utilis* or *Pichia pastoris*, but can also be a direct fermentation product from glucose by either *Z. mobilis* or *S. cerevisiae*. While hydrocarbons are industrially produced from petrochemical sources, it has been found that ethylene, propane, and propylene can all be fermented from sugars by microorganisms. Succinic acid is an important intermediate in the synthesis of butane-diol, tetrahydrofuran, and adipic acid, all of which can also be used in subsequent syntheses. Succinic acid has been successfully produced by the direct conversion of sugars by recombinant *E. coli*.

Another product of fermentation processes is single-cell protein, derived from the dried cells of microorganisms. These may include bacteria, fungi, yeasts, or algae, that produce protein to be used by humans or animals. Sugars in the form of molasses were used as the carbon source for Torula yeast (*Candida utilis*) in Germany during World Wars I and II to extend meat supplies. Lignosulfonates, from sulfite pulping, have also been used as the substrate, and lignocellulosic material, upon either enzymatic or acid hydrolysis, has been used to produce simple sugars, used by a number of fungi and yeasts.

The monosaccharides that arise from the acid hydrolysis of cellulose and hemicelluloses can undergo dehydration reactions upon continued exposure to acidic conditions. The products of these reactions are furfural from the pentoses, hydroxymethyl furfural from the hexoses, and levulinic acid (**Figure 6**). Levulinic acid has recently received considerable attention due to the wide range of potential products that can be derived therefrom. These include ethyl levulinate used as a component in biodiesel fuels, delta-amino levulinic acid (DALA), a biodegradable herbicide, and 1-4 butanediol for use in polyesters. Hydroxymethyl furfural may be used as an intermediate for plastics, resins, and nylon manufacture. Furfural is used as an industrial solvent and in resin production.

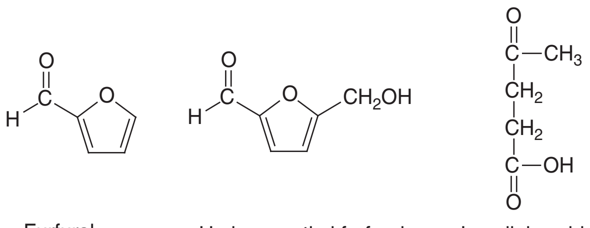


Figure 6 Dehydration products from acid hydrolysis.

The monosaccharides can also be converted to their corresponding alcohols (alditols) by chemical reduction. Xylitol, mannitol, and sorbitol are used as sweeteners, and sorbitol can be used in the synthesis of ascorbic acid.

The hydrolysis process, in addition to the monosaccharides, produces a lignin residue. While this material can obviously be burned as a fuel, ongoing research is examining its reformation into additives for gasoline. The lignin is initially depolymerized under alkaline conditions and is then subjected to deoxygenation and hydrocracking. These steps convert the lignin polymer into a mixture of hydrocarbons that are proposed as octane enhancers for gasoline.

Thermal Degradation

The production of chemicals from wood by the action of heat includes a broad continuum of processes, varying with respect to conditions and products. In general, these methods are done in the absence of air or other oxidizing agents, such that the substrate is thermally degraded, rather than combusted. The general terms used to describe this process include pyrolysis, liquefaction, and gasification, the latter two selectively producing liquid and gas, respectively, while pyrolysis results in a mixture of all three, the relative amounts of which are a function of the conditions.

Pyrolysis can broadly be divided into conventional pyrolysis and fast pyrolysis. The former encompasses techniques such as carbonization or destructive distillation, while the latter includes flash pyrolysis, rapid pyrolysis, and ultrapyrolysis. In any of these, the process variables are the residence time, temperature, and heating rate.

Probably the oldest of the thermal processes is destructive distillation, occurring under long residence times, on the order of hours to days, slow heating rates, and moderate temperatures (300–500°C). The main product is charcoal, with the liquid phase producing turpentine, pine oil, methanol, acetic acid, and a tar fraction that was originally used in sealing and waterproofing wooden ships. The technology used for this process ranges from a simple pit kiln, in which wood is stacked in a hole in the ground, ignited and covered to limit the amount of air, to industrial-scale furnaces. The charcoal that is produced may be used as either a fuel or a source for activated carbon, that can be applied to filtration and purification processes.

Under shorter residence times, higher levels of the more volatile liquid phase can be collected. The liquid consists of a water-soluble fraction containing methanol, acetic acid, acetone, and relatively low-molecular-weight terpenoids. A heavy insoluble pyrolysis oil or tar is also produced. This is an extremely complex mixture of hundreds of chemical compounds, any one of which is present in limited concentration. The cellulose present will preferentially produce levoglucosan, the hemicelluloses are degraded to furans, while the lignin is represented by a large number of phenolic compounds. These phenolics have been exploited in the proposed utilization of pyrolysis oils in adhesive applications. The gas from conventional pyrolysis is relatively low-energy (1–3 $MJ\,kg^{-1}$) and mainly consists of carbon monoxide and carbon dioxide, with small amounts of hydrogen, methane, and ethane.

Fast pyrolysis is characterized by very short residence times, and very high heating rates, with thermal flux values as high as 3000 $cal\,cm^{-2}\,s^{-1}$. These conditions quench the reactions, preventing the formation of secondary products. While all three phases can be produced, as a function of process conditions, at the very highest heating rates gaseous products are preferred, with the major component being acetylene. The heating methods by which fast pyrolysis is performed have been varied and novel, including microwave, radiofrequency, and focused solar radiation.

Liquefaction of wood involves treatment at elevated temperatures in the presence of various liquids and catalysts. At relatively high temperatures (300–425°C) and in the presence of an aqueous solution of sodium carbonate, wood is liquefied at yields as high as 80%. The liquid, which is a complex mixture, can nevertheless be largely composed of phenolic compounds. Alternatively, wood can be liquefied under less severe conditions (temperatures 80–150°C) in the presence of acid catalysts such as hydroiodic, sulfuric, hydrochloric, or phosphoric acids, or simply with solvents, such as phenols, ketones, alcohols, or glycols, at somewhat higher temperatures (240–270°C). These conditions will convert the wood into a liquid product with a paste-like consistency that has been used in adhesive applications, foams, and molded products.

Gasification, as the name implies, is the generation of a gas, with low- to medium-energy contents, and a composition that can be used in subsequent synthetic processes. Gasification can be broadly divided into pyrolysis, partial oxidation, and reforming processes. Under very high pyrolytic temperatures the solid and liquids phases will be suppressed, such that the gas is the main product. Partial oxidation uses less than the stoichiometric amounts of oxygen that would be needed to support combustion. This results in a partially oxidized product. Reforming in this context refers to gasification that is done in the presence of additional reactants, such as steam, steam–oxygen, or steam–air. The products of all of these processes are similar, with carbon monoxide and hydrogen being the main components of the gas. The energy content can range from 100–300 Btu/SCF (standard cubic foot) in processes that utilize direct contact of the wood with air (due to dilution), 300–700 Btu/SCF when oxygen is used, and 700–1000 Btu/SCF when conditions favor the formation of light hydrocarbons such as methane (which is responsible for a large proportion of the energy).

Cork Oak

H Pereira and M Tomé, Instituto Superior de Agronomia, Lisbon, Portugal

Introduction

The cork oak (*Quercus suber*) is an evergreen oak that spreads in the countries of the western Mediterranean basin, over a total area of 2 million ha. It extends in the western coastal Mediterranean and adjoining Atlantic areas between 34° and 45° N latitude.

The species has a particular characteristic that sets it apart from other evergreen oaks: its ability to produce a thick bark with a continuous layer of cork tissue on the outside, with a thickness and properties that make it a valuable raw material for industry. Whenever the outer cork bark is removed, the tree has the capacity to form a new cork bark by adding new layers of cork every year, and this may be repeated throughout the tree's lifetime.

Cork oak forests nowadays cover considerable areas in Portugal (*c.* 725 000 ha) and Spain (*c.* 475 000 ha), and also in Algeria, France, Italy, Morocco, and Tunisia. The annual world production of cork totals about 370 000 tonnes, mostly from the cork oaks of Portugal and Spain, which produce respectively 51% and 23% of the total.

The Cork Oak Tree

Cork oaks are low spreading trees with a short stem and thick branches (**Figure 1**). The trees do not attain heights greater than 14–16 m but open-grown trees may have very large crown dimensions, e.g., 500 m^2 of crown projection in some mature trees 150–200 years old. The circumference at breast height of these 'monument' trees can be as large as 9 m. When growing in dense stands, the shape of the tree is strongly influenced by competition, giving rise to trees with narrower crowns and higher stems.

Figure 1 Cork oak trees under cork production.

The root system is characterized by a strong and long taproot with thick lateral ramifications that in open-grown trees may show a large horizontal expansion with many superficial roots. The association of the root system with different micorrhyzae is quite frequent.

Cork oak is a monoic species with flowers emerging between April and June; the flowering period may sometimes be longer, with flowers emerging in autumn. Due to the long flowering period, the acorns do not ripen at the same time. The amount of acorns varies widely from year to year, with 2–3 years of high fruit production out of 10 years. Flowering and fructification begin at around 15–20 years of age.

Tree diameter and cork growth are concentrated in spring and the beginning of the summer and are highly controlled by annual weather variations, namely by the precipitation in the previous winter and spring.

The cork oak is a semitolerant species, well adapted to mild climates, like Mediterranean climates with Atlantic influence, with mild winters but hot and dry summers. It grows well with mean annual precipitation of 600–800 mm, even surviving with 400 mm of precipitation. The optimum mean annual temperature is in the range 13–16°C but it survives up to 19°C. Mean temperature of the coldest month should not be below 4–5°C and the absolute minimum survival temperature is −12°C. The optimum growth occurs at 300–600 m of altitude, although the species can be found at higher altitudes (up to 1300 m).

The species prefers deep and well-drained soils, however, it is very soil tolerant and will grow on poor and shallow soil sites. It grows poorly on calcareous or excessively sandy soils.

Cork Biology

Cork Formation

In the cork oak the phellogen is formed as a continuous layer surrounding the stem and branches and producing an external layer of cork cells with an appreciable thickness. Unlike most species, where the phellogen only lives for some years, in the cork oak it may be active as long as the tree.

The phellogen differentiates in the young plants during the first year of growth in the cell layer immediately under the epidermis after the formation of the vascular cambium and the initiation of its activity. Several layers of suberized phellem (cork) cells are produced to the outside by the meristematic division of the phellogen mother-cells during each growth season (**Figure 2**). In the very young stages, the phellem cells are tannin-filled and tangentially stretched due to growth stress, but after approximately 7 years they acquire the characteristics of adult cork cells with empty lumina, thin suberized walls, and a regular arrangement.

Cork Structure and Composition

Cork is a cellular material made up of a regular structure of closed, thin-walled, hollow cells. The cells may be described as hexagonal prisms, packed base-to-base in columns oriented parallel to the tree radial direction. There are no cell-to-cell communication channels (i.e., pits) nor intercellular voids, with the exception of the natural occurrence of lenticular channels.

The structure of cork is anisotropic. In the tangential section (perpendicular to the radial direction), cork cells have a honeycomb-type arrangement and are seen as polygons, mostly with five to seven faces and with areas of $4–6 \times 10^{-6}\,\text{cm}^2$. The radial and transverse sections (perpendicular, respectively, to the tangential and axial directions) are similar and show a brick-layered-type arrangement with the cells aligned in radial oriented rows and with a rectangular form of 30–40 μm length.

Corrugation of cork cells is an important characteristic of their prism lateral faces. Late cork cells show little or no wall corrugation, in contrast to the first spring early cells that are often heavily corrugated due to radial compression resulting from growth stresses.

One conspicuous macroscopic feature of cork is the presence of lenticular channels that cross the planks radially from the external surface to the phellogen; these are usually referred to as cork pores. In a tangential section the lenticular channels appear in cross-section with a more or less circular form, mostly elongated in the tree's vertical direction. There is a very large variation on the number and dimensions of lenticular channels, probably related to tree genetics. The porosity of cork is directly in relation to cork quality. In a good-quality cork, the porosity represents in general less than 4% of the area.

The chemical structure of cork cells is dominated by the presence of suberin as the main component (around 40%). Suberin is an insoluble tridimensional cell-wall polymer with an ester-linked glyceridic framework of long-chain fatty acids and alcohols. The supramolecular structure of this component is still a matter of investigation, regarding its connection to other cell-wall components. Cork cells also contain lignin to a considerable extent, as well as extraneous compounds such as fats and waxes and phenolics. Cellulose and hemicelluloses are also present but their role is much less important when compared to wood cells.

The summative chemical composition of cork is, on average: ash $<1\%$, extractives 14%, suberin 40%, lignin 23%, cellulose 9%, hemicelluloses 11%. Variability of chemical composition has been found between corks of different trees.

Silviculture

Cork oaks can be managed according to two different silvicultural systems:

1. In most cases, cork oak stands have a relatively small number of trees per hectare (sparse forest) and are associated with agricultural crops or pasture for cattle grazing (**Figure 3**); this system is called montado in Portugal and dehesa in Spain.

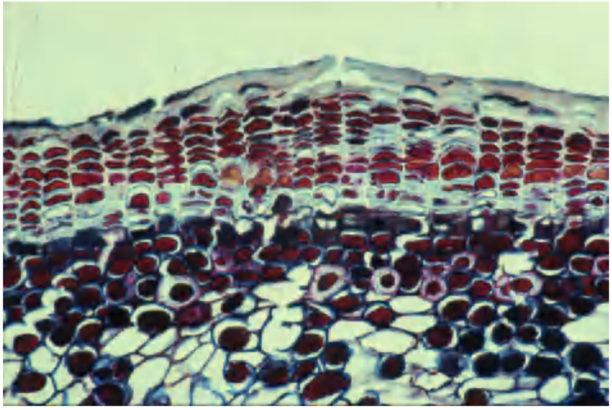

Figure 2 Phellem (cork) cells produced by the tree phellogen during its first year.

Figure 3 A montado in Portugal.

2. In some cases, in mountainous regions, cork oaks are grown in denser stands which do not permit the practice of agriculture underneath the trees.

Both systems are frequently associated with hunting, mushroom picking, and bee-keeping.

Most of the present mature cork oak stands resulted from the management of naturally regenerated stands by generations of landowners or, in some cases, through artificial seeding complemented by natural regeneration. As a result, a large percentage of the stands is characterized by a heterogeneous spatial distribution, and some can be classified as uneven-aged.

Harvesting of cork oaks usually occurs only for sanitary purposes and the present mature stands include a large percentage of old trees. The decision on the best management option or silvicultural system towards the rejuvenation and maintenance of these stands may consider:

- clearcutting the stand (as a whole or in small plots), followed by natural or artificial establishment of a new stand (even-aged silviculture)
- the gradual transformation of the stand towards continuous-cover forestry (continuous-cover silviculture)
- the use of successive regeneration fellings.

In several countries of the Mediterranean region, afforestation with cork oak has been emphasized in the last two decades and even-aged silviculture has been the option for these new stands.

Even-Aged Silviculture of Cork Oak Stands

Stand regeneration Artificial regeneration of cork oak stands is relatively recent but was greatly increased as a consequence of EU policy for the afforestation of agricultural lands. Either plantation or direct seeding by placement of two to three acorns in small holes is used. Acorns are very attractive to small rodents, and the use of repellents is recommended.

In both cases, correct site preparation is essential for the success of the new stand. This includes weeding, usually by disk-harrowing, and the improvement of soil characteristics for the development of the root system. Soil preparation depends on soil type and slope: it may include ripping or subsoiling to 60–80 cm depth, especially in soils overlying hard rock, or plowing and mounding along the contours followed by deep plowing and/or disk harrowing. Site preparation may cover the whole area or be concentrated on the planting line. Starter NPK fertilization is usually applied at 40–100 g per plant.

Plantation and/or seeding can occur either in spring or autumn. The number of trees per hectare at planting is not as high as in other species planted for wood production, and common spacings range from 4×4 m (625 trees ha^{-1}) to 8×4 m (312 trees ha^{-1}).

Operations in the regeneration stage The success of plantations with cork oaks is not guaranteed and mortality during the first years may be very high. The operation of beating-up is very common. The protection of young seedlings with individual tree shelters is considered to be beneficial against browsing and for stimulating initial height growth. However, in regions with high temperatures, this technique has caused higher mortality rates. Whenever spring and summer precipitation is too low, irrigation should be applied two to three times during periods of higher stress. During the first years after planting, weeding is highly recommended around each seedling or on the whole area. Suppression of cattle grazing during the regeneration stage is a precondition for the success of the plantation.

Operations in the juvenile stand The juvenile phase of a cork oak stand refers to the period until the beginning of cork extraction. Young cork oak trees show abundant ramifications without a leading shoot and pruning is therefore an important operation to obtain trees with a clear stem height of at least 2.5–3 m. Depending on site productivity, the first pruning occurs between 3 and 6 years of age and eliminates all the branches in the first two-thirds of the tree. A second pruning is made between the ages of 12 and 15 years. Depending on stand density at planting, this operation may be complemented by a first thinning to reduce stand density to 400–600 trees ha^{-1}. The last pruning is usually made immediately after first debarking. The first debarking for cork extraction is regulated in most countries by legislation. In Portugal only trees with a circumference at breast height ≥ 70 cm can be debarked. Depending on site productivity and stand density at planting, this operation is possible between 25 and 40 years of age.

During the juvenile stage of a cork oak stand, weeding may be undertaken. If the landowner aims at grazing underneath the future stand, the establishment of pasture may occur from the age of 10–15 years.

Operations in mature stands The most important silvicultural operations in mature stands are thinning and, naturally, cork debarking. Some managers sometimes consider applying fertilizers and tree pruning. Weed control, depending on the type of cultivation underneath, may also be needed. It is highly recommended that the method used to control weeds – usually mechanical weeding – does not damage the superficial root system.

Stand density after the first debarking is usually controlled according to a preselected spacing factor. The spacing factor is defined as the quotient between mean distance between trees and mean tree crown diameter:

$$\text{Spacing factor} = \frac{\text{mean tree distance}}{\text{mean crown diameter}}$$

It is usually assumed, even if there is not enough experimental data to confirm this empirical rule, that cork production is affected when intertree competition is too high. The use of a spacing factor that gives each tree enough space to develop its crown without substantial restrictions is recommended. The space between trees should be at least half of its mean crown radius. This rule is equivalent to the maintenance of a spacing factor of around 1.2.

After the first cork debarking, the rotation of cork extractions is also regulated in most countries. In Portugal and Spain, the minimum period allowed between successive extractions is 9 years. The cork extraction of a stand may be done either simultaneously in all the trees – even-aged cork – or in only a selection of the trees, therefore cork age is not the same for trees in the same stand – uneven-aged cork. In uneven-aged cork stands two cork-debarking rotations should be defined: (1) tree cork-debarking rotation, which is usually 9 years; (2) stand cork debarking, depending on how many different cork ages are present in the stand.

In an even-aged cork stand, thinning should occur after cork debarking, so that the landowner can profit from the cork income from the trees that will be thinned and also be able to use cork quality as an additional criterion to select trees to be thinned.

One important parameter of cork debarking is the so-called debarking coefficient, which defines the height in the stem to which cork can be stripped off (debarking height). The debarking coefficient is defined as the quotient between the debarking height and the perimeter at breast height over cork (pbh_{overcork}):

$$\text{Debarking coefficient} = \frac{\text{debarking height}}{pbh_{\text{overcork}}}$$

In some countries the debarking coefficient is also regulated by legislation. For instance, in Portugal, maximum legal debarking coefficient depends on the stage of development of the tree: 2.0 for the first cork debarking, 2.5 for the second cork debarking, and 3.0 for subsequent debarkings.

The application of fertilizers during the period between cork extractions is often made by landowners to improve cork quality. However, the few experimental results available do not show its effect on cork growth and quality.

The acorns of cork oaks were an economically important product in past years and the trees were pruned to increase fruit yield. This practice is still used by some farmers who associate pruning with tree vigor and cork yield, a fact that has never been experimentally proved.

Rotation period Cork oak trees may attain 250–350 years of age. The trees maintain their ability to produce cork but cork thickness decreases as trees age and 150–200 years seem to be the limit for an industrially useful cork production. Rotation periods between 100 and 150 years are usually assumed in most management plans.

Continuous-Cover Silviculture

Continuous-cover silviculture is a very interesting alternative to even-aged silviculture for the management of the existing mature stands, even if at present there are no examples of the use of continuous-cover silviculture in cork oak stands. Some tentative studies using growth and yield models have compared cork yield under this type of silviculture. The main conclusion is that the total production of cork in a continuous-cover silviculture strongly depends on the selected target diameter distribution. It is possible to find options that in the long term will originate cork yields comparable to those obtained with even-aged silviculture.

Three main consequences of using continuous cover forestry are: (1) the proportion of virgin cork – of low commercial value – is higher than in even-aged silviculture due to the continuous maintenance of a large number of young trees in the stand; (2) cork yield is highly dependent on one or two large trees, and if one of these dies, there is a strong negative impact on cork yield during the next period; (3) it is difficult to make this silvicultural system compatible with underneath grazing or game browsing.

Cork Extraction

The first cork taken from the tree is called virgin cork (**Figure 4**). It has deep fractures due to tissue failure upon the tangential stresses of tree radial growth and is of low commercial value. The second cork obtained in the following extraction is more homogeneous in

Figure 4 A young cork oak tree with virgin cork and second cork, respectively, in the upper and lower part of the stem.

thickness but still has numerous longitudinal running cracks (**Figure 4**). It is only from the third extraction that the cork planks show a continuous and uniform thickness that will allow their full utilization by the industry. The cork layer is removed from the tree as large planks by manually cutting with an ax along vertical and horizontal lines on the stem and thick branches and subsequent stripping-off (**Figure 5**). This operation is made in spring and early summer when the tree is physiologically active and allows easy separation of the outer bark.

The raw cork planks have variable dimensions, depending on the tree size and operational conditions at the tree debarking. They are rectangular with dimensions usually falling in the range of 1–1.8 m height and 0.4–0.8 m width. The cork planks are piled up in the field while waiting for transport to the industrial premises (**Figure 6**).

A distinctive feature of cork planks is the presence of a thin layer of lignous materials to the outside of the cork tissues, named the 'back' of the cork planks. The trees under cork production show on the stem and branches the characteristic dark grayish-brown color due to weathering of the back of cork planks and numerous fissures resulting from the radial tree growth. The inside surface of the cork planks corresponding to the tree inner side is industrially named the 'belly.'

Figure 5 Cork extraction from cork oak trees.

Figure 6 Field storage of raw cork planks.

Growth and Yield

Tree Growth

Cork oak is a slow-growing species. The SUBER model, the only published growth and yield model for the species based on data from Portugal, expresses site productivity as the number of years that dominant trees take to attain diameter at breast height (dbh) level. In this model this index is assumed to vary in the range 5–9.

Figure 7 shows the dbh growth of individual trees obtained in tree disks collected at dbh-level as well as the corresponding growth curves used in the SUBER model. As can be seen, dbh growth is very slow but trees can attain very large dimensions as a consequence of the large rotation period.

Cork Growth

The production of new cork is more intense in the years immediately after debarking and decreases from then on. Cork thickness after 4 years is around 75% of the thickness at 9 years of age. When analyzing cork growth, which can be done after cork harvest by measuring cork growth rings, one can show that the first cork growth ring, located adjacent to the cork back, is usually smaller than the subsequent rings. This ring corresponds to the growth of cork in the growing season during which cork was extracted, after debarking. Therefore it is not a complete growth ring and is usually called the first half-ring. Similarly, the last cork growth ring also corresponds to a partial growing period and is called the last half-ring. Cork growth capacity of a tree can be expressed by the accumulated thickness of the first 8 complete years. This index, the cork growth index (CGI), is used in the SUBER model.

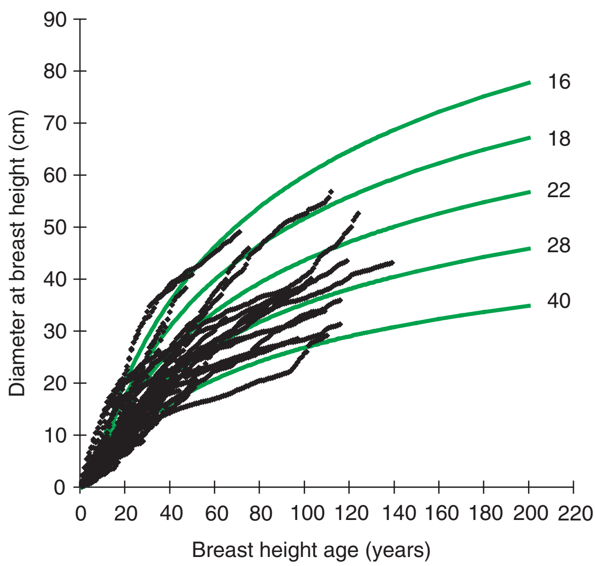

Figure 7 Diameter at breast height (dbh) growth obtained from stem disks at dbh-level as well as simulated dbh growth curves used in the SUBER model.

Stand Development

Stand development depends on site characteristics and on forest management. **Table 1** gives an example of the predicted development of a cork oak stand in a site of mean productivity, managed as an even-aged cork stand, maintaining a spacing factor close to 1.2, and following the maximum legal debarking coefficients. As can be seen, number of trees per hectare, in comparison with other species that are planted for wood production, is quite low, leading to low values of stand basal area. **Figure 8** shows cork yield and stand characteristics in four different stands with a percent crown cover of approximately 58%.

Cork Processing and Products

Cork is a light material, with a density ranging from 0.2 to 0.3. It is rather impermeable to water and other liquids. It is a very durable material, being stable as regards weathering and biotic attacks. On compression, cork behaves as a viscoelastic material, allowing large deformations without fracture and appreciable dimensional recovery. It is an insulation material, with low conductivity. Cork is also a sound and vibrational insulator.

These properties led to cork being used for several purposes, some ancient, others more recent: buoys and floating material, sealants of liquid recipients (i.e., wine bottles), insulation of buildings and industrial equipment, surfacing of walking areas, surface joint sealant in engines, and antivibrational joints in structures (i.e., antiseismic construction).

At present, the cork industry produces different products with variable incorporation of cork and technological transformation. However the economic viability of the whole sector is determined by the production of stoppers of natural cork for use in the bottling of wine. Nowadays it is the suitability of the cork raw material for this production that establishes its commercial quality and the objectives for the forest manager.

Table 1 Yield table for an even-aged stand of mean site productivity managed to maintain a spacing factor of 1.2 and using the legal debarking coefficients

Age (years)	*Stand characteristics after thinning*					*Cork weight (kg ha^{-1})*	
	N *(ha^{-1})*	G *(m^2 ha^{-1})*	d_g *(cm)*	d_{crown} *(m)*	*Crown cover (%)*	*Virgin cork*	*Mature cork*

Figure 8 Cork yield and stand characteristics in four different stands with a percentage crown cover of ≅58% (stands simulated with the SUBER model): 1, even-aged young stand; 2, even-aged stand close to rotation age; 3, uneven-aged stand with maximum diameter at breast height (dbh) in the class [62.5; 67.5]; 4, uneven-aged stand with maximum dbh in the class [92.5; 97.5]. dbh, diameter at breast height.

Figure 9 Cork planks after the water-boiling operation.

Figure 10 Boring of stoppers from a cork strip in the industry.

The processing of cork depends on the type of cork: virgin and second cork are directed for trituration to produce cork granules that will be used for cork agglomerates; the reproduction cork planks (from the third extraction on) are used to produce stoppers.

The cork planks undergo postharvest preparation for further industrial processing consisting of immersion in water at approximately boiling point for 1 h. The objective of this operation is to flatten the stem-curved raw planks and to soften the cork tissue for easier subsequent cutting (**Figure 9**). In boiling water the cork expands and the most important practical consequence is that the raw cork planks increase in thickness, on average by 12%. There is a high variation in thickness increase with water boiling between different cork planks, with values ranging from almost nil increase to more than one-third of the initial dimension.

Cork planks that have a thickness over 27 mm are directed for production of stoppers. For this they are cut into strips and the stoppers are bored with a hollow cutting cylinder with an inner diameter equal to the desired stopper diameter (**Figure 10**). The stoppers are dimensionally rectified, washed, bleached, dried, and classified into commercial quality classes according to the extent of the porosity shown on their surface, as given by the lenticular channels. In the stoppers the lenticular channels run parallel to the top and bottom faces.

The cork planks that have a thickness below 27 mm are directed for the production of disks. The planks are cut into bands, and laminated tangentially in the cork into 2–5-mm-thick cork sheets from which the disks will be punched out. The disks will be used glued on bodies of agglomerated cork, i.e., for champagne and sparkling wine.

The residues from the boring of stoppers and of disks (amounting to more than 75% of the initial cork plank) are triturated and agglomerated. Cork agglomerates are used to produce agglomerated stoppers and for cork boards and sheets used in various surfacing situations, i.e., flooring, paneling, joints. In a mixture with rubber, a composite material is produced for industrial and construction vibrational absorption.

A special insulation material called expanded cork agglomerate is made by high-temperature (*c*. 300°C) expansion and self-agglomeration of cork granules in autoclaves with superheated steam. The agglomerate has a dark brown color and is used for heat and sound insulation.

Resins, Latex and Palm Oil

P P Bhojvaid and D C Chaudhari, Forest Research Institute, Dehradun, Uttaranchal, India

Introduction

Besides timber and fuelwood, many commercial products of biological origin are sourced from forests all over the world. These comprise medicinal herbs, edible plants and plant parts, aromatic oils, gums, resins, latex, fibers, flosses, and a variety of other products commonly referred to as non-wood forest products. Resins, latex, and palm oil are one such category of product which have found place in industrial, commercial, and subsistence use with humans. While resins and latex are exudations which are secreted in response to natural and induced injuries to plants, palm oils are extracted from the fruits and seeds of certain tree species. The purpose of this article is to provide basic information on important resins, latex, and palm oil-producing forest plants with special reference to plant sources and description, uses, collection, primary processing, and value-added processing.

Resins

Definition and History

The term oleoresin is used to distinguish the fresh liquid exudation from trees having a high content of volatile oil. These are amorphous (noncrystalline) substances with a complex mixture of organic compounds called terpenes, which are insoluble in water but soluble in certain organic solvents. These yield on distillation two important commercial products, turpentine oil and nonvolatile solid rosin, which is also known as calophony.

Use of pine resins dates back to the period when wood was used for shipbuilding. The pitch obtained from pine trees for caulking the seams of wooden ships and preserving their ropes and rigging was the initial phase of the resin production industry. Consequently, the term naval stores industry denotes the industrial production of oleoresin or resin, used for waterproofing wood ships.

Resin Canals

Resin is produced in two types of resin canals, which are distributed in the tree stem. The large longitudinal ducts have an irregular distribution in the middle and outer portion of tree stem and the smaller horizontal canals are restricted to the outer part of the stem bark. These canals are formed by secondary division of growth cells (cambium), and are lined with a thin-layered wall of secretory epithelium enclosing a central hollow portion. The canals are interconnected to form a continuous network of resiniferous canals in the tree stem. Consequently, when one of these canals is cut at the stem surface, the resin flows to the openings from the inner portions of the stem.

Tapping Process

Resin is a secondary product which is produced by normal metabolic processes in trees; however, it exudes only in response to natural or induced injury to tree stems. Consequently secretion of resin is a defense mechanism in response to wounds and injuries and acts as a disinfectant against microbes and prevents the ingress of borer insects.

In normal resin tapping, a small superficial incision results in resin flow from horizontal canals, which in turn stimulate flow from longitudinal canals located deep in the stem. Trees above 30 cm diameter at breast height (1.37 m above ground level) are suitable for economical tapping. The best time for tapping is March to October; however, maximum resin yield is obtained in the months of May to July and September to October. In light-intensity tapping, superficial blazes result in minor injuries, which are healed in one to two growing seasons. However, unscientific blazing can cause irreversible damage and make trees prone to fire due to the inflammable nature of resin and pine-wood. Consequently, the classical method of tapping with the use of random blazes, which are frequently repeated, leading to large scars on tree stems, has been replaced by the environmentally friendly and ecologically sound rill method. In this method, only tree bark is chipped and small surface incisions are made in a definite geometric pattern using a sharp knife. The resin flow is enhanced with the use of dilute acid, 2-4-D, or other chemical stimulants, thereby increasing resin yield (**Figure 1**).

Processing of Resin

Processing of resin is essentially a technique to separate its main constituents, rosin and turpentine oil. Two different methods in vogue are direct heating and steam heating. The former involves heating resin in vats covered by light lids with the intermittent addition of water in small quantities. The resultant steam from the vat runs through a spiral pipe passing through cold water. This condensation process results in separation of turpentine, which is collected in a vessel at the end of a pipe. The rosin left in the vats is filtered before filling in packing vessels. This method, however, does not yield superior-quality rosin.

In steam heating, vats with a V-shaped bottom are provided with steam jackets for heating resin. Some quantity of inferior turpentine oil is added to the crude resin and the vat is covered with an airtight lid. The mixture is then heated by steam jackets and stirred by a helical belt mixer provided in the vessel. Subsequent cooling facilitates heavy impurities settling at bottom, while the lighter fraction accumulates at the surface and is removed by a ladle. The resin is then allowed to flow into a tank, leaving the sludge in the welter. Subsequently, resin is pumped for distillation in a still heated by a steam jacket. The lighter oil comes first, followed by heavier fractions during distillation. The steam injection is stopped and rosin is allowed to cool

Figure 1 Recurrent incisions on stem surface in the lip and cup method of resin tapping result in injuries (a) leading to fires and subsequent tree mortality (b). In the rill method of tapping (c), the application of chemical stimulants facilitates higher yields and the small superficial incisions are quickly healed by the natural process of bark growth (d).

for complete dehydration and evaporation of remaining traces of turpentine oil. The pine rosin obtained in this process is of much higher value than that obtained by direct heating.

Classification of Resins

The classification of resin is very complex. The resins occur in a pure to nearly pure state or as a mixture with essential oils and gums. Furthermore, resins are produced from several plant species. Consequently satisfactory classification and grouping of resins or of the resin-yielding plants become difficult. However, a simplistic classification can be into three broad categories: (1) hard resins; (2) oleoresin; and (3) gum resins, as shown in **Table 1**.

Hard resins These are usually solid, more or less transparent, colorless, odorless, brittle substances with a little amount of essential oils and are the best source of raw material for varnishes. The most important commercial resins in this category are copals, dammars, mastic, and dragon's blood.

Copal Copal is characterized by its hardness and high melting point. Copal is soluble in alcohol and oils; the oil-soluble forms were also used in the manufacture of linoleum. Commercial copal is obtained from *Agathis*, a tree species of Southeast Asia, found in Malay, Indonesian archipelagos, and the Philippines.

Damar (dammar) Damars are solid resins, less hard but more durable than copal, and white to yellow in color. Damars are soluble in hydrocarbon solvents and drying oils. Damar for international commerce is obtained from dipterocarp trees in Southeast Asia. The sal (*Shorea robusta*) tree is tapped in India to obtain damar. Its main use is in the manufacture of paper, wood varnishes and lacquers, and paints. Minor uses include manufacture of inks, polishes, and water-resistant coatings. In India, sal dammar is widely used as incense and in the indigenous system of medicine.

Mastic Mastic is obtained from *Pistacia lentiscus*, a small tree of the Mediterranean region. Bombay mastic is obtained from *P. cabulica*, occurring in Afghanistan, Baluchistan, and Gilgit (Kashmir). Mastic is produced in the form of small tears, pale yellow in color, clear and glassy in nature, and is liable to fracture. Its age-long use in Arab countries has been for chewing as a mouth freshener and to help preserve the teeth and gums. Its aromatic properties also make it suitable as a flavoring agent for alcoholic beverages. In the past, it was also used in the manufacture of high-grade varnishes for paintings, and for medicinal purposes.

Dragon's blood The plant sources of dragon's blood are *Daemonorops* spp. (Southeast Asian rattan), *Dracaena* spp., and *Croton* spp. *Daemonorops didymophylla* bears bunches of scaly fruits, which are covered with red resin. The major production of this resin comes from the islands of Sumatra and Borneo and some parts of peninsular Malaysia. The resin of commerce is in the form of powder, granules, sticks, or friable lumps with a deep dull red color and its use is largely confined to very specialized markets, such as violin varnish.

Oleoresins Oleoresins contain a considerable amount of essential oil in addition to resinous materials and have a distinct aroma and flavor. Among the oleoresins used in commerce, turpentine, balsam, copaiba, and elemis are prominent. The distinction between these groups is very slight and often confusing.

Turpentines Turpentines are oleoresins obtained almost exclusively from coniferous trees. For commercial purposes, crude turpentine is obtained by tapping trees of *Pinus* spp. On distillation, oleoresins

Table 1 Resin types, resin-producing species, and main resin-producing regions

Resin type	*Main genera*	*Plant family*	*Main producing region*
Hard resins			
Copal	*Agathis*	Araucariaceae	Southeast Asia
Dammar	*Shorea, Hopea, Vatica, Vateria*	Dipterocarpaceae	Southeast Asia
Mastic	*Pistacia*	Anacardiaceae	Mediterranean
Dragon's blood	*Daemonorops*	Palmaceae	Southeast Asia
Oleoresins			
Turpentine	*Pinus*	Pinaceae	Southeast Asia, Europe, USA
Benzoin	*Styrax*	Styracacae	Southeast Asia
Styrax	*Liquidambar*	Hamamelidaceae	Asia Minor, Central America
Peru/tolu balsams	*Myroxylon*	Leguminosae	Central and South America
Copaiba	*Copaifera*	Leguminosae	South America
Elemi	*Canarium*	Burseraceae	Southeast Asia
Gum resins			
Asafoetida/galbanum	*Ferula*	Umbelliferaceae	Asia Minor
Gambose	*Garcenia*	Sapotaceae	Siam, Indochina, India, Ethiopia
Myrrh	*Commiphora*	Burseraceae	Somalia, Arabia
Frankincense	*Boswellia*	Burseraceae	Southern coast of Arabia, Northeast Africa

yield the essential oil or spirits of turpentine and the solid residue is called rosin. Turpentine and rosin are one of the major forest-based industries in the world. Rosin has a variety of uses in industry, in the paper industry (paper sizing), printing-ink industry, paint and varnish industry, leather industry, soap industry, and in the production of batteries, synthetic rubbers, perfumes, joysticks, fireworks, and adhesives. Turpentine oil is one of the basic raw materials for chemicals for a wide range of industries such as paints and varnishes, polishes, aromatic chemicals and pharmaceuticals, soap, and perfumery. Its products are also used in the manufacture of synthetic rubber, waxes, insecticides, and germicides.

Principal sources of oleoresin Out of 100 species of pines, only a few dozen are being tapped commercially as a source of crude oleoresin for rosin and turpentine production. In others, the poor yield or quality of resin makes tapping uneconomic. More than three-quarters of pine oleoresin is obtained from *P. palustris, P. elliottii* (USA), *P. sylvestris* (Russia and Northern Europe), and *P. pinaster* (France, Italy, Portugal, and Spain). The principal sources for commercial production of oleoresin are listed in **Table 2**.

Benzoin Benzoin is obtained from trees of the *Styrax* species native to Southeast Asia. There are two types of benzoin of commerce: Siam benzoin is obtained from *Styrax tonkinensis* and Sumatra benzoin from *S. benzoin* and *S. paralleloneurus*. Fresh Siam benzoin is semisolid but soon hardens to form brittle drops, often translucent, and yellowish-red to brown in color. Sumatra benzoin also hardens to form solid drops. Both are traded as solid blocks and are used in aromatic chemical industries such as expensive delicate perfumes. Sumatra benzoin is widely used in pharmaceutical preparations, as inhalations for the treatment of catarrh and as antiseptics. In China, it is also used in traditional Chinese medicine.

Table 2 The principal sources for commercial production of oleoresin

Species	*Resin-producing countries*
Pinus elliotii	Brazil, Argentina, South Africa, USA, Kenya
P. massoniana	People's Republic of China
P. kesiya	People's Republic of China
P. pinaster	Portugal
P. merkusii	Indonesia, Vietnam
P. roxburghii	India, Pakistan
P. oocarpa	Honduras, Mexico
P. caribaea	Kenya, South Africa, Venezuela
P. sylvestris	Russia
P. halepensis	Greece
P. radiata	Kenya

Styrax Styrax or storax is a balsamic oleoresin extracted from the genus *Liquidambar*. Asian styrax is obtained from *L. orientalis* of Asia Minor and American styrax from *L. styraciflua* of Mexico and Central America. Asian styrax is a semisolid, sticky brown substance. American styrax is usually darker but cleaner than Asian styrax. Both contain cinnamic acid or derivatives of cinnamic acid, whereas American styrax has a typical balsamic odor masked by a styrene-like odor. On distillation, both types of styrax yield an essential oil which is widely used in perfumery. Styrax is also used in pharmaceutical preparations, particularly in bronchial medicine.

Peru and tolu balsams Peru and tolu balsams are oleoresins, obtained as exudates from the *Myroxylon* tree, which is native to Central America and northern parts of South America. Balsam of Peru is obtained from *Myroxylon balsamum* var. *pereiraie* (syn. *M. pereirae*), a tree of Central America. Balsams contain benzoic or cinnamic acid and are highly aromatic. True balsam contains much less oil than turpentine. Balsam yields essential oils on distillation, which is used in perfumes as a fixative and in medicine as a mild antiseptic for treating cutaneous disorders and in the preparation of expectorants.

Copaiba Copaiba is obtained from certain Amazonian species of *Copaifera*. This resin yields copaiba oil on distillation. Crude copaiba balsam is a clear, pale yellow in liquid form. It darkens and becomes less fluid on prolonged storage or exposure to air. It is employed in pharmaceutical preparations, mainly as an antiseptic and anti-inflammatory agent. Copaiba oil is one of the ingredients used in shampoos, soaps, and cosmetics. While *C. guianensis*, *C. multijuga*, and *C. reticulata* are the principal sources of copaiba in Brazil, the major production in Colombia, Venezuela, and Guiyana is from *C. officinalis*.

Elemi Elemi is a resinous product obtained from *Canarium* species in the Philippines and Manila. Manila elemi is soft and fragrant and is obtained from the trunk of *C. luzonicum*. Fresh elemi is oily and pale yellow or greenish in color, but becomes hard on exposure to air. It has a balsamic odor and a spicy, rather bitter taste. Distilled oil from elemi is used in the perfume industry. It is also one of the ingredients in the preparation of lacquers and varnishes.

Gum resins These are mixtures of gums and resins and exhibit the characteristics of both. Gum resins also contain a small amount of essential oils and are usually produced by plants of dry arid regions. The important gum resins are gambose, asafoetida, myrrh, and frankincense.

Asafoetida This plant exudate is obtained from *Ferula asafoetida* species, which occur in Afghanistan, Iran and Turkey. The product is obtained by cutting the stem of the shrubby plant close to the ground (prior to the flowering stage) to expose the taproot. A small quantity of latex exudes and this is collected every few days. Sometimes the root is sliced every few days to produce more exudate. Asafoetida has a strong odor and a bitter acrid taste due to the sulfur compounds present in the essential oil. It is used throughout Asia in spice blends and as a flavoring agent for meat sauces, pickles, curry and other food products, and as a medicine. Since it is so strong in taste and odor, asafoetida is often blended with diluents such as starch and flour and is sold in compounded form.

Galbanum Galbanum is obtained from *Ferula galbaniflua*. The natural distribution of this species is in Iran and northwest India. The oleoresin is obtained by making an incision or cuts on the stem and the resultant exudate is an orange-yellow gummy fluid, which hardens on exposure to air. Like asafoetida, it is also often mixed with extraneous matter. It has a tenacious and powerful aromatic odor. The essential oil contains a number of sulfur compounds. It is used in medicine as well as to a limited extent as a perfume fixative.

Gambose This is a hard, brittle, yellow gum resin produced by several species of *Garcinia,* specially *G. hanburyi* of Siam and Indochina and *G. morella* of India. It is used to color golden lacquers, as a watercolor pigment, and in medicine.

Myrrh This is the myrrh of antiquity, used in incense, perfume, and in embalming. One of the oldest and the most valuable gum resins, it occurs in two forms. The first type is derived from *Commiphora myrrha*, a large shrub or a small tree of Ethiopia, Somalia, and Arabia. The second type is sourced from *C. erythraea*, an Arabian species of similar appearance.

Frankincense or olibanum A fragrant gum resin obtained from the stems of *Boswellia* species, specially *B. carterii*, native to northeastern Africa and the southern coast of Arabia, its principal use is as incense in Roman Catholic and Greek churches.

Latex

Natural latex is a hydrocarbon polymer obtained from the sap of a number of plants. It is usually white, but rarely buff-yellow to grayish in color. Latex contains 30–40% rubber and the rest are nonrubber constituents such as proteins, amino acids, starches, sugars, organic acids, resins, gums, tannins, pectin, and minerals. Nonrubber constituents stabilize the rubber particles, which are otherwise in a state of continuous motion known as Brownian movement. Further details on the history and production of latex are given elsewhere (*see* **Papermaking**: Paper Raw Materials and Technology).

Palm Oil

History

The history of palm oil can be traced back to the days of the Egyptian pharaohs 5000 years BC. It has been used for a very long time for food, medicine, and industrial purposes. The palm oil of commerce is obtained from fruits of the tree *Elaeis guineensis*. This species is a native of West Africa and was introduced to Malaysia in the beginning of the twentieth century. Most of the introduced plants in Malaysia were obtained in 1884 from four palm trees growing at the botanical gardens in Bogor. Commercial production started in 1917 in Malaysia. Indonesia and the Philippines have also started massive palm oil plantation programs.

Next to soybean, palm oil is the most important vegetable oil in world vegetable oil trade. Tree species such as *Cocos nucifera* (coconut) and *Elaeis guineensis* (African palm oil) are major species, which are commercially cultivated throughout tropical regions for palm oil production. Two types of oil are obtained from the palm fruit: mesocarp oil and endocarp (kernel) oil. African palm oil is a source of both types of oils, the mesocarp and the kernel each containing about 50% oil. Palm oil is also obtained from the following tree species:

- *Jessenia bataua* occurs in North and South America, including Panama and Trinidad. Its fruit is a source of oil. The composition of its oil is similar to that of olive oil.
- *Bactris gasipaes* (Pejibaye palm) has great potential as a crop in humid neotropics for starch, protein, oil, and carotene. Its mesocarp yields 40–60% oil on a dry-weight basis.
- *Attalea colenda* is a native of the coastal plains of western Ecuador. The oil content of the seed is 56.9% on a dry-weight basis. This palm oil has a high concentration of lauric acid. Its kernel is similar to coconut oil and kernel oil of African palm oil.
- *Phytelephas aequatorialis* (Tagua palm) the interior mesocarp has 22% fat, and is rich in linoleic acid (21%).

Uses

Palm oil is used in food, chemical, cosmetics, and pharmaceutical industries. It is considered best for manufacturing solid-fat products. Palm oil olein and stearin are used worldwide in making margarine, shortening, and confectionery, and in frying snack foods. It is a cost-effective option as it does not require an expensive hydrogenation process for solidification. Palm oil has a high content of natural antioxidants and its stability at high temperatures makes it excellent as a deep-frying medium. It also gives fried products a longer shelf-life, while its bland taste brings out the natural flavors of food.

Palm oil is also used in the manufacture of soaps, detergents, and other surfactants. It is a good raw material for producing oleochemicals, fatty acids, fatty alcohols, glycerols, and derivatives for the manufacture of cosmetics, pharmaceuticals, household, and industrial products. Oleochemicals manufactured from palm oil and palm kernel oil are now popular for the manufacture of environmentally friendly detergents as they are readily biodegradable.

Nutritional Value

Nutritional scientists have established that palm oil is cholesterol-free and does not require hydrogenation. Red and golden palm oil are the richest natural sources of carotenoids, including β-carotene, a potent antioxidant and precursor of vitamin A. Palm oils are natural sources of the antioxidant vitamin E constituents such as tocopherols and tocotrienols, which play a protective role in cellular aging, arteriosclerosis, and cancer. Further, palm oil contains linoleic acid, an essential fatty acid, which facilitates absorption and availability for use in the body.

Palm oil production

Each tree is capable of bearing about 10–12 bunches of fruit per year. The number of fruits per bunch varies from 1000 to 3000 in mature trees. The average weight of each bunch varies from 20 to 30 kg. The fruit-producing life of the palm is around 20–30 years. The average yield of palm oil is more than 3700 $kg\,ha^{-1}\,year^{-1}$ compared to 857 $kg\,ha^{-1}\,year^{-1}$ for peanut and 389 $kg\,ha^{-1}\,year^{-1}$ for soybean oil. World production of palm oil is 25.66 million tonnes. Malaysia and Indonesia palm oil production accounts for 20% of all world vegetable oil production. Some basic data on production, consumption, and world trade of palm oils are given in **Table 3**.

Table 3 World trends in plantation area, production, export, and import of coconut and palm oils

Parameter	*Palm oil*	*Coconut oil*
Area planted (million ha)	6.5	11.9
Production (million tonnes)	25.66	10.0
Export (million tonnes)	14.2[a]	1.16[c]
Import (million tonnes)	8.89[b]	1.3[d]

[a] Indonesia and Malaysia.
[b] Europe, Middle East, China, India, and Pakistan.
[c] Philippines.
[d] Europe and USA.

Future Directions

There has been a general decline in the use of latex and resins in the world in the last century. This is due to the preference of industry for raw materials which are of consistent, predictable quality and are not subjected to the vagaries of weather, insect pest, disease, and political stability in producing countries, and which are available at an attractive price. In many cases the synthetic alternatives meet these needs and are also technically superior to the natural products they replace. However, certain gums, resins, and latex are still being used, either due to their functional properties, which synthetics cannot meet, or due to their lower price compared to synthetics. These observations are, however, limited to the larger consumer markets at a global level and essentially the natural products described in this article do contribute enormously to local, regional, and national economies. Consequently, this group of non-wood forest products has great potential in alleviating poverty and in the sustainable management of natural forests in developing countries. Therefore, there is a need to maintain quality and improve it in order to retain and increase the markets of these natural products. This will require focused efforts to improve, standardize, and catalog the collection, harvesting, and postharvesting techniques. This will facilitate increased yields and minimum damage to forests, thereby adding incentives to collectors in terms of green and sustainable marketing. In conclusion, there are good grounds for optimism that, despite recent changes in global markets, there will continue to be a demand for these natural products. There are opportunities in the producing countries, provided due attention is given to aspects such as quality control of the product, equitable utilization, and sustainable management of the resource.

Rubber Trees

P W Allen, Harpenden, UK

Introduction

The forest tree *Hevea brasiliensis*, native to the Amazonian rainforest, has been grown in Asia and Africa for over a century to produce natural rubber, a raw material used for the manufacture of a range of products, especially tires. Production and export of natural rubber has played a major role in the socioeconomic development of the producing countries. Until the start of World War II natural rubber was the sole supply of an elastic material. Since the 1950s it has had to compete with a variety of oil-derived synthetic rubbers; nevertheless natural rubber has managed to establish good markets in products that require natural rubber's specific properties. The obvious environmental advantages which natural rubber possesses over the synthetic rubbers have never translated into financial advantage: both kinds have for decades suffered, like most industrial raw materials and agricultural commodities, from poor prices. Despite this, producing natural rubber remains the main and often the sole source of family income for millions of small farmers around the world.

History

Natural rubber is found in the form of latex in at least 2000 species of plants: these include *Hevea* spp., *Manihot*, and *Castilloa* from tropical America; *Landolphia* and *Funtumia* from Africa; and *Guayule* from Russia. There is only one rubber-bearing species of commercial significance – *Hevea brasiliensis* – a native of the Amazonian (mainly Brazilian) rainforest.

Hevea is widely distributed in the rainforest, a few trees per hectare, and rubber had been extracted by forest-dwellers from these trees for centuries for the manufacture of playballs and religious artefacts. During the eighteenth century several European explorers noted the existence of the tree and its product. In England, the eminent chemist Joseph Priestley observed the ability of the product to erase pencil marks and gave it the name 'rubber.' It is odd that this name has persisted in the English language for it relates to a property of the material that is of little use. The name in most other languages (e.g., caoutchouc, Kautschuk) is more apt, stemming from the Tropical American Indian *cachuchu*: 'weeping wood.' The older English name 'india rubber' represents a misunderstanding of rubber geography.

With the development in the mid-nineteenth century, mainly in Britain and the USA, of technologies (shaping, vulcanization) for converting the raw material into useful products, the demand for natural rubber started to grow so fast that the supply from Brazil was proving inadequate, despite savageries inflicted on forest rubber-gatherers, and the price was rising excessively. During the 1860s Sir Clement Markham of the India Office (UK), who had been responsible for transferring the quinine-bearing plant *Cinchona* from tropical America to organized plantings (plantations) in India, had the inspiration of doing similarly with *Hevea*. He commissioned two English botanists to collect specimens of *Hevea* spp. for study at Kew Gardens: they identified *Hevea brasiliensis* as the most promising. After several failed attempts to collect and ship seeds from Brazil, the British government commissioned Henry Wickham to make another attempt: he succeeded and brought some 70 000 seeds to Kew Gardens. Just over 2000 seeds germinated; some were sent to Ceylon (Sri Lanka), some to Malaya (Malaysia).

By 1890 *Hevea* seedlings were widely distributed, forming the basis of a major new industry, first in Asia, subsequently in West Africa. Production grew fast, stimulated by the invention of the pneumatic tire by John Dunlop in 1888 and arrival of the motor car.

Brazil has long ceased to be a major producer of natural rubber for a number of reasons, especially that attempts to establish plantations of *Hevea* have been largely vitiated by South American leaf blight, an untreatable fungal disease which has providentially not arrived in the main rubber-growing countries.

Producing and exporting natural rubber has played a major role in the socioeconomic development of the producing countries (**Figure 1**), providing much employment, inward investment, and importation of hard foreign currency.

Until the entry of the USA into World War II in 1942 natural rubber had no serious competitors. There had been some modest development of synthetic rubbers in the USA and Germany but these were expensive compared with natural rubber. Following the Japanese occupation of the rubber-growing areas in Asia, the USA embarked on a massive program (in size, second to the atom bomb project) to devise a major synthetic rubber (styrene/butadiene copolymer). During the next two decades, a number of synthetic rubbers, of different properties and prices, were developed and commercialized in many countries. Thus, from the 1960s natural rubber was faced with serious competition. Today (2002) natural rubber accounts for some 40% of the world market for rubber, having climbed back from a low of 30% two decades ago.

The Tree

In the wild the rubber tree can grow to over 40 m with a lifespan over 100 years. Because the economic life in plantations is 25–30 years, the final tree height is some 20 m. From planting, it requires some 5–7 years before a tree yields a useful amount of rubber and the yield of rubber will steadily rise to a maximum after about 15 years, and thereafter decline. Good practice is to replant after about 30 years.

The rubber tree is relatively robust, a reason for its suitability for small farmers. It does suffer from a number of diseases (mainly fungi), e.g., varieties of *Phytophora* attacking leaves and bark, and some root diseases, especially *Rigidoporus*. These are all treatable, albeit sometimes with difficulty and

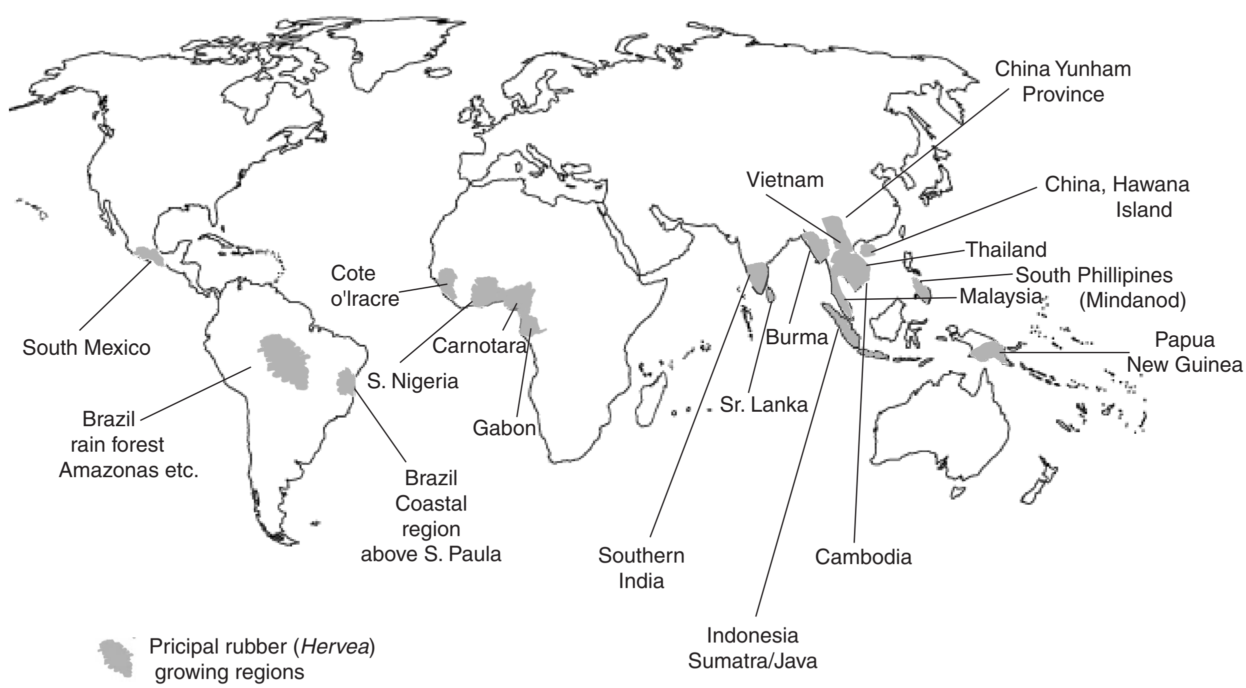

Figure 1 Principal rubber (*Hevea*) growing regions.

expense. Reference has been made to South American leaf blight (*Dothidella ulei*) for which no effective treatments have yet been found and has not yet appeared in the main rubber-growing areas.

The reason why *Hevea* and other rubber-bearing trees and shrubs produce rubber remains a mystery: various theories (e.g., wound healing) have been advanced but do not stand up to scrutiny.

The biochemical processes whereby the tree converts carbon dioxide and water into rubber have been fairly extensively studied, a number of intermediates (e.g., isopentenyl pyrophosphate) have been identified, and the basic pathway is more or less understood. It must be said that such work, though academically interesting, has not yet contributed to the well-being of the industry.

Breeding to Enhance Yield

As regards yield, the original importations into Asia yielded no more than about 500 kg ha^{-1}. There is a long history of work to enhance yields by breeding. In the early days of rubber growing in Asia, trees were replicated by growing from unselected seedlings; later, use was made of selected seedlings. Subsequently, from about 1920, largely from work by the Dutch in the former Netherlands East Indies, vegetative propagation from proven high-yielding trees by bud grafting became the standard practice resulting in the establishment of a number of well-characterized clones. The choice of a clone for a particular situation is a matter of judgment: some are very high yielders but oversusceptible to specific diseases or wind damage, etc., others yield less rubber but are more robust. Today, yields of around 3000 kg ha^{-1} are achievable under favorable circumstances, an almost 10-fold increase on nature.

The Producers

Traditionally, shortly after the original importations of *Hevea* into Asia, the normal way of growing and selling natural rubber was by establishment of large (>1000 ha) estates, owned by commercial enterprises, many of which were London-quoted companies especially in Malaya. Indeed, the impetus to establish such estates, from the early 1900s, was that it was a very profitable operation for the owners. During the past few decades growing and selling natural rubber became distinctly uninteresting compared with other investments: alternative crops (e.g., oil palm) gave better returns, so also did selling the land for industrial development or housing. Over the years virtually all the Western-owned estates have gradually withered away.

Parallel with establishment of estates, many small farmers (smallholders) in Asia and subsequently in Africa started to grow rubber on holdings of a few hectares; in some countries, notably Thailand, estates have never been a significant feature. It must be said that until the 1960s most observers of the industry disregarded the increasing dominance of the smallholder sector. Today, over 80% of natural rubber comes from smallholdings, a significant feature of the socioeconomic development of the industry. Rubber is in fact a very suitable crop for smallholders: it is very robust, will withstand much abuse and neglect, and is able to provide a modest family income.

As regards geography, in theory *Hevea* can be cultivated wherever conditions are similar to those in the Amazonian rainforest: high humidity, temperatures in the range 25–35°C, and rainfall not less than 5000 mm year^{-1}. The actual distribution is a matter of history, especially the former existence of British, Dutch, and French colonies in the tropics. Britain naturally sent the first *Hevea* seedlings to its then colonies in Southeast Asia; the Dutch to Netherlands East Indies; the French to Indochina.

Some 85% of production remains within Asia, especially in Southeast Asia where Malaysia, Indonesia, and Thailand have long been dominant: in recent decades China has become a significant producer. In Africa, Côte d'Ivoire, Nigeria, and Cameroon produce modest quantities; production in tropical America has been low and static for decades.

Production

Natural rubber exists in the tree as latex, a colloidal dispersion of rubber particles in an aqueous serum, contained in an interconnecting system of tubular vessels in the inner bark. It is extracted by 'tapping,' a semiskilled procedure involving paring away with a special knife a sliver of bark about 1 mm thick to a depth that just stops short of cutting the cambium layer. The first tapping opens up a 'tapping panel' which is developed by further tappings, working down the tree (**Figure 2**). Bark is renewed below the descending cuts. After some 5 years a new tapping panel is started, leaving the first panel to regenerate. There is a variety of tapping regimes such as 'half spiral, alternate daily' and there are other methods such as 'puncture tapping' involving making holes in the bark. Each has its adherents and critics. Whichever method is chosen, tapping is always carried out at dawn, when latex flow is fastest (**Figure 3**). The latex is collected in cups and then amalgamated into buckets to be taken to the collection center. Yields can be enhanced by use of ethylene-generating yield

Figure 3 Rubber tapper at work. Photograph courtesy of Tun Abdul Razak Research Centre.

stimulants applied to the tapping panel. This technique, devised in the 1970s, is now widely used.

Production of natural rubber by tapping *Hevea* is inevitably very labor intensive. In Western eyes this might seem a grave disadvantage but employment opportunities in most producing countries are often somewhat limited. Against this, in some producing countries the recent growth of new industries has started to encourage people, especially young people, to move from the growing areas into the cities. In Malaysia, for example, it has become increasingly difficult to maintain production on small farms. Nevertheless, over the decades growing and exploiting *Hevea* has been a major engine of growth in the producing countries.

Processing

One may distinguish between primary processing which produces 'raw rubber' for conversion into rubber products such as tires, and those processes that convert raw rubber into products. The former is undertaken close to the trees; the latter may be within a rubber-producing country or other countries which have imported raw rubber. Most raw natural rubber is exported.

Primary Processing

The latex from the tree contains about 30% rubber. Some 90% of production is converted into 'dry rubber' by coagulating the latex with formic or acetic acid. Until the 1960s most coagulated rubber was dried in smokehouses to produce 'ribbed smoked sheet' which was sold in various qualities dependent on appearance. This procedure, which seems quaint today, has been gradually superseded by the introduction by Malaysia in 1965 of technical specifications (Standard Malaysian Rubber), stimulated by competition from synthetic rubbers. At the same time, new processing techniques were introduced whereby the coagulated rubber is granulated, dried, and compressed into bales. The Malaysian initiative was rapidly followed by most other producing countries.

Natural rubber is also marketed in another form: latex concentrate, produced by centrifuging latex to increase the rubber content to about 60% so as to minimize the cost of shipping rubber in liquid form. This material is used to manufacture items such as gloves and condoms.

Conversion into Products

'Raw rubber' whether natural or synthetic is a soft rather weak material of little use until it has been 'vulcanized,' a process that introduces crosslinks between the very long molecules of which all rubbers are composed. The crosslinks comprise sulfur atoms: vulcanization involves mixing raw rubber with sulfur and various other chemicals (vulcanization agents, anti-aging chemicals, etc.) plus, usually, carbon black to impart extra strength. The resultant mix is shaped, for example in a mold or by extrusion and simultaneously heated to about 150°C for a period of time sufficient to achieve vulcanization.

Products made directly from latex concentrate, such as gloves, are made by dipping porcelain formers into the latex with its mix of added chemicals, drying and simultaneously vulcanizing, and then stripping off the product.

Markets and Competition

The term 'rubber' does not denote a unique chemical composition as does, for example, 'water.' Rubbers are a group of materials distinguished by elasticity – the ability to be stretched many-fold and to return more or less to the original size on removal of the stretching force.

In fact, natural rubber and the majority of synthetic rubbers do have much in common. All are long-chain high polymers with molecular masses around 1 million. Most are related to (but not synthesized from) butadiene, an unsaturated molecule with four carbon atoms. Replacing, hypothetically, one hydrogen atom in butadiene with a methyl group (CH_3) gives isoprene and natural rubber is a polymer of isoprene: *cis* 1.4 polyisoprene. Replacing a hydrogen atom with a chlorine atom gives the synthetic rubber polychloroprene. Some synthetic rubbers are copolymers: the most important synthetic rubber, in terms of tonnage, is a copolymer of styrene and butadiene. There is a synthetic replica of natural rubber. This has not proved to be a threat to natural rubber's markets, despite earlier fears: it is expensive to produce and its properties do not quite match those of natural rubber.

Competition

From the above it will be understood that there is a range of synthetic rubbers. Some are relatively inexpensive general-purpose rubbers; others are very expensive speciality rubbers used when their unique qualities, such as ability to resist very high temperatures as in, for example, gaskets in aero engines. The former group compete with natural rubber; the latter do not.

To give one example, the most important synthetic rubber – styrene/butadiene copolymer – has properties very suited to use in the treads of car tires, imparting good skid resistance. This synthetic rubber has entirely supplanted natural rubber in this application. Before the arrival of radial-ply tires, natural rubber had virtually ceased to be used in car tires. In radial-ply tires, the technical demands on sidewalls require use of natural rubber (**Figure 4**).

There has thus developed during the last few decades a reasonably clear view as to what rubber to use in a particular application: there have been winners and losers.

There was a time, around the 1960s, when some supposed that natural rubber would cease to be of any significance, that it would wither away. This has not happened, partly because of intelligent reactions by the main producing countries but – more importantly – because natural rubber has been endowed by nature with some unique qualities. It has very high resilience, indicating low heat build-up in tire carcasses; it has excellent strength at high temperatures which is why it is the material of choice for aircraft tires; it has excellent fatigue resistance. It is especially suitable for high-performance applications, and a number of new markets have been opened up from this, such as natural rubber/steel laminates used to isolate buildings from vibrations, including the protection of buildings against earthquake damage. Also, as noted natural rubber retains a good foothold in the tire market, to the extent that over 70% of natural rubber goes into the manufacture of tires.

Prices

Bearing in mind that several million small rubber farmers rely on selling their output to provide an income for their families, the price they receive is obviously of prime importance; sadly, the price history of natural rubber has been dismal for the past several decades. The same is more or less true for other agricultural commodities.

Natural rubber, like all agricultural commodities (and oil), is sold on the open market, receiving whatever price is, more or less, determined by supply and demand or, to be more precise, by buyers' and sellers' expectations as to future trends. The main markets are Singapore, Kuala Lumpur, London, and New York. As with stock markets, short-term price movements are essentially irrational, affected by rumors rather than by facts. This makes life hard for small farmers because they face fluctuating incomes.

Several attempts have been made to stabilize and if possible enhance prices. The Stevenson Scheme (1922) planned to restrict output but, since it was a British government initiative, its effect was limited to Malaya and Ceylon: it did succeed in raising the price but engendered fury among major consumers, especially in the USA. The Rubber Regulation Scheme of the 1930s, involving quotas for production, worked to an extent but was terminated by World War II. A much more ambitious scheme, launched under UN auspices from the 1970s but now terminated, was based on the creation of a buffer stock whereby rubber would be bought or sold from the buffer stock with the intention of stabilizing the price: this did not achieve what was expected by the progenitors.

Measures to Combat Low Prices

The natural rubber producers – and their countries – have realistically come to understand that there are no simple formulas for stabilizing and enhancing prices; that they must take actions on their own.

The obvious routes to helping the producers to derive a decent income are (1) to minimize production costs, for example by encouraging use of high-yielding clones, and (2) to establish new applications for natural rubber. In some but not all producing countries the first approach has been moderately successful: a small farmer with a reasonable area of rubber (around 10 ha) can make a reasonable living, whereas with a smaller area and low-yielding trees the income will be very poor. Use of intercropping also helps; growing other crops or even keeping animals such as goats between the trees can help to support the small farmer.

Much effort over many decades has gone into attempts to establish major new uses. Some – for example the use of rubber in road surfacing materials – turned out to be overly ambitious and unsuccessful, from which the lesson was learnt that it is better to establish a number of low-tonnage new applications that require natural rubber's unique properties. A number have been successfully developed.

The general strategy adopted by the major rubber-producing countries has comprised (1) to aim to enhance the incomes of the rubber farmers by various means, and (2) to improve the contribution of the overall rubber industry (the raw material and products therefrom) to national economies, recognizing that this strategy will not directly nor immediately benefit the farmers.

A relatively recent development is 'downstream manufacturing': establishment of rubber products factories in the producing countries, thus adding value to the raw material, creating new, skilled jobs, and enhancing national incomes. Malaysia has been especially active in this area, and to a lesser extent so also has Thailand. Rubber products, many of high technical content, are now being exported around the world.

Rubber Wood

Until the 1980s it was normal practice to get rid of rubber trees at the end of their economic life by using them as fuel, either domestically or for burning in smokehouses. It then became recognized that wood from *Hevea* had value in its own right as a medium-grade hardwood suitable for use in, for example, inexpensive furniture. Trade in rubber wood has become an important way of generating additional income for the producers.

Research

Since the 1920s most natural rubber-producing countries have established public sector research institutes whose activities range from agronomics, including extension services for small farmers, to product development work. These institutes are linked together by the International Rubber Research and Development Board, thus enabling effective communication between researchers in the producing countries. In addition to coordinating research programs, the Board has successfully raised large sums of money to operate international research and development programs ranging from agronomy to product design and development.

Final Comment

Professor Richard Shultes, the distinguished Harvard Professor of Botany and leading authority on tropical plants of economic value once wrote:

> No single of species of plant has, in the short span of 100 years, so utterly altered life styles around the globe as *Hevea brasiliensis*.

Seasonal Greenery

A L Hammett and M A Murphy, Virginia State University and Technical Institute, Blacksburg, VA, USA

Introduction

For generations, a multitude of non-wood forest products have been extracted from forests to supplement incomes and diet sources. Here we define non-wood forest products (NWFPs) as biological produce found in forests such as edible plants, medicinal and dietary supplements, decorative or floral products, and specialty wood products. Commonly collected edible forest products include mushrooms, herbs, and spices. Several plants are processed into medicines for household and local consumption and, more importantly for international markets. Decorative NWFPs include vines, ferns, and other plant products used for floral arrangements, dried decorations, and ceremonial or religious ornaments (**Figure 1**). Specialty wood products include handicrafts, carvings, turnings, utensils, containers, and crafts. For many landowners and forest dependent communities NWFP options diversify and complement traditionally timber-based forestry operations (**Figure 2**).

Figure 1 Examples of wreaths, boughs, and trees displayed for sale.

Figure 2 Example of a typical North American Christmas tree plantation.

In the USA, Canada, and several European countries, the Christmas tree trade flourishes during the months leading up to the holiday season. Several countries have an emerging Christmas tree trade including Japan, Ecuador, and Mexico. Closely tied to this trade is the cutting and sale of seasonal greenery. Often the greenery is produced from branches or branch tips which are the by-products of pruning necessary to shape trees so they are ready for market. In many instances, greenery is collected by cutting tips of branches in natural or planted

Figure 3 Tree farmer trimming branches and shaping a Christmas tree.

Figure 4 Floral wreaths and boughs displayed for sale.

forests (**Figure 3**). These tips are fashioned into wreaths for hanging on doors or walls, tied in roping sometimes 20 m long to drape over doorways or along railings, and tied into short 60–120 cm swags to decorate rooms or lamp posts during the winter season. In North America and Europe, local and regional markets are well developed, readily accessible to local producers, and offer opportunities for adding value to forest resources (**Figure 4**). However, recently the South America and Asia regions have emerged as greenery producers and markets for Christmas trees and greenery products. Increased markets for greenery products warrant further examination for impacts on forest management and the potential for economic development.

History of Greenery Use

Since the use of seasonal greenery is tied to the tradition of the Christmas tree it is important to review its history. The tradition of decorating a holiday tree began with Northern European tribes in traditional festivals and religious rituals to induce the return of the sun. The oldest record of Christmas tree use came from the early to late sixteenth century. A 1605 diary found in Strasbourg, France mentions a decorated tree, while in 1531 also in Alsace, there was mention of Christmas trees being sold in local markets and set up in homes. Several sources credit Martin Luther as being the first to decorate an indoor tree. He mentioned that after a walk through a forest of evergreens with shining stars overhead, he tried to describe the experience to his family and showed them by bringing a tree into their home and decorating it with candles. First evidence of a lighted tree appeared more than a century after Martin Luther's death in 1546.

Using greenery for holiday decorations is closely tied to the traditional Christmas tree. Greenery was brought into homes and places of worship as part of these ceremonies during the sixteenth century. Evergreens were the symbol of life because they do not die back over the winter – a feeling still commonly shared. Perhaps the first use of greenery documented was in Austria and Germany during the seventeenth and eighteenth centuries, where the tops of evergreens were cut, hung upside down, and decorated. The first holiday greenery use in the USA was in the German Moravian Church's settlement in Bethlehem, Pennsylvania during 1747. Wooden pyramids covered with evergreen branches were decorated with candles. The public display of decorated trees and seasonal greenery is now commonplace in several countries outside North America and Europe.

The Greenery Trade

Christmas trees are sold primarily in domestic markets as the trees are large, and difficult to keep fresh when shipping to distant markets in time for the Christmas holiday. The focus here is on greenery and greenery products, an NWFP that seems more suitable for more diverse and distant markets (**Figure 5**).

Holiday greenery products include wreaths, roping, door swags, and boughs or other hangings produced from evergreen or holly (*Ilex*) species. Some of these products are accented with dried flowers or cones, ribbons, or other decorative treatments. Since the whole tree is not harvested, greenery provides a seasonal source of income, while assuring the sustainable management of forest resources. Specialized greenery grown and harvested under forest cover in subtropical areas supports a large industry supplying accent material for floral

Figure 5 Example of decorated wreath and bough.

arrangements. For this article, we will concentrate on products that are produced from tips and branches of conifer trees – such as pine boughs – and assembled for Christmas and winter decorations.

Finding Greenery Markets

Greenery operations seem appropriate for small enterprises as the level of processing and marketing needs are low. Before starting a greenery enterprise one should first consider the size and location of markets. Visits to tree farms where raw materials may be gathered, trips to observe nearby and regional markets, and meetings with buyers of decorative products are important. It is important to note prices, sizes, how greenery products are assembled, appropriate decorative accents (ribbon, dried cones, etc.) that may be added to suit customer desires. The internet is increasingly a reliable source of information on products and competitors. Many small producers serve distant customers through website sales.

Planning for shipping is very important as greenery is perishable and needs to be delivered fresh. Producers need to harvest, stock, and transport their products in a timely fashion. Customers seek fresh (no needle drop) full-shaped greenery products in dark green colors. Labeling with species, care, and source information helps customers understand the product is high quality and fresh.

Once the holiday marketing season is over, leftover greenery stock often cannot be sold. To ensure extra greenery is not harvested some producers take advanced orders for club or civic organizations' fund-raising projects, and mail out brochures with order blanks or use a website to assure sales in advance. To help preserve freshness greenery products are often packed and shipped by express or overnight services. One small producer in the Appalachian Mountains sends much of his production several hundred miles to the New York City market.

There are two common ways to sell seasonal greenery – direct to the customer or through wholesale channels to greenery-product producers. For producers willing to invest time to cut and make greenery products themselves, direct sales through mail or visits to Christmas tree farms are common. Direct sales are effective in helping to learn customers' needs and how to increase markets. Taking orders from customers in advance helps producers plan for labor, raw materials, and shipping arrangements, and customers can be assured of fresh, high-quality products on a promised date. Recently, agrotourism or other promotional programs have drawn urban customers to visit farms where they learn about forestry, cut their own Christmas tree or greenery, and see first-hand how greenery products are made.

Selling greenery in large quantities to wholesale buyers as a raw material is a viable alternative. For instance, several large wreath manufacturers buy in bulk from landowners, or will send a crew to cut greenery under harvest contracts. However, such production of large volumes takes careful planning considering tips should be kept cool and moist until used to make wreaths and other products. It is preferred to have a contract to protect the producer and the landowner.

Cultivating an evergreen plantation with the goal of harvesting seasonal greenery can be very productive, environmentally sound, and economically beneficial. These plantings may help reclaim fallow land, prevent soil erosion, provide buffer zones to agricultural and other land uses, and serve as excellent cover for wildlife. Greenery plantations often require only small initial investments for planting, annual care, and harvesting, and their management involves few tools and equipment common to agricultural enterprises. Clearly harvesting greenery for making wreaths, boughs, sprays, roping, and other decorative purposes is a viable, often profitable, forest-based enterprise.

Species Used for Seasonal Greenery

Cut greens constitute a large share of the decorative floriculture market. In the USA alone, yearly sales of cut greens are estimated at US$2–3 billion. However, there are several countries that produce Christmas trees and seasonal greenery. The US-based National Christmas Tree Association has members from both Canada and Mexico as well as from Germany, the UK, and Australia. Production in Germany, Denmark, and Mexico serves as an example of an ever-broadening forest products sector. A study by the Food and Agriculture Organization of the United Nations (FAO) of conifer-based non-wood forest products reviewed greenery production in these and other countries. In Germany, boughs are produced from noble fir (*Abies procera*) and white pine (*Pinus strobus*) in forests managed to produce both timber and Christmas boughs. Douglas-fir (*Pseudotsuga menziesii*) and Norway spruce (*Picea abies*) are planted with beech (*Fagus sylvatica*) in mixed plantations.

In Denmark, greenery is produced from Nordmann fir (*Abies nordmanniana*) and noble fir – both cultivated for ornamental foliage. According to the FAO, Denmark is the largest European producer, with an annual yield of 27 000 tonnes of ornamental foliage, exporting most of these products to Germany, Austria, Sweden, and the Netherlands.

Mexico has an important seasonal greenery market. The sacred fir (*Abies religiosa*), known to the people of Mexico as *oyamel*, *abeto*, or *arbolito de Natividad*, grows in forests at elevations between 2700 and 3400 m. Both the scientific name and the common name of this tree originated from a tradition of the Mexican people gathering the branches of this tree to decorate churches and homes during religious festivals. The greenery laden forests in the state of Michoacan are the over wintering site for the migrating monarch butterfly (*Danaus plexippus*).

The US greenery industry utilizes several evergreen species, each desirable and successfully marketed for different purposes. Depending on the location, growers may have a choice of species, producing a variety of products. Species most commonly harvested for greenery include long-needled pines Austrian pine (*Pinus nigra*), red pine (*P. resinosa*), Scotch pine (*P. sylvestris*), Virginia pine (*P. virginiana*), and white pine (*P. strobus*). In the central and northern Appalachian regions, white pine is desirable due to its vivid green color and ability to stay fresh for longer periods than other species. In addition to harvesting pine and spruce species for holiday greenery, northern white cedar (*Arbor vitae*), pond cypress (*Taxodium ascendens*), dwarf juniper (*Juniperus communis*), holly (*Ilex opaca*), dwarf mistletoe (*Arceuthobium pusillum*), and laurel (*Kalmia latifolia*) are also popular.

Pines are popular because they grow quickly, in a wide range of climates and on most soils, and they are more drought resistant than many other greenery species. Firs, as well as spruces, grow well further to the north in the boreal zones of the USA and southern Canada. They have shallow roots and like the coolness and moisture content of north-facing slopes. However, several species that have early spring growth are vulnerable to late frosts.

Greenery production techniques are covered in more detail in several of the publications listed in the Further Reading section.

Opportunities for Income from Greenery

Greenery harvests provide interim income during the period between timber crops. Landowners can benefit from incorporating greenery production into existing activities. Greenery provides additional income from Christmas tree production, as pruning during shaping provides raw material for products such as fragrant Christmas and holiday wreaths, sprays, roping, and decorative centerpieces. As with other non-wood forest products, landowners may profit more from managing for greens and greenery products than from growing only Christmas trees. In addition, several other raw materials can be incorporated into greenery products. For instance, value can be added to corsages of evergreen when they are accented with a dried cone or berries, and then easily shipped to distant markets.

In Denmark, Christmas trees and greenery production are valued at US$38 million year. Because of the wildlife habitat created in the plantations, hunting values are also enhanced. In one study, forest landowners' greenery production combined with hunting revenue produced more income than from timber harvested.

Value added opportunities abound. Small, plastic bags of evergreen tips can be sold to decorators. Some enterprising growers market do-it-yourself wreath kits. Each kit will include fresh greens, a metal ring, metal wire, a length of ribbon to add color, and a few pine cones with instructions to build a wreath.

In the past few decades, wholesale prices have risen in the US market for both decorated and undecorated wreaths. Decorated items with artistic detail demand higher prices. Hand-produced items would seem ideal products for developing countries to market to local tourist and export markets. Landowners in boreal and temperate zones could develop new products simply by adding plantations of greenery species.

Additional by-products from greenery production offer year-round income opportunities. Scented pillows and air freshener products are made with dried greenery such as very aromatic balsam fir (*Abies balsamea*). Some firms produce greenery extracts for medicinal and cleaning products.

Opportunities for Increased Greenery Production

A greenery plantation may not be limited to a rural setting. Some urban renewal programs are encouraging Christmas tree plots and income generation projects in large urban areas in the USA such as Detroit and Baltimore.

Those who do not own land may also participate in this potentially lucrative enterprise. Forest lands may be leased for cutting greenery, and cultivation of greenery species.

Greenery raw material may also be close at hand and readily available in unique ways. Some producers collect tips and branches from forest stands prior to a scheduled timber harvest. This raw material would be destroyed and wasted as a result of timber harvest operations.

Agroforestry operations should lend themselves very well to greenery production. Planting desirable greenery producing species with other timber species and agricultural crops may offer additional income sources and product diversity. Establishing a buying cooperative will help with initial raw material consolidation and quality control, and will facilitate economies of scale for processing. Pooling resources of small greenery producers may help them access remote markets.

For example, Christmas tree production and sales in Ecuador have grown recently. Greenery would be a natural complement to this industry and to the country's huge cut-flower export trade. Ecuador has increased its production for cut flowers that are exported to regional and distant markets. It seems that countries such as Ecuador could well benefit from complementary products such as greenery sold to the same markets.

Emerging Issues

For those countries with coniferous forests, harvesting greenery and other related NWFPs could prove very lucrative. For those areas where previous forest cover is degraded or removed, planting evergreen plantations with their potential benefits should be considered.

However, greenery production should not be considered by many landowners and communities. One emerging issue for greenery producers is fire safety. After natural greenery becomes dry and brittle, it is more flammable and the risk of fire increases. With adequate product labeling and chemical treatment during processing, this danger can be greatly diminished.

Partly as a result of the perceived fire risk, natural greenery now has competition from substitute material. Some customers feel that the safety risk is enough to warrant purchasing flame-retardant greenery made of vinyl, metal, or other artificial materials. These materials can resist ignition and flame spread, perhaps have a 15–20-year lifespan, some are claimed to be made from recycled materials, and may be stored from year to year. However, their purchase price is higher, and they lack the natural aroma and ambiance so popular with natural greenery. There are now techniques that can preserve seasonal greenery extending its market potential.

Another problem is that the greenery business is labor intensive and sometimes not perceived to be equitable or fair. Many migrant workers move to high-production areas to make holiday garlands and wreaths, between mid-October and early December. During this heavy workload season, cutters climb trees and cut pine branches, which ropers feed into sewing machine devices that rope the branches together. Most laborers work for contractors who pay them piece rate wages, for each pound of pine branch limbs handled. In some cases it is alleged that operators do not pay adequate wages and hence can afford to undercut their competitors' prices.

Ergonomics

E Apud and F Meyer, University of Concepción, Chile

Introduction

Ergonomics is mainly oriented to the adaptation of work to the human being in order to obtain an adequate balance between workers' well-being and productivity. In forestry, there are two important aspects in which ergonomics can make useful contributions. One is the adaptation of heavy manual work. In this kind of job, a man using simple manual tools supplies most of the energy required to carry out his work. The opposite side is represented by mechanized work where human energy is replaced by machines. The workers become progressively more sedentary limiting their activities to perceiving and interpreting information and then executing their decisions with light muscular actions, usually highly monotonous and repetitive.

One aspect that is important to highlight is that forest work has evolved in a different way in developing and industrialized countries. In most developing nations, a high proportion of forest work is done using labor-intensive methods, while in most industrialized countries forest work is carried out using advanced mechanization. In the two types of work, ergonomics has a different approach, but based on a common root which is illustrated in **Figure 1**. This figure shows for two very different activities, such as barking logs manually and sorting logs with a forwarder, that in both cases workers perceive information from the surrounding environment, make decisions, and execute them through mechanical actions. Although the basic scheme is the same, the demands of the work are completely different; the decisions of the manual worker are simple but the physiological demands are high, while the operator of the forwarder makes a minimal physical effort but the complexity of his decisions are significantly higher. In both cases, independent of the kind of work, the workers are in a continuous feedback loop with their jobs, perceiving information, interpreting, deciding, and acting through mechanical actions to let the process flow. Ergonomic design should allow them to fulfill each stage of their job safely and efficiently, no matter whether the activity is manual or mechanized.

The previous description corresponds to the interaction of the man with his tool or machine. However, forest work is carried out in a physical environment where workers can be exposed to heat, cold, noise, and mechanical vibrations. These agents, when they exceed certain limits, may alter physical

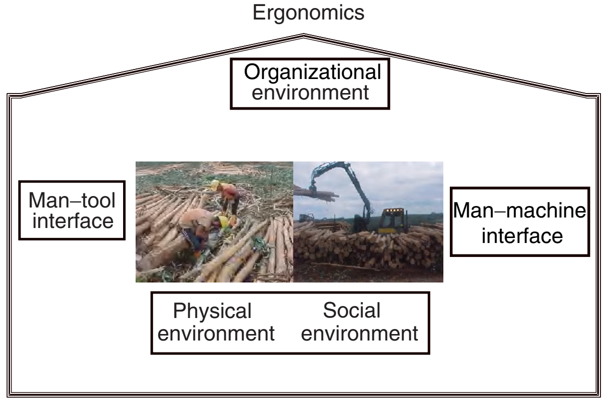

Figure 1 The ergonomic approach to manual and mechanized work.

and mental health and well-being. Some of them originate in the tools and machines, like for example noise and vibrations, while others, such as heat and cold, may have their origin in the environment. Although these agents may be present at levels that do not produce any disease, they may be the cause of occupational stress leading to psychological and physiological strain.

From the ergonomic point of view, there are other factors that are not related to the work station or the physical environment, but to the organization of the system in which each forest task is situated. Therefore, the modern concept of ergonomics considers the activities of a worker as part of a system which, as a whole, has to be efficiently designed. Work processes have an entrance and an exit, passing through a variable number of intermediary stages, where human beings interact with tools and machines to achieve their goals. This way of approaching forest work may be highly efficient, as human adaptation is suited to a multidisciplinary approach, with the participation of the workers and the managers who have the responsibility for planning and optimizing forest work.

One further aspect that cannot be ignored within the framework of ergonomics in forestry, particularly in developing countries, is the social environment. Forest work is usually carried out in isolation far from urban areas. Often, the workers have to remain in forest camps, not by choice. In such cases, forest camps become their temporary homes where they have to stay for different periods of time without the opportunity to choose their own options for food, recreation, or even sleep. Hygiene, privacy, and tranquility are basic requirements for these workers' well-being.

This is a brief synthesis of the purpose of ergonomics. As a summary it can be said that ergonomics provides integrative criteria for the solution of the problems of forest workers, both in manual and mechanized work.

Labor-Intensive Methods

Fundamentals for the Study of Heavy Manual Work

Most manual operations in forestry work are heavy. This statement is supported by a number of publications in which energy expenditure and work load have been reported for forestry tasks. However, a high energy expenditure does not necessarily mean that every worker within a crew will be strained when performing a similar task. To support this argument, it is necessary to answer at least two questions: (1) What is heavy manual work? (2) How can we fix limits of work load for sustained work? The answers are not easy to find because there are many factors determining the heaviness of a job, partly depending on the difficulty of the task and partly on the physical fitness of the workers. In other words, to define the limit of work that can be sustained during a shift, the relationship between the energetic demands imposed by muscular work and the physical working capacity of the laborers has to be established.

Human energetic processes are classified as aerobic and anaerobic. In mild or moderate exercise, oxygen supplied to the muscles is sufficient to oxidize food and thus to provide all energy aerobically. However, if work becomes more demanding available oxygen may not be enough and part of the energy has to be released by means of anaerobic processes. It is known that anaerobic work leads to the accumulation of lactic acid and this is related to muscular fatigue. For this reason, most human physiologists nowadays accept that work should be considered heavy when anaerobic metabolism starts contributing significantly to the total energy release. The higher the participation of the anaerobic processes, the more exhausting the activity is and shorter is the time that the job can be performed without a rest pause. Afterwards, when resting, the aerobic metabolism remains elevated because a major portion of lactic acid is oxidized. This is the reason why, when carrying out anaerobic work, an 'oxygen debt' is contracted which has to be repaid during recovery. As energy metabolism depends on the utilization of oxygen, the measurement of oxygen uptake is a practical method to estimate energy expenditure. It is known that 1 liter of oxygen consumed is equivalent to an energy expenditure of approximately 20.3 kJ (4.85 kcal).

To define whether a job is heavy or not it is not only necessary to determine the intensity of the activity, but also to understand the concept of physical working capacity. From all the factors influencing the aptitude for manual work, nowadays the maximal capacity of the aerobic processes, also known as aerobic capacity or aerobic power, is accepted as an international standard of reference for studying the fitness of world populations. The aerobic capacity can be assessed by measuring or estimating the maximal oxygen uptake, which reflects the combined capacity of the cardiovascular and respiratory systems to obtain, transport, and deliver oxygen to the working muscles, as well as the efficiency of this tissue to metabolize oxygen.

Although the transition from aerobic to a combination of aerobic and anaerobic effort is not clear-cut, in most people doing dynamic work, lactic acid will accumulate at loads calling for an expenditure of no more than 40–60% of the aerobic capacity. The intensity of effort at which anaerobic work starts can be measured with different methods and nowadays is called anaerobic threshold or lactic acid threshold. Based on these findings it is accepted that a laborer, during an 8-h shift, should not be loaded on average at over 40% of his aerobic capacity. This will ensure that the work is carried out under aerobic condition or, more precisely, that the sum of heavy and light operations, after the complete shift, will not exceed this limit. This means that the rest pauses after heavy operations are sufficient to recover and that lactate will not accumulate. It has to be considered that manual labor, carried out for 8 h, varies in energy requirements and, therefore, the limit of 40% of the aerobic capacity is meant to be the average value obtained from heavy and light operations and rest pauses.

In studies of heavy manual forest work, measurements of energy expenditure and cardiac frequency are the most useful for field surveys. Common methods for measuring energy expenditure demand the isolation of all the operations carried out by a worker and the measurement of the time employed in each of them. Afterwards, oxygen uptake can be measured to estimate energy expenditure in each representative activity. It is not easy to obtain reliable information because it is difficult for the forest workers to accept repetitive measurements of oxygen uptake, specially if they are carried out for more than a few minutes in each activity. For that reason, when the purpose is to evaluate the work load it is preferable to measure cardiac frequency since it reflects the demands imposed by work on the cardiovascular system. It may be argued that cardiac frequency also increases when the subject is exposed to other agents, e.g., environmental heat, but in such cases, it is a better indicator of strain than energy expenditure. Cardiac frequency can be registered, during a whole shift, with simple noninvasive methods that do not interfere with the activity of the subject. Nowadays it is accepted that, as an average for an 8-h shift, the cardiovascular load should not exceed 40%. This is because, if the work is carried out in a temperate environment, there is a good relationship between cardiac frequency and energy expenditure, so one can assume that workers will perform as average under their anaerobic threshold. In cases where the work is done in a hot environment, this limit seems also a reasonable load for the cardiovascular system, in spite of the fact that the work is performed at a lower pace due to the heat.

On the basis of the criteria already discussed, systematic studies of workers' physiological responses have proven to be a powerful ergonomic tool in assisting work organization. A number of examples will be given to illustrate this statement.

Selection of Tools and Techniques: Medial Pruning as an Example

Pruning is becoming more and more important in commercial forests to obtain wood of high quality. This activity has the purpose of eliminating branches, cones, and epicornics in order to obtain wood free of knots. To make this job efficient, the worker must have a good technique. If a branch is not properly cut, occlusion will be delayed and the amount of clearwood will decrease.

Until a few years ago a common tool for pruning was a hook which for medial pruning, at heights from 4 to 6 m above ground, was supported by a pole 6 m long. The working posture was very poor and the neck of the worker was kept in a very uncomfortable position. His arms, supporting the tool, were kept high and he had to move them rhythmically to operate the sawing hook at the other end of the pole. All in all, this was a very fatiguing job. The workers complained of pains in the neck, shoulders, arms, and lower back. On the other hand, it is an ergonomic rule that the longer the distance from the work object, the greater is the risk of doing a job of bad quality. Therefore, pruning at a 6 m distance from the ground produced wounds or other defects in the cortex of the tree which delayed occlusion.

An alternative method is to use ladders which the workers fix to the trunk of the tree. Afterwards they climb and when they are close to the branches they proceed to saw them. The advantage of that method is that the worker can do his job close to the work object, which facilitates a better cut. Furthermore, the job is not as uncomfortable for the neck, arms, and shoulders which are kept in a more natural position. The main disadvantage of this technique is that the workers have to climb up and down the ladders, but when they are properly fixed, the risks of accidents are minimal.

Table 1 shows the results of the evaluations carried out to compare both techniques. The workers using ladders to prune could trim an average of 125 trees per working day, whereas the workers on the ground covered only 96 trees per working day. Very important, cardiac frequency was not significantly higher with the more productive method, even though tree trimmers had to climb up and down the ladder. This was because pruning from the ground required constant movement to maneuver into a position where the branches could be seen. Pruning from a ladder also produced a much better quality cut. The

Table 1 Mean values and standard deviations for cardiac frequency and output when pruning was carried out with the laborers standing on the ground using a long pole hook (Method A) and when the job was done with the workers climbing up a ladder cutting the branches close to the work object with a saw (Method B)

Variable	*Method A (n = 10)*		*Method B (n = 10)*	
	Mean	*Standard deviation*	*Mean*	*Standard deviation*
Cardiac frequency (beats per minute)	98	11.3	102	11.8
Output (trees per shift)	96	18.8	125	22.0

workers mentioned that they did not experience arm or leg fatigue, while neck and shoulder complaints were fewer. As can be seen the incorporation of a physiological variable to work studies may help to select productive alternatives less dangerous for the workers.

Scheduled Rest Pauses

When rest pauses are not properly scheduled, the trend is toward diminished output and, in some cases, to an increase in the physiological work load because of insufficient recovery. The following example is based on a study of pruning. In **Figure 2**, a follow-up of trees pruned per hour and cardiovascular load for the equivalent period is shown. As can be seen, work in the first hour of the morning starts with a high level of production and a relatively intense work load. As time goes by, the number of trees pruned per hour tends to decrease but the work load is maintained. In the last hour of the morning, the cardiovascular load increases significantly but the output of the workers decreases. In general terms, an increment of cardiac frequency with a reduction in the level of performance is a signal of fatigue due to the shortness of rest. A very common error is not to schedule the rest in such a way that the workers can take at least 15 min after 2 hours' work. Depending on the type of work sometimes it is even convenient to give 10 minutes of rest per hour. As a general rule, short and frequent breaks are more effective than long and spaced pauses. Of course, the decision has to be evaluated in the field.

To show an example of the positive effect of rest pauses, a study conducted in a group of workers delimbing trees with axes will be described. The workers cut branches without any rest during the whole morning. To evaluate the effect of rest pauses, breaks of 15 min duration were introduced at mid morning and mid afternoon. As can be seen in **Figure 3**, the output of those workers increased 16%, from 2.6 to 3.2 $m^3 h^{-1}$, while the cardiovascular load diminished from 35% to 33%. In other words, the good recovery allowed the workers to do more work with a slightly lower physical work load.

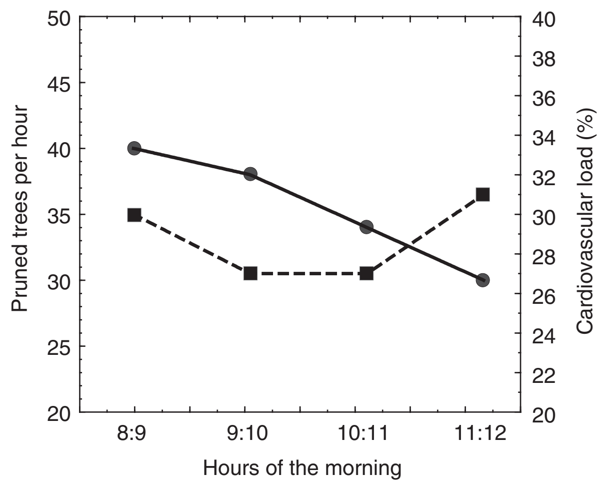

Figure 2 Average number of trees pruned per hour (solid line) and percent cardiovascular load (dashed line) as average of 10 workers controlled during the first 4 hours in the morning.

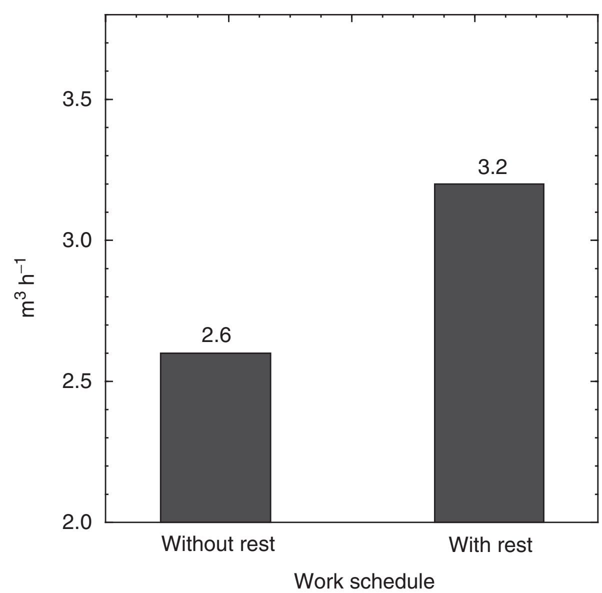

Figure 3 Average output ($m^3 h^{-1}$) and cardiovascular load (%) in a group of ax workers debranching with and without scheduled rest pauses.

Job Rotation

Another aspect which has been demonstrated to be very useful, when working conditions allow it, is to

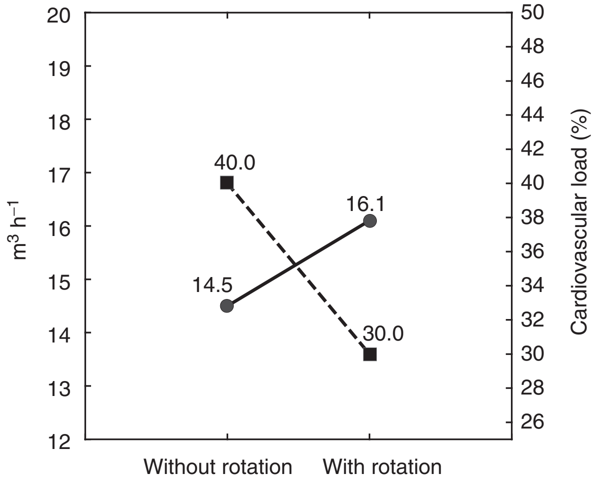

Figure 4 Average output ($m^3 h^{-1}$) (solid line) and percent cardiovascular load (dashed line) for a group of power-saw operators felling trees during the whole shift and rotating job with the power-saw operators who were doing cross-cutting in a log-yard. Rotation was done three times per shift (10 a.m., midday, and 3 p.m.).

introduce job rotation. Changing activities may reduce the work load for those doing the heavier part of the job.

A clear example is the work of power-saw operators felling trees in the forest compared to that of workers cross-cutting in log-yards. The first activity is far heavier than the second. Therefore, these are the sort of jobs that can be rotated. A good example is a study in which the chainsaw operators started working at 8 a.m. and rotated after 10 min rest at 10 a.m. Then they had 1 hour for lunch at 12 when they changed again and finally after another 10 min rest they rotated at mid afternoon. **Figure 4** shows that, with rotation between felling and cross-cutting, the physical work load was lower than when the workers were only felling trees, and their output was 11% higher.

Number of Workers per Activity

Different studies have shown the importance of the balance within working groups. Although harvesting can be fully mechanized (*see* **Operations**: Forest Operations Management), in many countries it is still carried out with manual tools. In some cases power saws are used for both felling and debranching while in others, axes are used to remove the branches. In this last case, it has been demonstrated that when power-saw operators work with only three ax workers, the work load for the latter can be extremely high, so the recommendation is to organize the work with four persons cutting branches with axes for each power-saw worker felling the trees. It has been shown that power-saw operators can increase their level of productivity, within reasonable levels of work load, if the crews are organized with the correct number of workers. For example, in the study illustrated in **Figure 5**, power-saw operators increased their productivity by 36% (from 11.1 to 15.1 $m^3 h^{-1}$) when they worked with four instead of three ax workers.

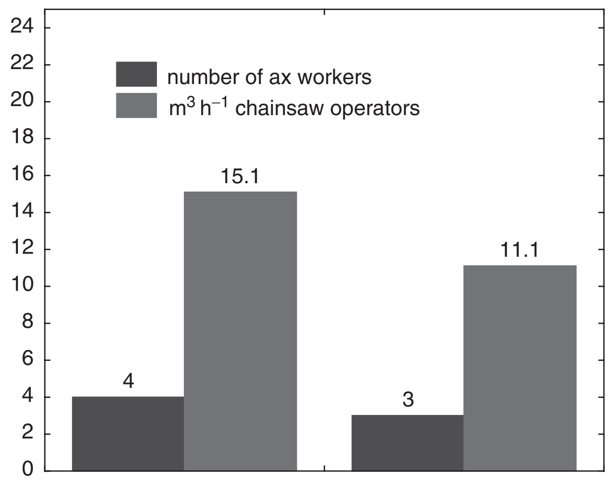

Figure 5 Performance of a power-saw operator felling trees when working with three or four ax workers debranching.

Standard Performance as a Basis for the Calculation of Salaries and Incentives

On many occasions it has been confirmed that forest work is a heavy task. However, the question is: How much is too much? To answer this question it has to be considered that output depends on the physical workload that a worker can reach in a sustainable way during his working life without fatigue or other risks and on the difficulties he encounters in carrying out his job, mainly related to type of trees, climate, and ground. In other words, in forestry it is not possible to demand of a worker that he always performs the same amount of work. This makes it difficult to calculate incentives and salaries, specially when workers are paid by piece rate. In the literature several functions for calculating output of different forest activities have been proposed, based on studies in which performance has been measured as well as physical workload and characteristics of the forests, ground, and climate. A brief example will be given from a study of power-saw operators cross-cutting in a log-yard. After a detailed statistical analysis it was found that around 75% of the variation in output of those power-saw operators could be explained by the average volume (AV) of the trees they cross-cut, the time devoted to the principal activities (PT), and the effort they did as judged by the cardiovascular load (%CL), according to the following formulae:

$$\text{OUTPUT}(\text{m}^3\,\text{h}^{-1}) = -7.5 + 0.16 * \text{CL} + 0.23 * \text{PT} + 8.1 * \text{AV}$$

Using the formula, **Table 2** was calculated to show the estimated variation in performance, for two levels of cardiovascular load, for 70% and 80% dedication to principal activities, and for trees of different average volume.

The idea of such tables is to show the companies and contractors that when salaries are paid according to the amount of work that the workers can do, they should consider carefully how much work they can really expect to be done. In a practical sense, with these tables a company engaging the services of a contractor and the contractor himself can plan his job considering part of the difficulties that the worker will find in the field. These tables can also be used to calculate basic salaries and incentives. For example, if a previous sampling of the forest shows that the average volume of the trees is $0.9\,\text{m}^3$, an average worker with a cardiovascular load of 30%, devoting 70% of the time to principal activities, should produce around $20\,\text{m}^3\,\text{h}^{-1}$. To reach this production a fair salary should be paid allowing the worker to fulfill his and his family's needs. Of course, a motivated laborer can still do more work without risk. **Table 2** shows that for the same forest with average $0.9\,\text{m}^3$ per tree, if the laborer devotes 80% of time to the principal activities and makes a higher effort at the limit of 40% cardiovascular load he may produce $24.2\,\text{m}^3\,\text{h}^{-1}$, which is nearly 20% more. So, to stimulate the laborer, incentives should be paid. Although to work at that level is still safe, we are talking of the higher limits of physical performance and that is not possible to obtain if the worker does not feel that his effort is recognized. It has to be warned that incentives should be discontinued over the higher levels given in the table since there are serious risks of fatigue, accidents, and work of poor quality when these limits are exceeded. On the other hand, the main limitation of the system is that we are talking of an average worker and not every human being is alike, so the tables cannot be used in a rigid way; they are more useful in calculating group incentives.

Table 2 Expected output for power-saw operators cross-cutting in a log-yard

AV (m^3)	*CL30%*		*CL40%*	
	PT		*PT*	
	70%	*80%*	*70%*	*80%*
0.3	15.5	17.8	17.1	19.3
0.5	17.1	19.4	18.7	21.0
0.7	18.7	21.0	20.3	22.6
0.9	20.3	22.6	21.9	24.2
1.1	22.0	24.2	23.5	25.8
1.3	23.6	25.9	25.2	27.4
1.5	25.2	27.5	26.8	29.1

AV, average volume; CL, cardiovascular load; PT, time devoted to principal activity.

Mechanized Work

Mechanization in forestry is increasing. The part of the work usually done with great human muscular effort is being replaced by machines. Although mechanized work is physically lighter it involves other risks for the machine operators, e.g., those derived from the working posture, the noise and vibrations produced by the machines, and also a noticeable increment of the mental work load. For this reason, job rotation and scheduled rest pauses are also very important for the machine operator.

The 'man–machine interface' is an imaginary plane across which information is exchanged between man and machine. Man receives information from the displays of the machines. In the use of forest machines the information that the operator obtains from the surrounding environment is also important. The signals received by the worker have to be interpreted based on knowledge which has to be acquired through previous training. In consequence, the laborer takes decisions which usually means decisions to operate the controls of the machine. In simple words, the operators are in a constant feedback with the machine 'perceiving–deciding–acting.' What is important is that at any stage there might be problems leading to errors which may result in accidents, health impairment, and inefficiency. Therefore, well-designed machines should allow the worker to see and perceive what is needed and they should also have well-designed controls so the worker can make fast and precise responses from a comfortable position. It is equally important that the worker should be trained for the correct interpretation of the information received.

We have illustrated very simply some of the facts that may impair the processes of perception, decision, and action in machine work. However, these are not the only problems faced by machine operators. In forest work, machines are used in the open air, where often the workers have additional stresses because of the climate and the terrain. Furthermore, machines produce noise and vibrations.

All the agents previously described can be quantified. However, the main problem is that when machines are not correctly built, it is easy to detect what is wrong, but is extremely difficult to modify the design, mainly because most of the modifications are very expensive and also because some of the required adaptations may produce other problems, leading to a vicious circle. In such cases 'remedy can be worse than disease.'

Foresters, administrators, and in general all those who plan technological innovation should consider not only cost and output but should also add basic concepts of the adaptation of the workers. However, this is easy to write but difficult to put into practice. At present there are ergonomic checklists for machines which allow the evaluation and selection of forest machinery. By definition they contain an ordered list of questions on different aspects to be checked when evaluating a machine. In current literature, several checklists are described for different purposes. Some of them are brief and concise and others are very detailed. Experts state that check lists do not substitute for knowledge; however, they may provide help which will be the more effective the more knowledgeable the user is.

Logistics in Forest Operations

B Dahlin, Swedish University of Agricultural Sciences, Alnarp, Sweden
D Fjeld, Swedish University of Agricultural Sciences, Umeå, Sweden

Introduction

Logistics concerns the organization of business operations in order to maximize the total benefit. Besides the flow of material (in forestry mainly wood), personnel, machinery, capital, and information are important factors. Different strategies may be chosen for the supply chain depending on the overall conditions. Harvesting operations in most of the industrialized world have changed from a seasonal activity to a round-the-year occupation. Due to uncertainty in the planning process a buffer in the wood supply needs to be met. This can be done by storing wood, but also by having an overcapacity in the harvesting organization. A supply chain management perspective is important not to suboptimize a system. Transport planning is the final subprocess in the wood supply chain from forest to mill. The high number of possible transport methods, combinations, and the restrictions applied to transport planning make it difficult to achieve economically optimal transportation without the help of computerized planning functions. This article explains the basic content of and requirements for planning functions for truck transport. The implementation of these functions relies upon an advanced information and communication (ICT) infrastructure. Mobile data systems (MDS), consisting of vehicle PCs linked on-line to a central company server, represent one such configuration of an ICT infrastructure. This article explains how transport planning is implemented and the role of such an ICT infrastructure in efficient implementation.

General Logistics

Logistics may be defined simply as methods for planning, execution, and control of operations governing the flow of material, machinery, personnel, and information. The role of logistics in forest operations is to coordinate roundwood supply with mill demand. This is in the context of demands for high capacity utilization and low levels of roundwood storage, in a geographically dispersed supply chain subject to numerous climatic disturbances.

Logistics in forest operations can be based on two different supply chain strategies efficiency and flexibility. With lower degrees of customer orientation (harvest-to-stock) it is primarily efficiency of forest operations which is in focus. With an increasing degree of customer orientation (harvest-to-plan for pulpwood or harvest-to-order for saw-logs) increasing flexibility and control is demanded (**Figure 1**).

Figure 1 Logistics in forest operations. The supply chain strategies (below the line) corresponding to different degrees of customer orientation (above the line).

The whole wood supply process can generally be divided into five subprocesses; prognosis planning (yearly horizon), demand and supply planning (rolling 3-month horizons), delivery planning (confirmed harvesting teams production aimed for specific mills on a monthly horizon), and finally harvest planning and transport planning (on weekly horizons). The supply chain from forest to mill can be described in terms of three nodes (forest harvesting, roadside inventory, and mill inventory) and two connecting links (extraction and transport). Each link with its connecting nodes is the basis of planning of delivery, execution of supply, and control of flow for harvesting and transport.

These two planning, execution, and control (PEC) cycles are used to adjust the rates of flow from both forest to roadside and from roadside to mill to meet varying mill demand under varying conditions (**Figure 2**).

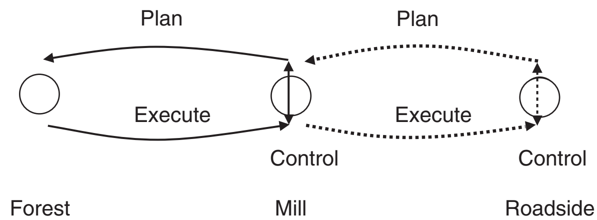

Figure 2 Planning, execution, and control (PEC) cycles for harvesting and extraction (forest–roadside) and transport (roadside–mill) operations.

Harvesting

In many parts of the world forest operations used to be a seasonal activity. Winter was in many places preferred for harvesting, the increased flooding in spring was used for river driving and silvicultural operations were conducted during the growing season. Changes in technology, employment law, and costs for inventories have altered the wood procurement process as well. Today, all year round harvesting and wood delivery are most common. But this also put new demands on the logistics of the operations.

Normally, the prognosis planning (yearly horizon) is based on the predicted harvesting, estimated by known factors if the forest is in control by the organization or experience if the harvesting is done for other landowners. In the latter case, the identity of harvesting objects may only be known at very short notice, depending on the type of agreement made by the seller of the harvesting and the buyer. The task of prognosis planning is to allocate known and anticipated harvestings in time and space to match the requirements from industry, the machinery and personnel available, and probable seasonal variation in harvesting conditions. If conditions change during the period, e.g., the demands of industry or weather, plans must change as well. The very nature of forestry makes it susceptible to climatic uncertainty. Heavy rain may cause terrain and roads to be inaccessible and harvesting plans must be changed accordingly. The role of harvesting planning is to make as good decisions as possible with the information available. The closer a specific harvesting is in time, the more accurate information is at hand and the more precise the planning can be made. However, harvesting planners must act with a great deal of flexibility.

One feature of forestry that makes it somewhat different from many other businesses is that it has a divergent flow of materials. Different assortments, based on use and tree species, cause one harvesting to produce material for many industries. Saw timber, pulpwood, wood for board mills, and wood for energy are examples of such assortments, and most often the industries are tree-species specific. This complicates the planning further. As an example, if there is an increased demand for pulp from hardwoods, as these trees very often grow in mixed stands other tree species will be in the harvested volume as well, and so will hardwood saw timber.

To achieve the flexibility in meeting fluctuations different strategies can be chosen. One way is to have large inventories. Inventories buffer the harvestings from changes, allowing a longer time to respond. However, inventories cost money in terms of capital and degrading quality. Another way is to have a very flexible harvesting organization that can adapt very fast to changes. Good planning routines can achieve some of this flexibility, but some overcapacity in the organization is required. This also costs money. A balance between those strategies must be found, and logistics theory emphasizes the importance of looking at the cost and benefits for the whole supply chain. Otherwise, suboptimizing is a big risk. Forest operations may solve a problem in a way that is very efficient for the harvesting, but which introduces costs into other parts of the supply chain that may well exceed those benefits. Hence, the growing interest in supply chain management which is based on a holistic perspective of the problem. This also points in a direction where harvest planning is much more integrated with the other parts of the supply chain: transport, industry, and customers. Without doubt, this is a development that is only just beginning.

Transport

Transport work from forest to mill has undergone considerable changes during the last 50 years. Structural changes in the forest products industries have led to a reduction in the number of roundwood destinations with a corresponding increase in average transport distances from forest to mill. At the same time road standards and transport capacity has increased.

Transport planning is the final subprocess of five in wood supply and is therefore subject to the greatest number of planning constraints. The high number of possible transport methods, their combinations, and the restrictions applied to transport planning make it difficult to achieve an economically optimal transport organization without the help of computerized decision-support tools. The most common transport method for short distances (<100 km) is truck transport. Rail and boat transport dominate on longer distances.

There are two general classes of trucks: self-loading trucks that work alone and trucks that work in groups and require a separate loader. For truck transport there are two general classes of planning functions: roundwood destination and vehicle routing. Destination aims to minimize the loaded transport distance between all forest supply nodes (active landings) and demand nodes (mills). This is done within the supply and demand restrictions imposed by the supply and demand planning process. Vehicle routing aims to maximize capacity utilization of the transport fleet within the constraints imposed by destination. Different goals may be used and minimizing the unloaded distance from mill back to forest by locating backhauls is one of the most common. Typical planning horizons are less than a month for destination and less than a week for routing.

Destination Functions

The destination function in transport planning can be studied from different perspectives. The first is that of the large forest companies with long-term wood supply responsibilities to major mills. The second is that of forest owners' associations or wood procurement groups who act as independent traders purchasing roundwood and selling to mills on short-term contracts on an open market.

Destination of roundwood may be optimally solved as a network model with the application of the classic transport algorithm and linear programming to minimize the loaded transport distance. This formulation may be well suited for large forest companies with long-term wood supply responsibilities to their own mills. There are important differences in the model formulation between the independent trader perspective and the forest company case. Independent trade aims to maximize the net revenue between price paid to the forest owner and the price received from the customers. Since contract prices for wood received may be at forest roadside or at the customer's location, this must be included in the model. This ensures that when the price is based on delivery at the roadside, the transport costs for wood transported from forest owner to customer is not taken into account. When the prices are based on delivery at mill site the transportation costs are included in maximization of net revenue. Often the prices paid to forest owners are also reduced with increasing transport distance to the nearest mill according to an agreed norm. Prices paid by the pulp mill, on the other hand, are determined through negotiations for each delivery contract specifying the prices for roundwood, and the delivery location.

There are also differences between assortments of roundwood which are important in the rigidity of restrictions of delivery. With the cut-to-length system it is more difficult to change the destination of wood which is already cross-cut for specific sawmills. Pulpwood, however, is often a by-product which it is possible to deliver to a number of different customers. Deviations from the delivery plans may therefore be compensated for by purchase from other suppliers. In this case it is therefore possible to relax the constraints of delivery precision.

Vehicle Routing Functions

Routing of timber trucks demands the comparison of a great number of possible driving patterns and combinations. For this reason mathematical techniques creating smaller subproblems involving the use of heuristics have been common for optimal routing. These subproblems are then easier to formulate and solve by a simpler algorithm such as the 'traveling salesman' algorithm. More exact methods such as tree-searching or 'column generation' (where each possible route represents a column) followed by tree-searching are efficient methods for solving more complex problems. While general vehicle routing problems have been in use for many years, roundwood transport represents a special case where the number of restrictions are especially large. This includes, for example, factors such as the geographic movement of supply nodes (active landings) and the specificity of certain landings for certain truck types. The influence of climate on infrastructure standards and the effects of roundwood freshness (time from harvest to use) for mill processes and product quality are also critical restrictions. Examples of successful implementation are to be found in ASICAM in Chile, EPO in Finland, and SMART in Sweden.

The probability of successful implementation increases with the stability of operational conditions and the simplicity of the planning function. Under stable conditions relatively advanced tools will function well. While under changing conditions, the number of restrictions increases, leading to the need for real-time operational data. Destination is the simplest of decision-support tools. Requirements concerning both computational capacity and operational data are limited.

Transport Administration Systems

A wood supply system which gives complete control should include the following modules:

- communication with both external and internal networks
- delivery follow-up in real time
- transport infrastructure databases
- decision support for optimizing transport plans
- mobile data systems.

Implementation decision support for optimizing transport planning requires an advanced information and communication technology (ICT) infrastructure. Mobile data systems (MDS), consisting of vehicle PCs linked on-line to a central company server, represent one such configuration of an ICT infrastructure. MDS consists of hardware and software with the following functions:

- distribution of transport orders and plans
- monitor with navigation aid to forest site (global positioning systems (GPS)/geographical information systems (GIS))
- reporting of transport volumes.

MDS support is a necessary element for future wood supply where structural changes create larger procurement areas which grow beyond each truck operators' area of local knowledge.

In transport planning there are two key interfaces where complexity management is important: (1) an external interface between the transport environment and the transport organization, and (2) an internal interface in the organization between its operating system (trucks, operators) and its management system (planners). Because of the complexity of the system as a whole, most of the organization's management capacity is aimed at handling the complexity of its operating system. The remaining capacity can be focused on handling the complexity of the environment (a multitude of roads, roadside inventories, and disturbances in operating conditions or supply).

In the absence of computerized decision-support systems and ICT infrastructure, the most common response to the complexity of transport planning is to reduce larger routing systems to a number of smaller subsystems through decentralized transport planning. Responsibility for operative planning is then moved from the company or regional level to the district level, reducing the number of possible transport combinations to a number readily solved with local knowledge and routines. This leads to each district's roundwood flow being executed independently of transportation in neighboring districts or companies, with drawbacks including difficult coordination and reduced backhauling. Reducing uncertainty of the transport system by real-time access to current information (e.g., road conditions and inventory volumes) is important to meet disturbances within these complex systems. The most advanced transport planning solutions with optimized functions, however, offer direct countermeasures to system disturbances.

Nursery Operations

K McNabb, Auburn University, Auburn, AL, USA

Introduction

Forest regeneration is the very foundation of sustainable forestry. While many forests are regenerated using natural techniques, increasing annual wood harvests will depend upon plantation forestry. Moreover, planting is necessary for afforestation on degraded lands, abandoned agricultural lands, or anywhere that trees are to be reintroduced without a natural seed source. According to the most recent Food and Agricultural Organization (FAO) Forest Resource Assessment, there are close to 4.5 million ha planted each year. If one assumes that planting area is also a reflection of nursery production and using an estimated average spacing of 3×2 m (1666 trees ha^{-1}), this is an annual nursery production of 7.5 billion seedlings. Asia has the largest planting area with 62% of the world total, followed by Europe with 17%. Pines occupy 20% of all plantations worldwide, other conifers 11%, and eucalyptus 10%. The stock used for planting these areas almost invariably come from forest tree nurseries. Nursery managers are responsible for producing a seedling of suitable quality in a reasonable amount of time at a reasonable cost, which can withstand the rigors of processing, storage, transportation, planting, and what is more likely as not, harsh environmental conditions. If the stock does not survive, more is lost than just the cost of the planting stock. Also forfeited may be the cost of preparing the site, growth forfeited until the next planting date, and the expenses incurred if additional weed control, fertilization, or other cultural practices must be conducted. These costs may be, and usually are, substantially greater than the cost of planting stock. It is no wonder that organizations dependent upon successful plantation management consider nursery operations to be the heart of their regeneration program.

As a general rule, there are two types of planting stock – bareroot and container. The decision to rely on bareroot or container technology depends upon many factors. Certainly the physiological requirements of the species is tantamount in importance. Certain genera, such as *Eucalyptus*, are invariably grown in containers and survive poorly when planted bareroot. Other genera, such as the pines, are commonly produced bareroot. Even so, certain pine species, particularly those in the tropics (e.g., *Pinus caribaea)* require containerization. Boreal species may be containerized to shorten their time in the nursery. Whereas producing plantable bareroot stock may take 2–3 years for some boreal species, the environment of container production can produce smaller planting stock in far less time. The ability to control the growing environment is also important when producing vegetatively propagated material which is high in value and/or may require more exacting conditions to root and/or develop. Finally, planting adverse (droughty) sites may require the use of containerized stock. A possible disadvantage to containerization is a substantial increase in cost. In the southeastern United States, for example, the price of container grown stock is generally four to five times higher than the same species grown bareroot. Container stock is also more expensive to transport.

Bareroot Production

Site and Facilities Requirements

The selection of a good site is of paramount importance to the efficiency of a bareroot nursery. The most important characteristics are soil texture and water quality. Only a few decades ago, a medium textured soil was generally considered a requirement for a good bareroot nursery site. Older nurseries tend to be found on loams and silt loams. These soils, however, are not always conducive to using machinery during the wet season which is also frequently the planting season when seedling harvesting must take place. Sandy soils are preferred for bareroot nurseries as for the most part they can be better worked during wet seasons without damage to soil integrity, machine use is more efficient, and equipment may re-enter a field sooner after a rain. Slope to insure efficient yet low energy water flow is a requirement. Slopes of around 0.5% (50 cm over 100 m) are generally considered ideal. When constructing a bareroot nursery, topsoil is usually removed from the site, and the site leveled using modern techniques. The topsoil is then redistributed over the site for a final grading.

Water availability, both in terms of quality and quantity, is essential to bareroot nursery management. There is little a manager can do if the water supply, be it underground or surface, is only seasonally available or of insufficient quantities. Perhaps the most commonly overlooked of these two factors is that of water quality. Managers tend to look for the quantity of water and often forget to check the quality. Extremes of pH, particularly alkaline water with high salt contents, will greatly increase the difficulty of producing quality bareroot seedlings. A simple chemical test will determine if there are hidden problems in the water supply.

The physical facilities normally required for a bareroot nursery are: office and managerial space including a space for nursery workers to meet and eat, an area for seedling processing, a seedling cold storage facility including a truck loading area, sheds for equipment and machine storage, equipment maintenance shop, pesticide storage and mixing facility, irrigation pumping station, and a seed storage unit, with the size of each of these components depending upon seedling production goals. Seedling cold-storage units are typically built to store millions of seedlings with easy loader access and maneuverability. Although this is expensive space, larger seedling storage units allow the nursery manager more flexibility in the harvesting process. As long as seedlings can be stored, the manager can make use of good weather and labor availability by lifting seedlings. Another facility that deserves considerable thought is the pesticide storage and mixing facility. These are specialized structures that may have special legal requirements regarding their construction. Specific airflow volumes, shelf spacing, spill containment, backflow prevention, and other safety specifics should be considered.

Soil Preparation and Sowing

A typical sequence of ground preparation for bareroot production is; subsoiling, plowing and/or harrowing, and bed shaping (**Figure 1**). Subsoiling is usually done with a 3 to 5 shank agricultural

Figure 1 *Pinus radiata* in a bareroot nursery in Chile. Bareroot stock is typically produced on a large scale in raised beds with several rows per bed. In this particular case, the plants originated from cuttings planted directly in the bed. Most bareroot stock, however, is produced by sowing seed.

implement to a depth of 40–60 cm. Many nursery managers will subsoil in perpendicular directions across their fields. Depending upon soil type and previous crop, the site should be turned with a plow or simply harrowed to incorporate and chop plant materials, aerate the soil, and break up soil clods. The bedding plow is then used to shape and level a bed, usually 120 cm in width and approximately 20 cm deep. Alleys between beds are typically the width of one tractor tire, around 40 cm. The number of beds per irrigation unit varies but is selected in function of the irrigation system. The life blood of the nursery is water, with the irrigation system consisting of a network of pumps, pipes, controls, and sprinklers. Most modern bareroot nursery irrigation systems are removable to facilitate soil preparation. Field pipes may be laid out and connected anytime after subsoiling, to facilitate bed layout.

Sowing in bareroot nurseries may be done using machines, or by hand, with species usually the determining factor. Fairly sophisticated tree seed sowers have been developed. Commercially available vacuum sowers are adjustable to seed size and spacing. Such sowers usually provide more control of within-row seed placement and theoretically result in a more uniform spacing for individual seedlings, producing a more uniform crop. Other common sowers dribble the seed along a furrow in the bed in a semicontrolled rate. In either case, the seed are pressed into the soil by a roller following seed placement. In many cases, however, particularly for very large seed or very small seed, hand-sowing is still the typical sowing method. After sowing, bareroot seedbeds are mulched to protect the soil surface from rain impact and maintain bed integrity. Although chemical soil adhesives are used with common success, many nursery managers prefer organic materials such as bark or other by-products from fiber processing that have the other advantages of helping maintain seedbed moisture and contributing to soil organic matter content.

Controlling Morphological Development

Seedling spacing has a tremendous impact on individual seedling development. Larger seedlings survive and grow better after outplanting and are more expensive to grow, but might reduce overall reforestation costs. Seedbed spacing, therefore, is a compromise between production costs and seedling size/quality. Spacing is also species dependent, although as a general rule pine are sown with a seedbed density target of around 150 to 300 seedlings m^{-2}. Hardwood spacings generally require more bed space for production, but again this is species specific. Seedbed density targets may typically vary from 50 to 150 m^{-2}.

Application of the major fertilizer elements of nitrogen, phosphorus, and potassium is almost always necessary to produce seedlings of suitable size within a reasonable time-frame. Fertilizer applications should be based on a soil chemical analysis and professional recommendations supported by empirical observations. Phosphorus and potassium may both be applied to the soil at the time of harrowing. Nitrogen is generally applied over the top of seedlings, either in liquid or granular form, beginning 1 to 2 months after germination. Most species respond well to nitrogen and fairly significant amounts of this element (100–200 kg ha^{-1}) may be applied to nursery beds. Because large amounts of nitrogen are used in bareroot production and because nursery soils are often well drained, nitrogen use efficiency and loss through leaching may be a concern to nursery managers. Micronutrients can be important in specific cases depending upon local soil conditions. Micronutrients are typically applied in a liquid spray. Soil organic matter maintenance is a variable that profoundly affects soil quality and nutrition management. Other than organic matter additions and seedbed mulching, nursery managers typically follow a rotation of 1 or 2 years of seedling crops with 1 or 2 years of cover crops in order to increase or maintain soil organic matter levels as well as a possible reduction in soilborne disease populations.

Top-pruning and root pruning may be used to manipulate morphological development of planting stock. Top-pruning involves the removal of the top of the seedling using a rotary or shearing blade. The primary objective of this treatment is usually to slow the growth rate of the crop. An anticipated secondary benefit is increased crop uniformity resulting from allowing smaller (unpruned) seedlings more of an opportunity to catch up to the larger (pruned) seedlings. An even more severe reduction in seedling growth rate can be achieved by undercutting or wrenching seedling root systems. Another important objective of root pruning may be to provide for a more fibrous root system (expanded water absorbing surfaces) and a better root to shoot ratio. Both shoot and root pruning are species dependent and may not be employed in all cases. Transplanting in the nursery, for example, may be a better method to promote a more desirable root to shoot ratio (**Figure 2**).

Pest Control

Weed, insect, and disease pests are serious threats to the production of quality planting stock. Many pests can be controlled through the use of modern

Figure 2 Transplanting Sitka spruce (*Picea sitchensis*) in a nursery in Scotland. Boreal species and temperate conifers are often transplanted in the nursery to improve seedling quality. A 3-year-old tree having been grown for 1 year in a seedbed and 2 years in a transplant bed is known as 1 + 2 stock. Subtropical and tropical species are rarely transplanted in the nursery and are usually outplanted to the field as 1 + 0 stock.

pesticides. Even so, constant vigilance is necessary on the part of the nursery manager as significant losses to pests can occur in a relatively short time. Nursery herbicides include oxyfluorfen, napropamide, glyphosate, and sethoxidim, to name a few. Both oxyfluorfen and napropamide are pre-emergence compounds, while glyphosate is a postemergence compound used as a directed spray. Sethoxidim is active against grass species only and with appropriate caution may be used over the top of most species. Cost-effective herbicides tremendously impact seedling cost and quality. An integrated pest management program should be employed for insect and disease pest control. Careful almost daily monitoring of pest levels is necessary in nursery operations, with insect and disease pests easily controlled if identified early enough. On the other hand, many nursery managers use prophylactic pesticide applications for soilborne diseases such as damping-off. Soil fumigation prior to seedbed preparation is a common approach in this case. All pesticide use requires a knowledge of the compound, how it works, and any potential environmental impact. It is the ultimate responsibility of the nursery manager to see these compounds are used appropriately.

Seedling Processing

Bareroot seedlings may be harvested by hand or machine. Machine lifting is much more efficient, enabling nursery workers to lift 600–800 thousand pine seedlings per day (spacing $200\,\mathrm{m}^{-2}$) with a crew of fewer than 12 people (**Figure 3**). There are questions, however, as to whether machines may damage the stems and roots of seedlings and therefore decrease seedling quality. After lifting seedlings may be 'graded' (separated into morphologically based classes) or 'culled' (removal of 'nonplantable' seedlings). The decision to grade or cull seedlings has significant influence on the cost of processing. The definition of a 'quality' seedling (i.e., the 'target') is species dependent, and affected by many factors including acceptable seedling cost, environmental conditions at the planting site, and planting method. This is a broad and often debated topic that must be considered by each nursery operation. Upon grading, bareroot seedlings are packaged in one of three ways: boxes, bales, or bags. Both boxes and bags provide a nearly complete seal for seedling storage, while bales protect only the roots and may need watering if stored for several weeks. Water or water-absorbent gels may be sprayed on the roots prior to storage. Cold storage of bareroot seedlings helps reduce the heat of respiration and slows metabolic rate. Storage temperature varies by species with some, particularly boreal species, stored at below freezing temperature, while others are stored at 2–5°C. Storage time before seedling quality is compromised is species dependent and may vary from 1 week to several months.

Figure 3 Mechanical lifting of slash pine (*P. elliottii* Engl.) in the southeastern United States. This nursery produces 1 + 0 bareroot stock that is sown in April (spring) and is lifted 8–10 months later during winter. The machine lifts the entire seedbed in one pass. In this example, packing in bags is done in the field as opposed to transporting to a central processing area.

Container-Grown Stock

Site and Facilities Requirements

There is a great deal more flexibility when selecting a site for a container nursery. Because soil quality has been removed from consideration, a container nursery can be placed at nearly any location where power, roads, labor, and water are available. Many container operations require a reliable semiskilled workforce and labor availability is an important consideration. Water quality, however, is of paramount importance. There is little buffering capacity in the small cells of container-grown plants. Water quality problems may appear and become significant in a relatively short time-frame. In addition, because nursery operations invariably use fertilizers and pesticides, proximity to habitation, streams, or environmentally sensitive areas should be considered.

About the only buildings that are universal to container nurseries are those related to personnel requirements (e.g., administrative, meeting, eating, and restroom locations). Other common structures are a medium preparation and container filling facility and their associated storage spaces for media and containers. The types and requirements of other structures are highly dependent upon the propagation techniques used. Most operations require a seed germination or misting chamber for rooting cuttings. In this case, tight control of water amount, spray droplet size, humidity, and temperature are important (**Figure 4**). Some facilities have heated pads to increase the temperature of the root environment. After the initial seed germination or rooting phase, plants are typically transported to protected plant development areas. These areas may be entirely closed systems, or may be outdoors. Finally, upon reaching a suitable size, the stock is transported or exposed to ambient conditions so they may begin the process of physiological acclimation to planting conditions. Each of these phases may require a specific facility.

Container and Medium

Forest tree seedlings are grown in a variety of containers. In nurseries in many developing nations, small plastic bags filled with subsoil are common. However, most containers used today in modern nurseries are small polyethylene (hard plastic) tubes or styrofoam blocks with cavities. In both situations, the container is reused after cleaning and disinfection. The small tube-type container may be hung in wire or plastic racks at waist height, while styroblocks are typically placed on benches. Both systems should allow roots to air-prune on the bottom. The size of the cavity varies widely but those used for pines and *Eucalyptus* are commonly about 2–4 cm in diameter at the top and 12–18 cm deep, narrowing to a smaller drainage hole at the bottom and ribbed along the length of the cavity to prevent root

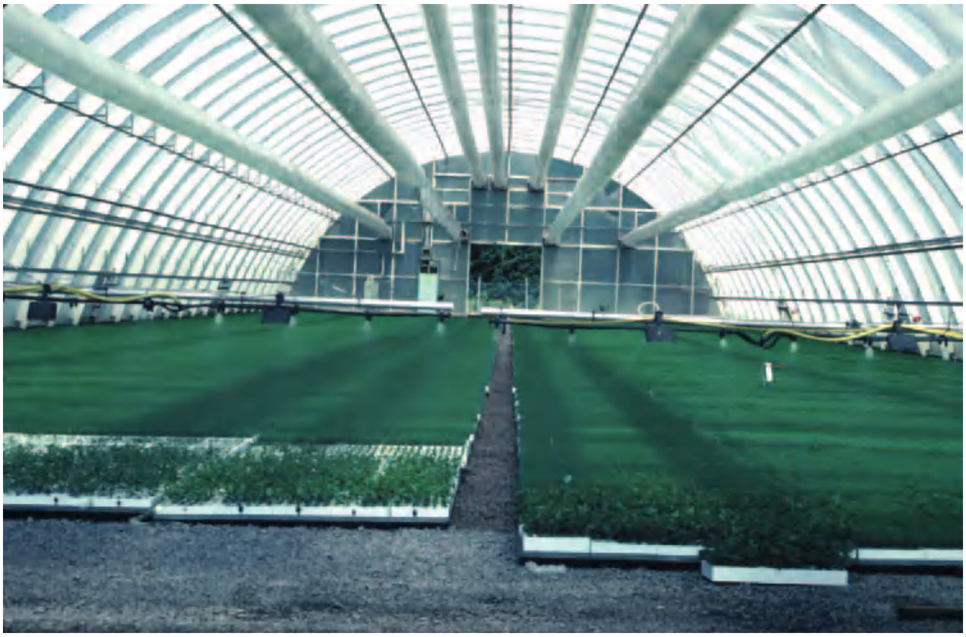

Figure 4 A single indoor unit of a container nursery in Sweden. Temperature, humidity, irrigation, and, to some extent, light can be managed in such structures. This speeds up the morphological and physiological development of the plants. Fertilization and pest control is typically done through the irrigation system, which in this case is an overhead traveling boom sprayer.

spiraling. Other than water quality, the container medium is the most important factor contributing to successful container growing. While media are often available commercially, many growers create their own mixtures. Normally, the medium is based on a locally available and abundant organic compost (e.g., pine bark, rice hulls, or other processing residues) that is used alone or mixed with vermiculite, soil, or other materials. These mixtures attempt to provide a well aerated, well drained, disease-free medium, with good water-holding capacity. The correct mixture promotes root growth throughout the medium. Commercially available and 'homemade' machines are used to fill containers.

Starting the Crop

Container stock may originate from seed, germinants, cuttings, and plantlets. Seed may be hand- or machine-sown. Automatic sowers are commonly used for pine and *Eucalyptus*. Whether or not to sow more than one seed per cell depends upon germination percentage, value of the seed, and the availability of labor to thin and transplant. Transplanting may well result in uneven growth between seedlings and the need to segregate later by size. After sowing, seed may or may not be covered depending upon the species and sowing technique. Germinants are produced by germinating seed in special flats or beds and transplanting the young plants (usually with the cotyledons still attached) into the containers. A number of species may be transplanted from specialized seedbeds to containers including species of both the genera *Pinus* and *Eucalyptus*. Usually transplants are shaded and maintained in high humidity conditions until well rooted.

Vegetative propagation through the use of cuttings is increasingly common for initiating container-grown planting stock, particularly for the genus *Eucalyptus* (**Figure 5**). To be successful, such a program depends upon an intensive clonal selection effort which includes research regarding the age, size, location, and season for taking woody plant cuttings for cost effective success. There may be physiological conditioning of the cutting source, the use of rooting hormones, and the posttransplanting environment may require exacting conditions. Large-scale production nurseries must have adequate rooting success if this technology is to be cost effective. Cutting based programs usually manage 'clone banks' or 'clone gardens' as a ready source of superior genotypes used as a source of material.

Container-grown planting stock may also originate from plantlets which are small plants or cuttings produced *in vitro* using various tissue culture methods. Individual clones may be 'stored' in jars in the laboratory and then 'bulked up' according to the requirements of the planting sites. Although not as common as using traditional vegetative propagation

Figure 5 A container nursery in southern Brazil. The majority of these plants are *Eucalyptus* spp. originating from cuttings. After rooting the cuttings in indoor facilities with humidity and temperature controls, the stock is moved outdoors to acclimate to planting conditions. The different colors seen in the photograph are different clones.

techniques based on cuttings, the use of plantlets will undoubtedly become more frequent as biotechnology programs are further developed.

Morphological Development and Pest Control

Fertilization of container-grown stock is done both by adding nutrients to the container medium prior to filling the containers, and as supplemental foliar sprays. Fertigation is particularly appropriate for container-grown technologies, requiring the use of specialized injectors and fertilizer holding tanks. It is imperative that irrigation systems provide even distribution of water over the growing area. In addition, slow-release fertilizers may be effectively added to the container medium, insuring nutrient availability over an extended period of time. A factor of increasing importance relative to container stock fertilization is the ultimate fate of fertilizers (and pesticides) used in the production process. Container operations usually have fast and efficient drainage away from the site. Also, unlike bareroot operations there is no soil medium to hold, transform, or otherwise process fertilizer elements. The result is an increased possibility of chemical movement from the production site. Many container operations now ‘close the system,’ by collecting and reusing water that drains from the seedling racks.

Container-grown stock needs to be segregated by size. For whatever reason, growing medium, seed vigor, transplant shock, or fertilizer distribution, container stock frequently shows remarkable variation in morphological development. Larger plants may be the first sent to the field for transplanting or segregated so that their growth may be slowed through irrigation reduction. Smaller plants may receive additional fertilizer to accelerate their development in order to reach plantable size. Sorting by size is a labor-intensive operation and adds considerably to planting stock cost.

Because container-grown stock is generally produced in soilless media, pest problems tend to be less frequent. Weed control, for example, is greatly reduced and occasional hand-weeding often suffices. Likewise, the protected environment of the greenhouse limits insect pests. The most serious pest problem for container stock is normally disease, particularly those associated with damping-off, although leaf molds such as *Botrytis* and *Cylindrocladium* may quickly become destructive without quick resolution. The high humidity and temperatures often associated with the early stages of container production are ideal for fungal development.

Storage and Shipment

The existence of a functioning soil/root interface provides a great deal of flexibility in the storage of container-grown plants. With protection from desiccation provided by the medium plug and occasional

Figure 6 A truck used for transporting seedlings from the nursery to the field. Note these seedlings are in containers and resting on a stack of specially developed platforms for placement on to the truck.

watering, plants may be stored just about anywhere, including the planting site, for an indefinite period of time. What is gained in storage flexibility, however, is lost in transportation cost, as the amount of space and energy needed for container plant transportation is considerably higher than for bareroot planting stock (**Figure 6**). In addition, because container stock cannot be vertically stacked, specialized transportation structures are required.

Final Considerations

Clonal Technology

The increased used of clonal technology has impacted seedling production in many areas of the globe. Although the decision to use container techniques for planting stock production has generally been mandated by biological and environmental factors in the past, this is changing with the increasing importance of clonal propagation to maximize the benefits of genotypic selections. Whether through tissue culture techniques such as somatic embryogenesis or cutting propagation from clone banks, the production of forestry planting stock is becoming more associated with the 'bulking up' of highly productive genotypes derived from intensive programs of selection and testing. Some genera, *Eucalyptus* for example, easily lend themselves to vegetative techniques necessary for clonal production (**Figure 7**). Others, such as the pines, require a higher economic threshold as they are so cheaply produced in bareroot systems. The continual progress in the science of biotechnology, however, may profoundly influence the economics of planting stock production. If lignin content, disease resistance, or drought tolerance can be introduced into cell lines through such technology, the economics of bareroot versus container grown stock will have to be rethought.

An Integrated Approach

In the past, individuals working in nursery science did not regularly interact with those working in site preparation or weed control. Each was typically viewed as an independent topic. Forestry enterprises, whether investigatory or managerial, were typically organized along these different areas and acted independently of each other. Forest regeneration managers are coming to view plantation establishment as an integrated process. That is, none of the parts in the process is wholly independent of the others. This is important because seedling quality is now mandated by considerations broader than just a 'survivable' seedling. Larger seedlings may compensate for chemical weed control, for example, or planting may take place year-round through the use of irrigation so that nursery and planting operations are seamless and independent of season. Nursery operations directly affect seedling quality, both morphologically and physiologically. Nursery managers can manipulate their product through cultural techniques such as spacing, fertilization, and pruning.

Figure 7 Multiple shoot tips of a *Eucalyptus grandis* and *E. urophylla* hybrid (known as urograndis) produced through tissue culture techniques. Individual clones can be kept in this form and then bulked up to produce indoor 'clonal gardens' which in turn are used to produce planting stock based on cutting technology. Such systems may become much more common with the development of biotechnology science.

It is becoming more recognized that seedling quality interacts with silvicultural techniques used in site preparation and weed control and therefore seedling cost should be evaluated as related to the entire regeneration process. As the forestry research community further investigates this important topic, we may find that nursery techniques are more important to plantation establishment and growth than has been believed in the past.

Forest Operations Management

E Mikkonen, University of Helsinki, Helsinki, Finland

Introduction

Modern information and communication technology (ICT) is widely used in forest operations management nowadays. In particular large forest industry companies operating globally have developed sophisticated systems to manage their forest operations. Many of the smaller companies are introducing these systems as well. The necessary condition for the use of these systems is a well-developed communications infrastructure in the country concerned. Similar systems are applied elsewhere, too, but maybe not as sophisticated as these.

The basic data on forests are continuously gathered and monitored through inventories at all levels: national, provincial, company, and private woodlot owner. The data are available in digital form which allows use of modern geographic information systems (GIS). The data are based on satellite and aerial images as well as field surveys, i.e., multisource data. This is important for managing companies' own forests and national forests.

Modern tools are used at every level of management and planning, i.e., strategic, tactical, and operative.

Operational harvesting plans are based on these basic data. Maps and other relevant marked information on the stand are shown on the screen of an on-board computer of a harvesting machine. The harvester optimizes the utilization of the tree stems according to a bucking-to-order scheme radioed to the machine. Environmental aspects are monitored through on-line follow-up of the location of the machine warning the operator of the hazards of exceeding the cutting area borders, protection zones, etc. Forwarding follows immediately after the logging, and the location information of the log piles is sent to the database. The performance record of the machine is stored in the memory automatically.

After logging the information is sent to the company's district office, which organizes optimal long-distance transportation schedules given by the optimization routines. The truck fleet can be monitored on-line with global positioning systems (GPS) and rescheduled easily. There are several vendors for these systems on the market.

These systems have intensified wood procurement and cut the costs of operations considerably. Another advantage is that the environmental risks of traditional harvesting can be minimized, thus increasing the acceptability of direct commercial use of forests.

Forest Operations Today

Activities of the woodland division of a forest industry company or an independent wood procurement organization may consist of many tasks that have an effect directly or indirectly on the outcome of the operations and thus need to be taken into consideration when managing these activities.

In the following presentation 'forest operations' are understood as 'technical activities to deliver wooden raw material from the forest to the place of utilization continuously and the supporting tasks to maintain this flow.' A supporting task could be forest road construction, for instance. The term 'wood procurement' is used often as a synonym for 'forest operations' although its meaning is more restricted. Another quite frequently used expression is 'supply chain.' A supply chain does not include similar supporting activities, as forest operations does.

Forest operations management is an activity to steer the outcome of forest operation towards a desired goal. In modern wood procurement information and communication technology plays an essential role. The tools provided by the ICT are GIS, GPS, the World Wide Web, mobile phones or cellular phone networks such as NMT, GSM, and UMTS, to mention a few.

Wood procurement is basically a logistic process that can be managed with the above mentioned tools. Proper management requires measurement of the efficiency of the organization. This means that planning of activities as well as monitoring is needed at every level of management. Planning can be strategic, tactical, or operative. The management structure can be a hierarchical, functional, matrix or teamwork type organization. The modern solution seems to be in most cases a functional, teamwork-based organization. When dealing with its interest groups different levels of partnership may be applied by the companies. This varies from purely owned operations to complete outsourcing.

In the following account, forest operations are dealt without the supporting activities, i.e., as wood procurement activity. This excludes public organizations working, say, on afforestation or road construction as falling outside the scope of this article.

Wood Supply

The wood supply chain is shown in **Figure 1**. It forms the framework for forest operations management.

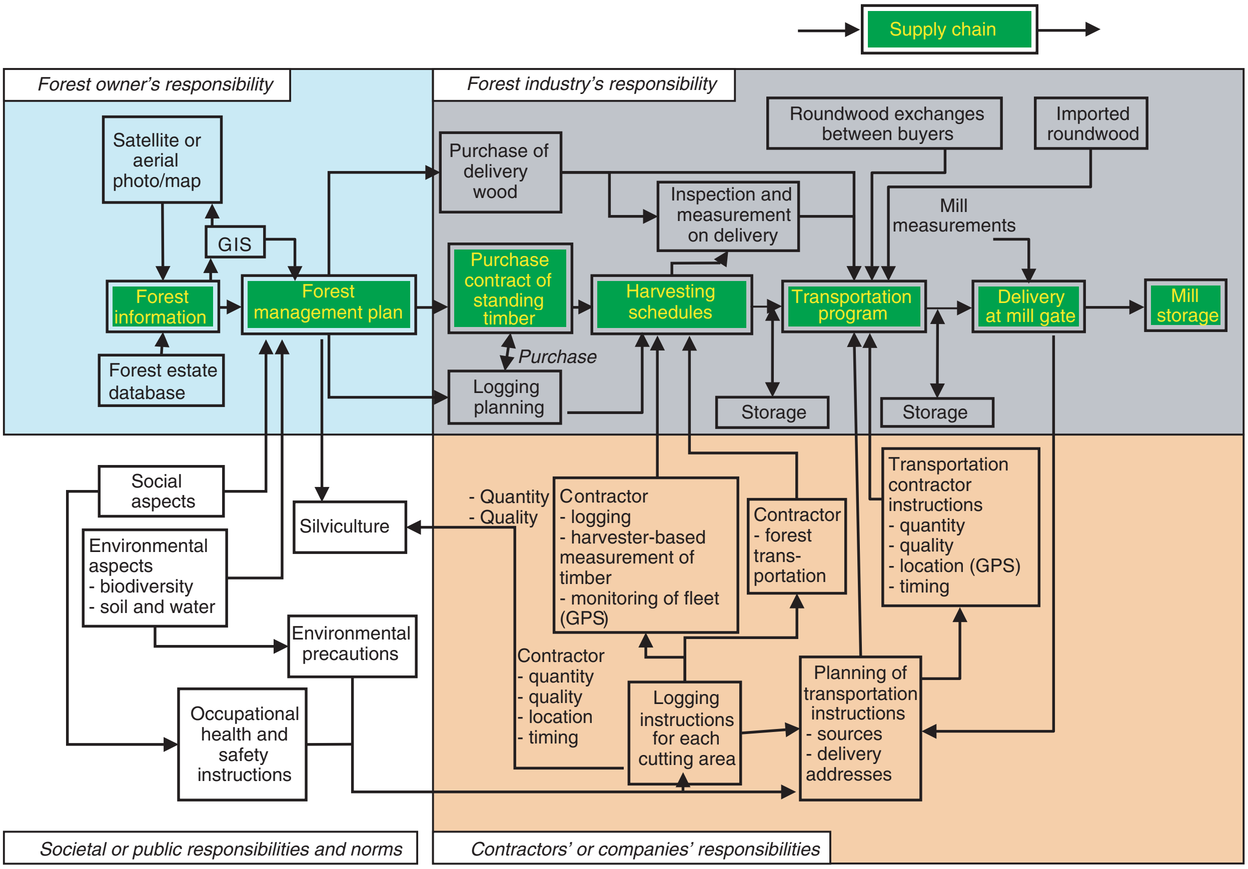

Figure 1 Framework of forest operations management.

The arrows in the figure show the relations between the activities and auxiliary activities. Auxiliary activities are needed to help carry out the actual forest operations more cost efficiently. Such an activity is wood measurement, for instance.

There are basically four independent actors in the wood supply activity. They are forest owners, forest industry, contractors, and public authorities as well as organizations of citizens (these four are shown in **Figure 1** as differently colored blocks).

Harvesting in these examples is supposed to be carried out using shortwood or cut-to-length (CTL) systems which is typical in the Nordic countries. Of course, similar types of structure can be found in any wood supply system.

Forest operations management starts with an annual strategic wood procurement plan based on pre-orders of the mills drawn from market development estimates for products. From that information a tentative wood purchase plan as well as a preliminary transportation plan can be developed. These plans allocate the volumes of different assortments needed to the procurement districts, and calculate the other resources required to carry out the task. At this stage just a small portion of the stands to be cut is known, most likely only the geographic area where they are supposed to come from. This is due to the fact that the raw material needs to be bought from the free timber market in the form of premarked stands. Only a small portion comes from the company's own forests.

In countries where the state owns the forests and sells harvesting concessions the approach might be different as regards planning.

These provisional plans are revised quarterly to become the tactical plans. At this stage the stands have been bought and full information on them is available. In the sales contract the forest owner and wood buyer agree upon the length of the time period during which the harvesting must be completed.

In the next step monthly and weekly operative plans are developed including the harvesting and transportation schedules for the stands to be harvested.

Wood Purchase

Procurement

Buying of timber on the free market is the most important activity in conditions where the public supply of timber is insignificant. In a team-based organization this activity is carried out by a specialist who knows the local conditions very well. In the wood procurement team there is also a substitute who can do the task if the specialist is not available at that moment. The information on the stand characteristics from the sales contract is transferred into the information system of the company for further planning activities.

The reliability of this information is crucial, because all the following management measures are based on this. Forest owners' forest management plans are a very important source of information for this purpose. However, they are confidential and controlled by the forest owner.

Forest Ownership

Own forests are a minor source of wood for Nordic companies but worldwide this is rather common. However, companies have long-term forest management plans for their own forests. Nowadays these utilize modern planning tools such as GIS. From these data the actual harvesting schedules can be defined and carried out. Companies tend to use their own forest resource to balance the timber flow. One typical trend today is to outsource the forest property and forestry to separate companies due to the low return on investment expected from traditional forestry. Owning the forests would decrease the return on investment figures of the actual forest industry business.

Silviculture

Silviculture operations must be carried out due to strict forestry laws and environmental aspects. This guarantees the new growth and sustainability of forestry after harvesting.

Planning and Management of Operations

As was presented in **Figure 1**, the raw material flows from the forest to the mills and management information basically flows in the reverse direction. In **Figure 2** the planning levels for forest operations management are presented. (More detailed descriptions are presented in **Figures 3**, **4**, and **5**.)

Strategic Planning

Strategic planning is carried out both at company's woodland division and district levels.

Tactical Planning

Tactical planning concerns basically logistics, i.e., how to get the raw material most efficiently to the mills. These plans are made at district level except for imported wood which is handled at woodland department level. These plans are updated quarterly.

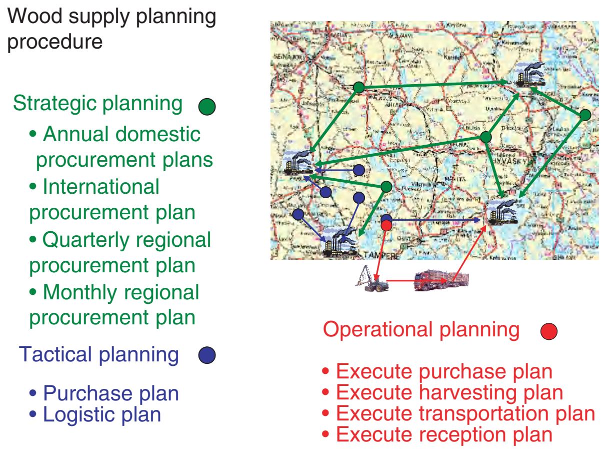

Figure 2 Typical tasks in wood supply planning.

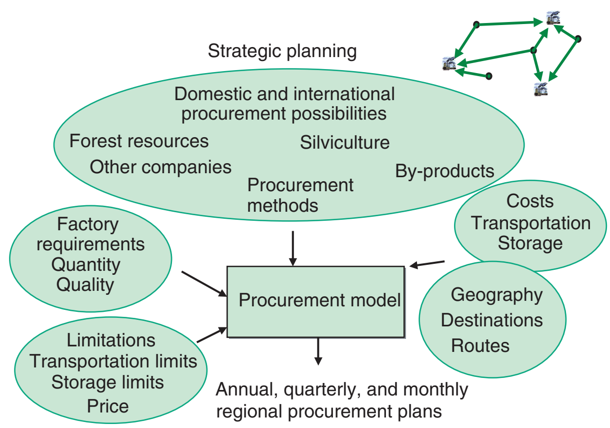

Figure 3 Concepts in strategic planning for managements of operations.

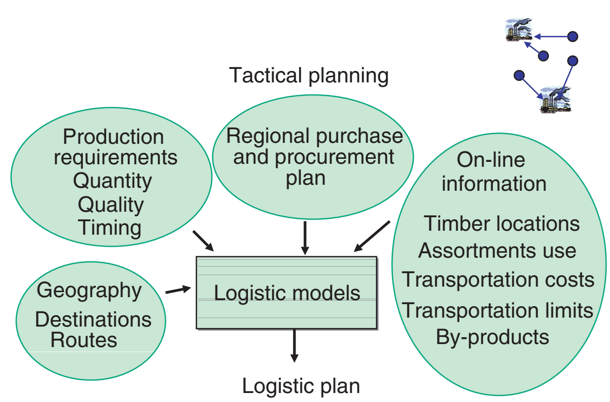

Figure 4 Concepts in tactical planning for managements of operations.

Operational Planning

Operational plans consist of the actual instructions by whom, how, and when the operations must be completed.

Once the company has obtained the authority to cut the stand owing to sales contract and the information is passed to the planning system, the operations management, i.e., harvesting and transportation plans are prepared. These include the selection to be made, the destinations for each type, schedules of the actions and other necessary plans such as precautions for environmental risks. These are then adjusted to the other stands information purchased from the same area to optimize the use of resources available. The plans are then converted to day-to-day instructions for the contractors available for the task. The companies have outsourced their forest operations to contractors almost to 100%.

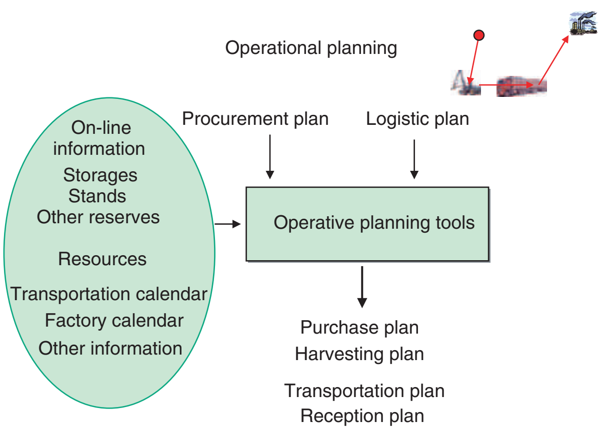

Figure 5 Concepts in operational planning for managements of forestry operations.

Monitoring Monitoring of the operations produces daily and weekly reports of the progress of operations. If something goes wrong, the team can quickly intervene in the situation by smoothly adjusting instructions.

Harvesting Harvesting of the stands includes logging and hauling. Logging is almost completely mechanized with harvesters in company operations in the Nordic countries. To some extent chainsaws are used, especially in thinnings and special wood logging, as well as in small-scale forest owners' logging. Regardless of the level of mechanization, the shortwood system is applied.

Transportation Off-road transportation is carried out by forwarders, which carry the load to the roadside. Skidding is a very exceptional operation in the Nordic countries. Long-distance transportation is carried out mainly by full trailer trucks.

Role of ICT

Modern wood procurement relies heavily on quick and reliable transfer of information. Tools are GIS, GPS, mobile phones, text messages, and wireless communication (**Figure 6**). There is a lot of information technology in a modern harvesting machine. They are equipped with an on-board computer that in addition to wood measurement functions also monitors the state of the machine operation itself.

From the operations management point of view the correct wood measurement and cross-cutting instructions are essential. At this point a wrong decision might destroy the value of the timber. This is

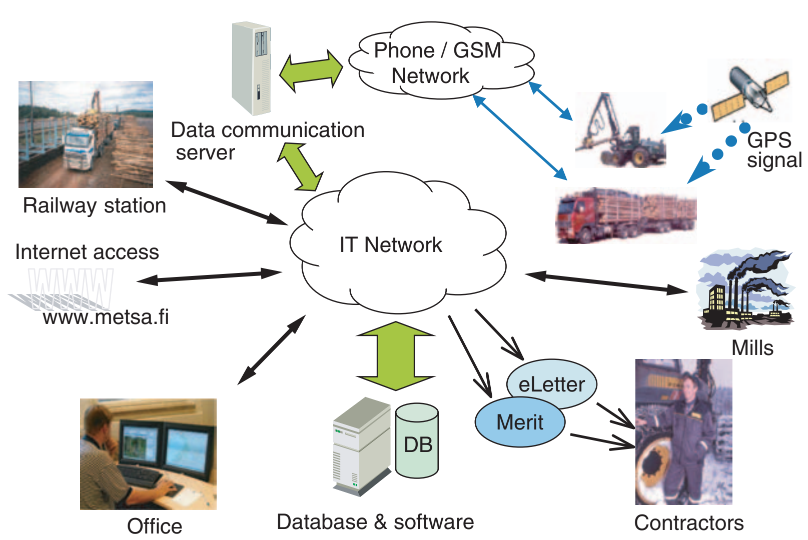

Figure 6 Data collection for operations management. Courtesy of the Finnish Forest Service (Metsähallitus).

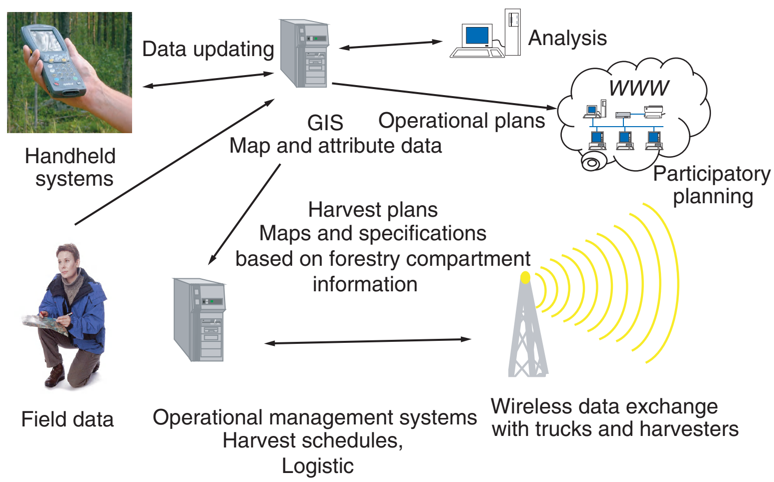

Figure 7 An example of information and communication technology application for forest operations management. Courtesy of the Finnish Forest Service (Metsähallitus).

because a customer-oriented approach is used. Bucking instructions for individual trees are defined by the bucking-to-value tables or bucking-to-order tables from the sawmill or plywood mill using the logs. These tables are transferred to harvesting machines wirelessly almost daily, according to the needs of the customer. Because of the variety of wood types and sometimes the requirement for a large quantity of special wood, a group control system for the management of a fleet of harvesters has been developed.

Productivity

Production and productivity figures can be followed continuously as well as the location of any machine through GPS. Once the location of the next harvesting site and the stand characteristics in addition to the selections to be made are known, the contractors can work independently. They only report daily to the team's office the state of the work and the finishing of the site. This information is used to define the readiness for transportation of the harvested wood. Coordinates of the log piles are also available for the route optimization routines of transport scheduling programs.

A well-functioning mobile communication network is a must for efficient data transfer between the harvesting equipment and supervision of the work (**Figure** 7).

Development of the Work Organization

The forest companies seem to pursue an ideal of having their own organization as light as possible. This has brought outsourcing into the management of operations. If someone can offer a better cost efficiency than the company's own operations would provide, they are willing to change. For instance, the measurement of wood at the mill is outsourced to specialized companies; only the information is transferred to the end users.

As mentioned earlier, modern organization for forest operations management is based on teams that cover a certain geographic area. Otherwise teams are quite independent; they report their performance to the district office and select the means to reach the goals set by the next organization level.

The supply chain for industrial wood has become faster and shorter, such that already at the stump the destination of the harvested wood is known. Delivery is as quick as possible and the running capital is kept as low as possible.

We will see even better management in the future once automation advance. This will allow even higher productivity, remote monitoring of the operations, and better utilization of raw material, and at the same time will protect the valuable production environment, nature itself.

Small-scale Forestry

P Hyttinen, Regional Council of North Karelia, Joensuu, Finland

Introduction

This article reviews various aspects of small-scale forestry in the world, with an emphasis on industrialized countries. Definitions and demographic information on small-scale forestry are discussed. Aspects of administrative structures and policy instruments for small-scale forestry are presented. In particular, the importance of forestry to social welfare is noted, and the role of small-scale forests in conducting environmentally and socioeconomically sustainable forest management is discussed.

Small-Scale Forestry in the Center of Interest

Forestry has traditionally been conducted in most countries mainly by the public sector on public land or by industrial companies on large-scale natural forest areas or plantations. On the other hand, private nonindustrial and small-scale management of forests has been dominant in Western Europe and Japan, where forests may remain in the ownership of the same family for centuries. In recent years, there has been a trend to move gradually away from large-scale forestry towards landholder-based small-scale forest management. This trend is especially clear in developing countries in Africa and in Asia, as well as in the former socialist countries of Eastern Europe.

Small-scale forestry has been recognized as a promising tool in achieving the multiple forest-related objectives of society, as well as in addressing the various global environmental issues of today. Regardless of the fact that the demand for forest industry products is continuously growing, environmental considerations and recreation have become increasingly important, often competing with financial considerations and wood production. Around the world, loss of biodiversity has become a major concern in the management of forest lands. Substantial deforestation has taken place in many developing countries. The wide range of social, economic, and ecological objectives of forest management are seen to be better met by small-scale forestry rather than by large-scale forest management.

What is Small-Scale Forestry?

It is apparent that small-scale forestry means different things in different parts of the world. There is no simple or consistent definition of what constitutes small-scale forestry. A farmer operating with a woodlot of 5 ha would certainly be a small-scale forest owner, whereas an industrial company with thousands of hectares would be large. But in between these examples there exists a wide variety of sizes that can be considered either small or large depending on the viewpoint taken.

There is no comparable or consistent statistical information about the amount of small-scale forests in different countries and continents. According to the latest United Nations Economic Commission for Europe/Food and Agriculture Organization statistics, private forest ownership plays a significant role in Japan (59%), Europe (55%), North America (37%), and New Zealand (31%). However, it is important to make a difference between small-scale forestry and private forestry, as private does not always mean small.

The terms 'small-scale forestry,' 'nonindustrial private forestry,' 'family forestry,' and 'farm forestry' are parallel and they are used rather synonymously to separate this type of forestry from industrial or public large-scale forestry. Small-scale forestry differs in many ways from large-scale forestry, for example, in aspects such as motivations for the establishment and management of forests, social and economic objectives of forestry, and the likely markets for wood and non-wood forest products.

Appearance of Small-Scale Forestry in Selected Countries

In the USA, the term adopted for small-scale forests is nonindustrial private forests (NIPFs) referring to forestlands owned by farmers, other individuals, and corporations that do not operate wood-processing plants. NIPFs account for 59% of total timberland in the USA, and contribute nearly half of US timber production. In total, there are about 7 million NIPF landowners. Only about 600 000 holdings are larger than 40 ha, yet they contribute 80% of the NIPF harvest.

In Canada, private land ownership is unusually low in comparison with other developed countries. Only 6% of forest land is privately owned, whereas some 70% is provincially owned, with an additional 23% being owned federally by the national government.

In Japan, family-owned small-scale forestry is present in an extreme form: of the 2.5 million forest households, 1.5 million hold less than 1 ha. Nearly 90% of forest holdings are less than 2 ha. The national average for a forest holding is 2.7 ha. Private small-scale forests make up 59% of all forested area, providing almost 75% of the timber harvested. In recent years, these small-scale forests have become increasingly important because of drastically decreased timber production in national forests. No large forest land-holding companies are currently active in Japan.

In Australia, the term 'farm forestry,' or 'agroforestry,' is widely used due to the fact that forestry is often integrated into the farm business, generating revenue and environmental services to complement other enterprises on the farm. Unlike many European countries and Japan, farm forestry is a relatively new phenomenon in Australia, with the majority of farm forests being early in their first rotation. This is due to the fact that forestry activities were traditionally based on the exploitation of the extensive eucalypt forests that existed at the time of European settlement. However, nowadays significant areas of native forest have been withdrawn from timber production and placed within conservation reserves. As this trend is likely to continue, the role of plantation forests is becoming increasingly important. These plantations are mainly established by large-scale industrial companies, but plantations among small-scale farmers are also increasing.

In Europe, there is no commonly adopted term for small-scale forestry, though 'family forestry,' launched by the Nordic countries, has recently gained ground in Central Europe where the term 'farm forestry' has traditionally been used most often. Forest land ownership in Europe is approximately equally distributed between public and private owners. However, in Western Europe two-thirds of forest land is privately owned, whereas in Eastern Europe forests are mainly public domain, although this is now changing rapidly with privatization in the formerly socialist countries.

Most European countries have large numbers of smallholdings. In the 15 member countries of the European Union, there are approximately 12 million private individuals who can be classified as forest owners. In France and Belgium, more than 90% of the holdings are under 5 ha. This is in contrast with Sweden and Finland, where 25% and 14% of holdings respectively are larger than 50 ha. Private forests contribute most of the industrial timber as well as other wood and non-wood products. Due to the significance of private ownership, small-scale landowners are an integral part of forest policies, forest management planning, and forest extension in Europe.

Administrative Aspects of Small-Scale Forestry

In most countries small-scale forest owners have established voluntary national organizations, associations or other such establishments, to promote sustainable forest management, to serve as a link between forest owners, and to represent them in forest policy-making. In many countries these organizations, varying with legal bases and organizational arrangements, also provide help in timber sales and silvicultural operations.

A number of international organizations for forest owners also exist. For example, the Confederation of European Forest Owners (CEPF) was established in the 1990s to form an umbrella organization of the national forest owner organizations in Europe. The most recent establishment is the International Family Forestry Alliance (IFFA), representing some 30 million family forest owners in Europe and North America.

In the governmental systems of most countries, small-scale forestry has traditionally been under agricultural administration, due to close linkages between forestry and farming. Only in some countries, e.g., Finland, has the role of forestry been emphasized by naming the ministry as Ministry of Agriculture and Forestry. A few countries, including Portugal, have a separate Directorate General for forestry administration.

The practical implementation of public forest policies on private lands typically falls under the responsibility of governmental field organizations at the regional and district level. Recently, there has been an international trend towards lighter public administration. Therefore, forestry administrations throughout the world have also faced budget reductions. In addition, along with the increasing number of nonfarmers as forest owners, the link between forestry and agriculture has gradually weakened. There has been some consideration about whether forestry administration should be made more independent of agriculture; whether there should be a common administration for all natural resources; or whether forestry should be merged with the environment (as in Denmark), industry, or trade portfolios (as in Sweden).

Small-Scale Forestry in Resolving Global Issues

In the past, the main emphasis of forest policies on small-scale forestry was to ensure a constant flow of timber to the processing industries. In recent decades, growing environmental consciousness has raised the ecological perspective to a more central position. Countries around the world have been active in taking on commitments concerning the protection, development, and sustainable management of forests.

A crucial step in this direction was the United Nations Conference on Environment and Development (UNCED) held in Rio de Janeiro in 1992. The UNCED has given forests an increasingly important role in the context of sustainable development and environmental conservation. The concept of sustainable forest management has been recognized as a fundamental guiding principle by all participating countries.

As many as 149 countries, representing 85% of the world's forests, are engaged in efforts to identify criteria and indicators of sustainable forest management, and to collect information on the indicators. Over the last 10 years, a number of private initiative certification systems have evolved based on these criteria and indicators. There seems to be no 'one-fits-all' solution when it comes to certification of sustainable forest management, but one has to support bottom-up approaches within the different regions and countries.

During the international follow-up processes of Rio, small-scale forest owners have been seen as key partners for the implementation of sustainable forest management. In the first phase, the emphasis was on ecological aspects of sustainability. The contribution that forests can make to the environment in such diverse areas as water catchment protection, habitat creation and conservation, and recreation is now widely recognized. Increasingly, forest owners are either required by statute or influenced by financial incentives to alter their management practices to increase these environmental benefits, or to decrease environmental costs.

Recently, socioeconomic aspects of small-scale forestry have gained increasing attention. For example, in the resolutions of the European Ministerial Conference in Lisbon in 1998, socioeconomic sustainability was given the main emphasis. Probably the most important socioeconomic aspect related to small-scale forestry is the income from forests, which can play an important role in maintaining a sound social structure, and thus, forestry can contribute to the overall economy of rural areas.

Generally, farm forests are concentrated in rural and mountainous areas, which are economically disadvantaged compared with industrialized areas, and undergoing depopulation. Therefore, farm forestry has a key socioeconomic role relevant to policies at regional, national, and international levels. Attention is paid not only to traditional questions such as the continuing viability of individual farms, to which the production of timber and other products can contribute, but also to more recent questions such as the contribution that the landscape value of attractive woodlands can make to the rural economy through tourism.

In the ongoing debate on forest policies, the role of forests in implementing the 1997 Kyoto Protocol to the Framework Convention on Climate Change has also raised much discussion. Developments towards a market for carbon emissions by governments and industries preparing for national reductions of greenhouse gas emissions have stimulated interest in the carbon sequestration values of forests. Forest owners could have the opportunity to manage their forests for carbon, along with other wood and non-wood products. Emissions trading could provide positive cash flows earlier than usually available from wood production, thus improving profitability. For the moment, however, the forest policy implications and practical consequences of the Kyoto Protocol remain unclear.

The most recent milestone in the international debate on the various aspects of sustainable development was the World Summit on Sustainable Development, held in Johannesburg in 2002.

Forest Policy Instruments for Small-Scale Forestry

Considerable differences exist in forest policy instruments between countries. In most countries the full range of policy means – normative, financial, material, and informative – has been adopted. However, the policy instruments are modified by so many conditions and variations that it is not possible to draw simple comparisons.

A fundamental review and reappraisal of forestry legislation has recently been or is currently being undertaken in many countries, in the light of the new priorities identified during the widespread debate on sustainable forest management.

Taxation and subsidies strongly influence the economic performance of small-scale forests. Differences can be observed in the balance between property taxation and income taxation, as well as indirect taxes such as value-added and fuel taxes. In this connection, special mandatory fees connected to timber sales have to be mentioned, as well as the general tax load on income, including social security fees which influence labor costs.

In general, financial support for forestry measures is at a rather low level, and normally only part of the costs of forestry measures can be covered by public support. Partial public support is typically available in many countries for measures such as regeneration of harvested areas, noncommercial thinning of young stands, forestry road building and maintenance, and forest fire protection.

The economic performance of small-scale forests is of importance for various policy objectives, but the availability and comparability of the information required to assess economic performance are not sufficient. Hence, evaluation of the efficiency of the policy tools is difficult. Indeed, the recent economic and political developments suggest a need for a more comprehensive information base and analysis on the socioeconomic situation of small-scale forestry.

Due to agricultural overproduction, one of the major concerns in industrialized countries has recently been the extent to which agricultural land can and should be converted to forestry or woodland, and the policy measures which would achieve this. For example, in almost all European countries there are policies to support farmers who convert their agricultural land to forestry.

Extension services, information distribution, and education are increasingly important forest policy tools. They activate forest owners to own contributions, and thus compensate for the reduced direct financial support for forestry measures. Indirect subsidies can be found in various forms, the most common example being the provision of management consulting services to small-scale private landowners by members of the forest service or foresters employed by semigovernmental institutions. Systematic forest management planning is seen as being one of the most important and efficient tools in many countries in this respect.

There appears an international trend to increase public participation in forest-related policy-making and decision-making. One sign of this is that national forest programs have become an important tool in the preparation of the future strategies for forestry. Evidently, small-scale owners play an essential role in these strategies. Especially in countries where small-scale forestry is dominating, only the strategies that are accepted by small-scale owners can be successful.

Final Remark

An important aspect to be noted here is that the land ownership structure and management goals for forestry around the world are heterogeneous and becoming even more so. One indicator of relative importance of forests for society is the share of forest area per capita. Even within Europe the extremes are from 0.2 ha in the Netherlands to 4.0 ha in Finland. It is self-evident that the owner's expectations as well as public values related to forests cannot be the same in these two countries. Indeed, the significance of forest resources for owners, as well as for the public, varies tremendously between countries and continents. This, on the other hand, guarantees the diversity of forest uses and management practices in the world.

Paper Recycling Science and Technology

M R Doshi, Progress in Paper Recycling, Appleton, WI, USA
J M Dyer, Weyanwega, WI, USA

Introduction

The principal raw material used in making paper, cellulose fiber, is derived chiefly from the wood of trees, although other plant residues such as rice straw, kenaf, and bagasse are also potential sources of fiber. Several pulping processes ranging from mechanical, chemimechanical, to chemical, are used to separate fibers in wood to produce virgin pulp (*see* **Pulping**: Chemical Pulping; Mechanical Pulping). Important hardwood species include aspen, oak, maple, and eucalyptus, while softwood types include species of pine, spruce, fir, and larch. If the fiber is not severely contaminated or has not deteriorated during its use in the paper or board product, it can be reused again as secondary or recycled fiber.

During the paper-recycling process, cellulose fibers are separated from recovered (waste) papers and reused to manufacture new products. In 2001, the US supply (= production + import − export) of pulp and paper was estimated to be 98 million tons, of which 47 million tons, or 48% of the total, was recovered (**Table 1**). The amount of paper land-filled decreased from 40.6 million tons in 2000 to 36 million tons in 2001. As shown in **Table 2**, the world production of paper and paperboard decreased from about 324 million tons in 2000 to 318 million tons in 2001, whereas paper recovery increased from 45.3% in 2000 to 45.9% in 2001. (Note that **Table 1** includes paper and board recovered for paper-making as well as for other uses, while **Table 2** includes paper recovered primarily for paper-making.)

Paper mills have many choices for the selection of raw material. Virgin sources include many species of softwoods and hardwoods while secondary sources include various grades of recovered papers. There are more than 50 grades of recovered papers. Four widely used recovered paper grades are described in the next section. The choice of raw material, virgin and/or secondary, will depend on many factors, such as geographic location of the mill, product manufactured, and economics.

Once the right paper grade has been selected, the next task of the mill is to separate fibers and contaminants like paper clips, staples, inks, and

Table 1 Paper and paperboard recovery in the USA

Year	*Supply (000 tons)*	*Recovered (000 tons)*	*Recovery rate (%)*
1990	86 796	29 112	33.5
1991	85 071	31 201	36.7
1992	88 273	33 954	38.5
1993	91 538	35 460	38.7
1994	95 718	39 691	41.5

adhesives. Unit processes like pulping, screening, cleaning, flotation, and washing are used to remove contaminants from the pulp. One of the contaminants that poses a serious challenge to paper recycling arises from adhesives, glues, and binders used in inks and coatings. Strategies to handle stickies are presented, followed by a brief presentation of the changes in paper properties due to recycling.

Paper Grades

The Paper Stock Institute of the Institute of Scrap Recycling Industries (ISRI) publishes a list of more than 50 recovered paper grades. Each grade has its own characteristics related to fiber species, the original pulping process, brightness, contaminant content, and degree of converting. In general these grades can be segregated into four main categories:

1. Corrugated or boxboard.
2. Newspapers.
3. High grades.
4. Mixed papers.

The recycling process changes the properties of the fiber so that it performs differently compared to virgin fiber. Additives, coatings, and inks used to increase the value and performance of the paper or board product can cause problems during the recycling process and must be removed during the recycling operations. The value of the recovered paper or board is a function of how difficult it will be to defiber, the degree of contamination, and the requirements to restore the fiber characteristics necessary to produce paper meeting the required specifications.

Corrugated Containers

Approximately one-half of the paper recovered in the USA in 2001 was old corrugated container (OCC). Corrugated includes corrugated boxes, kraft grocery bags, multiwall shipping sacks, and similar unbleached containers. The American Forest and Paper Association has estimated that, in 2001, 75% of the OCC was recovered in the USA. The chief source of OCC is from grocery stores and retail businesses, with an increasing quantity coming from individual households and small businesses. Most of the OCC is recycled into linerboard, corrugating medium, and containerboard. A typical OCC system is shown in **Figure 1**. Some of the unit processes shown in **Figure 1** are described in the next section.

OCC quality varies depending on the source. In the USA, a large percentage of corrugated containers have virgin fiber, usually unbleached softwood kraft, in the liner. Softwood kraft fibers are desirable due to their strength properties. In the USA, liner containing up to 20% recycled fiber is still classified as virgin. When a high proportion of recycled fiber is used, the liner may be termed test, jute, or bogus liner. The use of recycled fibers in the production of liner grades does not permit the stringent control of the fiber types as in the virgin grade. Since there are differences in the distribution of long and short fibers in recycled grades, the characteristics such as strength properties seldom match those of the virgin grade.

A requirement of fibers used in corrugating medium is stiffness, which gives the medium its crush resistance. Virgin medium is usually produced from hardwood fibers pulped by one of several processes, including neutral sulfite semichemical and alkali carbonate process (*see* **Pulping**: Chemical Pulping). Recycled medium may contain OCC, old magazines, and mixed papers.

Recovered OCC is used in the manufacture of solid folding boxboard. The application of fractionating permits the separation of the recycled pulp into a long and a short fiber fraction, each of which can be directed to the desired end use. Short fibers, which tend to be stiffer, are used in the top ply to provide good printing characteristics. The longer fibers, which provide better strength and runnability, may be used in the filler plies.

Notes

1. High-density cleaning corresponds to cleaning in large-diameter (30–75 cm) hydrocyclones, usually at consistency of 3–4%.
2. Cleaning in hydrocyclone to remove contaminants with density greater than that of water is termed heavy-weight cleaning or forward cleaning.
3. Cleaning in hydrocyclone to remove contaminants with density less than that of water is termed light-weight cleaning.
4. Disk filter is used as a thickening device.
5. Dissolved-air flotation (DAF) is generally used here for water clarification.

Reproduced with permission from Spielbauer JL (1998) Recycling systems overview. In: Doshi MR and Dyer JM (eds) *Paper Recycling Challenge*, vol. III, *Process Technology*. Appleton, WI: Doshi & Associates, Inc.

Other uses for OCC include use in absorbent grades such as industrial toweling and in packaging papers such as grocery bags and industrial wrappers.

Newspapers

This category includes old newspapers (ONP) collected from residences, offices, and other sources. In the USA, approximately 78% of the newspapers printed are now being recovered. In 2001, 9 million tonnes of ONP were recovered, or nearly twice the recovery rate in 1989. About 60% of all ONP recovered is recycled domestically to manufacture newsprint or recycled paperboard. In paperboard, ONP serves as filler.

ONP has a high percentage of mechanical fiber, which includes groundwood and thermomechanical pulp. Chemical fiber such as kraft may comprise up to 30% by weight and is added to improve the strength properties of the paper. Other constituents may include additives such as starch, inorganic fillers, and dyes for color control. Inorganic filler content (ash) may range from 3 to 12% by weight. Newspapers are printed by letterpress, offset, and flexographic processes. Ink content in printed newspapers comprises 1–2% by weight.

When recycled to produce newsprint, ONP is processed through a sequence of deinking steps. While there are several variations in the deinking process, the common unit processes consist of:

- pulping (and detrashing)
- washing (and thickening)
- screening
- dispersion
- cleaning
- bleaching
- flotation deinking
- water clarification.

A typical deinking system is shown in **Figure 2**.

Deinking technology for recycling ONP is well established; however, there have been distinct differences in the approaches developed in Europe and Asia compared to North America. Dispersed-air flotation deinking was traditionally applied in Europe and Asia, whereas in North America washing was the primary deinking process. In recent years, flotation deinking has gained acceptance in North America, where it is commonly used in combination with washing.

In mills deinking with flotation, ONP is commonly blended in a 70 : 30 ratio with old magazines (OMG). The presence of OMG in the furnish aids in flotation due to the high filler content (clay and/or calcium carbonate) which may stabilize the foam. OMG also enhances product brightness and strength due to the presence of bleached chemical fibers. Deinking chemicals such as fatty acid soap, sodium silicate, chelants, and caustic are added to the pulp to aid in ink detergency. Soap promotes ink particle attachment to air bubbles by making the ink more hydrophobic and it promotes a stable foam, allowing the flotated ink to be removed from the process before the bubble breaks.

High Grades

These grades are usually processed by a deinking operation. High grades are primarily printed and unprinted white papers collected from converting

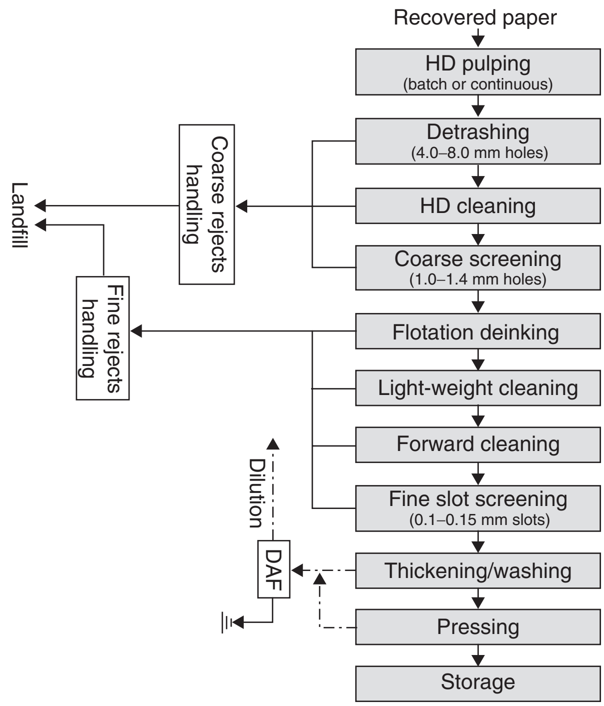

Figure 2 Flow diagram for old newspaper deinking system. *Notes*:

1. HD (high-density) pulping stands for pulping at solids concentration (consistency) of 12–18%.
2. HD cleaning corresponds to cleaning in large-diameter (30–75 cm) hydrocyclones, usually at a consistency of 3–4%.
3. Cleaning in hydrocyclone to remove contaminants with density less than that of water is termed light-weight cleaning.
4. Cleaning in hydrocyclone to remove contaminants with density greater than that of water is termed heavy-weight cleaning or forward cleaning.
5. DFA stands for dissolved-air flotation. DAF is used here for water clarification.

operations, printing plants, and offices. These grades are versatile raw materials and have been recycled to make a range of products, from tissue to recycled paperboard to printing and writing papers. Demand for some grades is high, for example pulp substitutes; however, the potential for growth of some high grades is limited since virtually all sources have been exploited. Additional supplies of mixed and sorted office papers will be generated through expanded office paper recovery programs.

Mixed Papers

Unlike the preceding categories, mixed paper grades are not segregated. The category mixed papers is comprised of several types of papers commingled together. As a result, the fiber is more heterogeneous, filler content is variable, and contamination levels are higher. However, demand for mixed papers is increasing as the more valuable grades reach the limit of recovery, and as recycling technology advances. Mixed papers are generally substituted for other grades such as ONP and OCC in containerboard. Mixed papers are generally collected from homes and offices.

Recycling Unit Processes

The recycling of recovered paper involves several unit processes that separate the paper-making fibers from contaminants which may detract from the appearance or strength properties of the final product. Contaminants include sand, staples, wood, inks, plastics, adhesives, coatings, and inorganic fillers. The number and sophistication of the unit processes increase as the requirements for cleanliness and brightness in the final product increase.

Pulping

The primary purpose of pulping is to defiber the paper into its constituent fibers without significantly degrading contaminants. Important parameters in pulping include stock consistency, temperature, pulping intensity, pH, and pulper configuration. Progress has been made in understanding and modeling pulping and ink detachment.

Pulping is accomplished through three basic mechanisms:

1. Wetting the paper to the desired consistency.
2. Circulation either to return the material to a high shear zone or to promote fiber-to-fiber friction.
3. Attrition, by which flakes are torn apart in a high shear zone.

Pulpers are characterized by their operating mode, whether batch or continuous, geometry, rotor type, operating consistency, and accessories. They can be broadly classified as either vat-type or drum-type. A typical vat-type pulper is shown in **Figure 3a**. This pulper consists of a vat or tub in which the stock is mixed by a rotor positioned at the bottom or side of the tub. The type of rotor used is dependent upon the consistency requirements, operating mode, and fiber type. Helical rotors, which resemble a large screw (**Figure 3b**), operate at high consistency and promote fiber-to-fiber friction through radial motion. Attrition rotors, used in low-consistency pulpers, have blades that maximize turbulence and shear.

The drum-type pulper consists of a rotating vessel through which the recovered paper tumbles and is

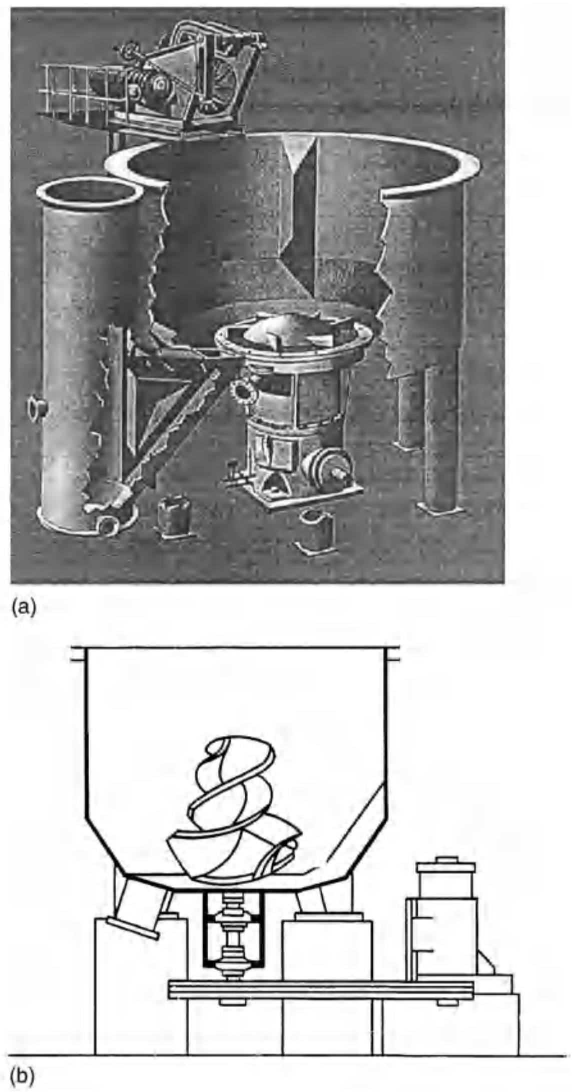

Figure 3 (a) Side cut-away of a vertical pulper. (b) Helical rotor pulper. Reproduced with permission from Silveri L and Wagner MM (1998) The pulper/detrasher module in the recycle system. In: Doshi MR and Dyer JM (eds) *Paper Recycling Challenge*, vol. III, *Process Technology*. Appleton, WI: Doshi & Associates, Inc.

defibered as it is transported along the length of the drum. Drum pulpers operate at high consistency (15–20%) and are used for treating low-strength materials such as newspapers which defiber easily. A schematic of a drum pulper is shown in **Figure 4**. Recently, variations in the design of drum pulper have been introduced. Applications of drum pulpers have been extended to other paper grades such as office papers and OCC.

Many modern pulpers are fitted with ancillary equipment that removes trash and contaminants before they are broken down into small pieces. This equipment includes the ragger to remove wires and rope-like contaminants, junk tower, for larger trash, and the secondary pulper. The secondary pulper, or detrasher, which receives a small side stream from the main pulper, consists of a dual-chamber device in which the rejects chamber and the accepts chamber are separated by an extraction grate, a perforated plate. The rotor wipes the extraction plate to keep it free of contaminant build-up during the passage of accepted fiber.

Pulpers are operated in one of two modes: batch or continuous. In batch pulping, paper stock, water, steam, and chemicals, if necessary, are charged to the pulper and the entire mixture is processed for a set amount of time before it is dumped to a receiving chest. Batch pulping is more commonly used in deinking where high consistency is desired and when the residence time in the pulper must be controlled to ensure sufficient detachment of ink from the fibers.

Continuous pulpers are fed with recovered paper and water on a continuous basis while defibered materials pass out of the pulper through an extraction plate. The residence time of the material in the pulper is a function of the feed rate, size of the pulper tub, and the opening size of the holes in the extraction plate. Generally operating at 4–8% consistency, this mode of pulping is used where high production is desired and is commonly used in OCC processing systems.

Screening

Screens are able to separate a multicomponent flow into two fractions on the basis of differences in morphology or shape. Screening is the most common separation process used in recycled fiber systems. While screening is most commonly associated with the separation of contaminants from fiber, several applications are based on screening or barrier separation technology:

1. Contaminant screening.
2. Fractionation.
3. Washing.
4. Dewatering.

Contaminant screening The object of contaminant screening is to remove nonfibrous contaminants while minimizing the loss of fiber. Pressure screens are the most commonly used devices for this purpose, although some gravity screens are operating in tailing systems. The pressure screen consists of a cylinder with either perforated holes or fine slots: it is attended by a rotating hydrofoil or other rotating element providing alternating pressure or vacuum pulses to the screening surface to keep it from plugging or blinding with debris or fiber. The materials that pass through the screen openings, considered accepts, are sent forward in the system,

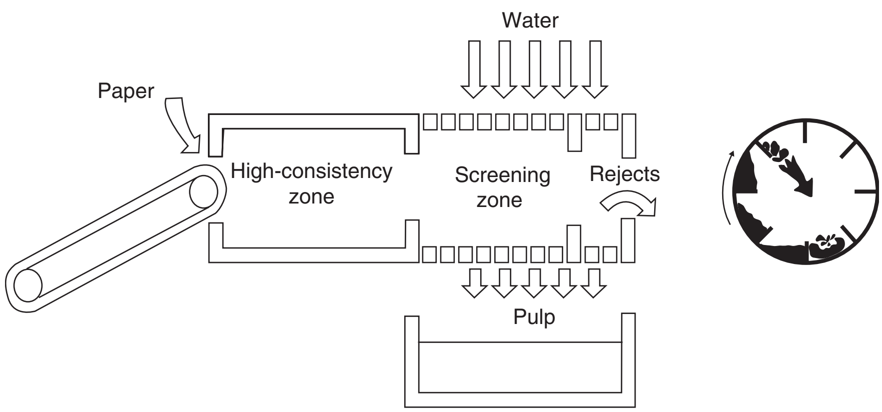

Figure 4 Drum pulper. Reproduced with permission from Silveri L and Wagner MM (1998) The pulper/detrasher module in the recycle system. In: Doshi MR and Dyer JM (eds) *Paper Recycling Challenge*, vol. III, *Process Technology*. Appleton, WI: Doshi & Associates, Inc.

while the materials that are blocked at the openings are rejected and are either reprocessed in another area of the system or discarded. Coarse screens, generally positioned early in the system, process relatively contaminated stock and have perforated cylinders. Perforations are usually 1.38 mm (0.055 in.) or larger. Fine screens, with slotted cylinders, are positioned after coarse screens where they are more effective in removing small contaminants. The slot opening width of fine screens ranges from 0.10 to 0.60 mm (0.004–0.024 in.).

Fractionation Fractionating screens separate the stock into a long fiber fraction and a short fiber fraction. These devices normally use holes in the range 1.3–2.0 mm and operate in the consistency range 2–4%.

Washing When used for washing pulp, a fabric is used to retain fibers while allowing the fines, fillers, and ink to pass with water through the fabric. Traditionally, sidehill screens and deckers were used. During the last 15 years more aggressive washers, which minimize the formation of a mat on the fabric, have been developed.

Dewatering The function of dewatering screens is to maximize the removal of water from stock while minimizing the loss of solids. Disk filters are used for low-consistency applications, while belt presses, screw presses, and twin wire presses are used at high consistency.

Cleaning

Cleaners or hydrocyclones remove contaminants from pulp based on the density difference between the contaminant and water. These devices consist of a conical or cylindrical–conical pressure vessel into which pulp is fed tangentially at the large-diameter end (**Figure 5**). During passage through the cleaner the pulp develops a vortex flow pattern, similar to that of a cyclone. The flow rotates around the central axis as it passes away from the inlet and toward the apex, or underflow opening, along the inside of the cleaner wall. The rotational flow velocity accelerates as the diameter of the cone decreases. Near the apex end the small-diameter opening prevents the discharge of most of the flow which instead rotates in an inner vortex at the core of the cleaner. The flow at the inner core flows away from the apex opening until it discharges through the vortex finder, located at the large-diameter end in the center of the cleaner. The higher-density material, having been concentrated at the wall of the cleaner due to centrifugal force, is discharged at the apex of the cone.

Cleaners are classified as high-, medium-, or low-density depending upon the density and size of the contaminants being removed. A high-density cleaner, with diameter ranging from 15 to 50 cm (6–20 in.) is used to remove tramp metal, paper clips, and staples and is usually positioned immediately following the pulper. As the cleaner diameter decreases, its efficiency in removing small-sized contaminants increases. For practical and economic reasons, the 75-mm (3-in.) diameter cyclone is generally the smallest cleaner used in the paper industry.

Reverse cleaners and throughflow cleaners are designed to remove light-weight contaminants such as wax, polystyrene, and stickies. Reverse cleaners are so named because the accepts stream is collected at the cleaner apex while the rejects exit at the overflow. In the throughflow cleaner, accepts and rejects exit at the same end of the cleaner, with accepts near the cleaner wall separated from the rejects by a central tube near the core of the cleaner.

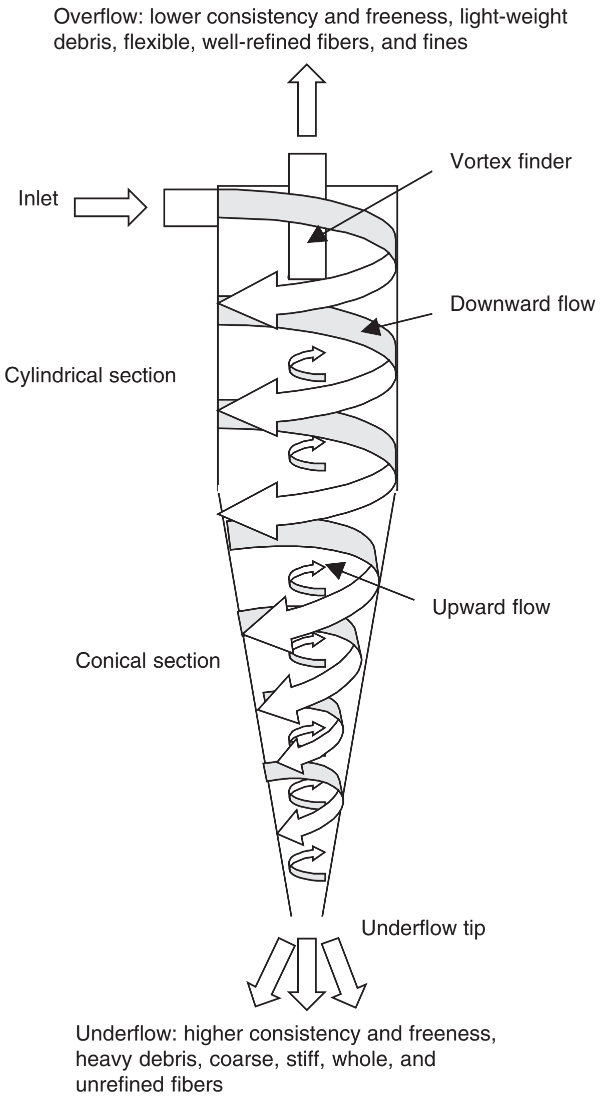

Figure 5 Parts of a hydrocyclone, major flow patterns, and separation trends.

Continuous centrifuges used in the 1920s and 1930s to remove sand from pulp were discontinued after the development of hydrocyclones. A recently designed cleaner, the Gyroclean, developed by Centre Technique du Papier, Grenoble, France, consists of a cylinder that rotates at 1200–1500 rpm. The combination of relatively long residence time and high centrifugal force allows light-weight contaminants sufficient time to migrate to the core of the cleaner where they are rejected through the center vortex discharge.

Deinking

In grades that are destined to be recycled into printing and writing grades, tissue, etc., deinking is applied to remove ink from the pulp. The deinking process begins in the pulper where fiber-to-fiber rubbing and added chemicals for detergency detach ink from the fiber surface. Processes present in the system for removing ink from pulp include cleaners, washers, froth flotation, and, to a certain extent, screens. Kneaders and dispersers are used to disintegrate residual ink into smaller particles too small to be seen by the naked eye. Kneaders and dispersers also assist in the detachment of inks and other contaminants from fibers.

Deinking chemistry The goal of deinking is to provide the conditions in the pulper that will advance the detachment of ink from fiber, and then, in subsequent equipment, separate the detached ink from the pulp. Chemicals are commonly used to enhance deinking. Sodium hydroxide is used to adjust pH. Surfactants affect detergency and dispersed ink particle size, critical for effective ink removal in the processes following pulping. In the pulper, the mechanisms of ink detachment include:

- surfactant-promoted solubilization of ink into the aqueous pulping medium
- surfactant-promoted wettability alteration of cellulose surfaces promoting ink detachment and emulsification
- cellulose fiber swelling, promoted by high pH, to enhance ink detachment from fiber
- fiber-to-fiber rubbing promoted by mechanical agitation.

Inks differ in surface chemistry and composition. As a consequence, the selection of chemistry and removal processes must focus on the type of ink that is encountered in the particular recovered paper grade. The role of the surfactant used for wash deinking is to create hydrophilic, dispersed ink particles. Flotation deinking surfactant must make the detached ink particles more hydrophobic so that they attach to air bubbles, and the surfactant must produce sufficient air bubble stability so that the froth can be removed from the pulp. Sometimes a dispersant like sodium silicate may be necessary to stabilize detached ink particles and avoid redeposition back on to fibers.

Washing Washing is effective for removing dispersed ink, fines, and filler particles of less than 15 μm. Washing devices function in a manner similar to a laundry process whereby finely dispersed particles are transported away from the pulp with the filtrate as the pulp thickens on a mesh or wire. The formation of a fiber mat during washing can reduce the removal efficiency of fine particles, therefore highly turbulent washers tend to be more efficient, but at the sacrifice of lower yields, i.e., greater fines and/or fiber losses.

Dispersed-air flotation Originating in the mining industry for enrichment of ores, the flotation process developed in Europe for deinking has gained importance in North America. In this process, hydrophobic particles such as ink and small contaminants attach to air bubbles injected into the pulp and get carried upward to the froth while fibers remain in the bulk. The particles are separated from the pulp by removing the froth from the surface of the pulp. Surfactants are commonly used to enhance the hydrophobicity of the particles and to improve the stability of the froth. The optimum consistency range of froth flotation is 0.6–1.0%, and particles in the size range 25–300 μm can be removed by the process. Several factors influence the effectiveness of flotation units in removing ink particles from pulp. These include water hardness, temperature, ink particle size, ink particle chemistry, air bubble diameter, hydraulic flow patterns, air-to-stock ratio, and the froth removal system.

Kneading and dispersion Kneading and dispersion devices mechanically treat the pulp to reduce visible particles such as ink to subvisible sizes. In disk dispersion, pulp at high consistency is forced between two parallel disks, one stationary, and one rotating at 1200–1800 rpm. The disks are separated by an adjustable, narrow gap. Under the conditions of high shear and friction within the zone between the disks, ink and contaminant particles are reduced in size.

Kneading, also referred to as low speed dispersion, imparts relatively longer mechanical treatment to the pulp with a moderate shearing effect. In principle, the kneader consists of a shaft, to which are affixed several rows of fingers, slowly turning within a stator wall on which other fingers are attached. Pulp is fed by a screw conveyor into the narrow passage between the rotating shaft and stator where it is subjected to rubbing action. A discharge door controls the pressure on the pulp and the volume of pulp in the device. Double-shaft kneaders have two counterrotating shafts, turning at different rates.

Dispersers have been used to mix bleaching chemicals into the pulp. Located near the end of the process, dispersers can disintegrate the remaining contaminants which are then removed from the pulp by a postdispersion screening, cleaning, flotation, and/or washing steps.

Bleaching

The reasons for bleaching recycled fibers include color stripping, delignification, and brightening of fibers. In oxidative bleaching, agents such as hypochlorite, hydrogen peroxide, oxygen, and ozone are used. Reductive bleaching compounds include sodium hydrosulfite and formamidine sulfinic acid (FAS). Recovered paper pulps may contain chemical pulp, mechanical pulp, and dyes, each of which requires a specific bleaching approach for maximum effectiveness.

Bleaching mechanisms The bleaching agents can be categorized as nondegrading reagents and degrading agents. The nondegrading reagents such as hydrogen peroxide reduce color bodies (chromophores) in pulp by oxidizing carbonyl groups, while FAS and hydrosulfite reduce the quinone structures. These chemicals are useful in bleaching wood-containing grades since they do not react with lignin.

The degrading agents, which include oxygen, ozone, and the chlorine-containing compounds such as hypochlorite, are used primarily for bleaching chemical pulps and act by destroying the phenolic groups and the carbon–carbon double bonds. In recycled pulps containing higher amounts of mechanical fibers, the degrading agents tend to reduce the yield and yellow the pulp due to the fragmentation and/or modification of the lignin.

Dyes pose a special problem since, with the exception of ozone, no single bleaching agent is effective in destroying the broad range of dyes found in recovered papers. In general, direct dyes that contain conjugated nitrogen–nitrogen double bonds are readily decolorized by hydrogen peroxide and the reducing agents. Basic dyes, which contain conjugated carbon–carbon double bonds in aromatic compounds, are more prone to degradation by strong oxidizing agents. High temperature (above 100°C) peroxide bleaching seems to be effective in bleaching office papers.

Microbial enzymes such as xylanases and ligninases can improve lignin and chromophore removal, thereby facilitating bleaching in subsequent processes. When followed by peroxide bleaching, enzyme-pretreated pulps show a higher level of brightness and cleanliness than conventionally deinked pulps.

Bleach application methods Three main application points for bleaching agents include the pulper, bleach tower, and disperger/kneader. Hydrogen peroxide is commonly used with chelants and/or sodium silicate directly in the pulper to increase the brightness of mechanical grades such as ONP/OMG. In bleach towers, bleaching chemicals are mixed with pulp and the mixture is allowed to remain for an extended time period, usually 0.5–1.5 h. This longer residence time permits the completion of the bleaching reaction. Dispersers and kneaders are used in bleaching since they commonly operate at elevated temperatures which drive the bleaching reaction, and they promote excellent mixing of the chemical with the pulp. Following the disperser or kneader there may be a chest in which the bleaching reaction is allowed to proceed.

Commonly, bleaching sequences comprised of two or more bleach stages, each using a different bleaching reagent, may be used to maximize the brightness increase and color removal from the recovered fiber. For example, an oxidative stage using hydrogen peroxide bleaching may be followed by a reductive stage using sodium hydrosulfite.

Water Clarification

Considerable quantities of water are used for dilution, conveying, and washing during the processing of recovered fiber. Processes that enable the reuse of water are important from an environmental and financial standpoint. Water clarification is the unit operation which removes the bulk of suspended solids and the small amount of dissolved solids from the water, thus making it possible to reuse it in the system. By reusing clarified process water both the volume of effluent discharged to the wastewater treatment plant and the amount of incoming fresh water that must be treated are reduced. For example, a deinking stock preparation system will require 11–30 m^3 (3000–8000 gallons) of water per ton of production.

Clarification processes are usually attended by a chemical conditioning program. Flocculation and/or coagulation chemicals and polymers are used to aggregate solids in water, thus making the particle size larger.

Several techniques for clarifying process water are practiced. Some of these include sedimentation, dissolved-air flotation (DAF), and filtration. In the sedimentation process, process water is held in a clarifier tank at quiescent conditions for an extended time period. Solids separate from the liquid due to differences in density, interfacial tension, degree of hydrophobicity, or a combination of these factors. The net result is for the solids either to sink to the bottom or float to the top of the clarifier where they are removed.

In the DAF process, very fine air bubbles are introduced into the clarifier to provide buoyancy to the solids. Prior to introduction into the clarifier, a small portion of clarified water is pressurized and semisaturated with air. When this water is released into the clarifier, the dissolved air leaves solution and forms very small bubbles (0.01–0.1 mm diameter) which attach to the flocculated solids. The solids containing air bubbles become buoyant and are carried to the surface of the clarifier where they are skimmed from the tank. In a subsequent process, the solids, or sludge, is dewatered for disposal. DAF has the advantage of requiring low residence time (3–8 min) compared to sedimentation clarifier and it is able to separate solids with a fairly broad range of specific gravities.

Filtration technology includes drum filters, which remove larger suspended solids such as fibers and fiber fines, and membrane filtration, including reverse osmosis, nanofiltration, and ultrafiltration. Ultrafiltration, effective on particles down to 0.005–0.13 μm diameter, is being considered for the removal of flexographic inks from ONP deinking process water. Due to high energy, maintenance, and capital costs, ultrafiltration is not widely used in the paper industry at this time.

Stickies

Contamination from adhesives, called stickies by paper-makers because they adhere to paper machine felts and wires and cause operating problems and product quality defects, are a major problem during both the processing of recovered paper and paper-making operations. Stickies are the undesirable recovered paper components that originate from pitch, ink, plastic films, converting aids, coatings, and adhesives. Adhesives are either hot melts, commonly used in book-binding and case sealing, or pressure sensitives, used in labels and tapes.

Stickies have been classified based on their behavior and size. The reason for categorizing stickies is because methods for removing the different types are different, and the strategies for minimizing their impact on paper-making are different. The size-based classification divides stickies into the two groups macro and micro. Macro stickies are those which are separated when pulp is processed through a laboratory slotted screen (>100 μm), while micro stickies are those which are able to pass through the slots of the screen (<100 μm). Based on behavioral characteristics, stickies are divided into two classes, primary and secondary. Primary stickies result from the disintegration of adhesives during pulping and subsequent stock preparation. Secondary stickies are derived via a two-step sequence: (1) formation of soluble and/or colloidal materials during pulping, and (2) destabilization of the pulp suspension either by the addition of cationic polyelectrolytes, pH, and/or temperature shock, or other means which decrease solubility, causing soluble or colloid substances to precipitate.

Strategies to control stickies during the recycling process include: (1) selecting recovered paper with lower concentrations of stickies and monitoring quality; (2) keeping pulping conditions mild in order to minimize degradation of adhesives; and (3) use of slotted screens, flotation cells, and reverse cleaners to remove macro stickies. Methods used to control dispersed and colloidal stickies include pacification by the addition of talc, cationic polymers, enzymes, and dispersants. These substances affect the surface of stickies by binding to them or modifying the tackiness. Dispersed stickies may be removed from pulp during washing; however, effective clarification of washer filtrate is essential to prevent the build-up of stickies in the process water system.

US Postal Service initiated a project at Forest Products Laboratory, Madison, Wisconsin, with the goal of implementing recycled compatible pressure-sensitive adhesives to postage stamps. Many articles resulting from this project were presented at the TAPPI Recycling Symposium in 2002.

The Effect of Recycling on Paper Properties

The suitability of fibers for recycling is a function of the origins and past treatments to which the paper product has been subjected. The manner in which the wood was pulped, the paper-making process, the printing and converting method, the consumption and collection history, and the manner in which the paper will be recycled all affect the quality of the recycled fiber.

Refined chemical pulps behave differently from mechanical pulps upon recycling. When pressed and dried, the lumen and fibrils of chemical pulps collapse. During the rewetting in recycling, the degree of fiber swelling and fibrillation decreases due to a phenomenon referred to as hornification. Because the recycled chemical fibers are less flexible, physical properties that rely on bonding such as tensile, burst, and density decrease while tear and stiffness increase (**Figure 6**). The opposite effect is seen for recycled mechanical fibers which, due to the presence of lignin that minimizes the hornification in the fiber wall, become more flexible and may show small increases in tensile strength and density.

Several strategies are available for increasing the potential of recycled fibers for paper-making. Refining can be applied to improve fiber bonding through the reswelling of the fiber wall. However, refining recycled fibers tends to shorten the fiber length and produces fines that decrease the pulp's drainage rate. Cationic starch is added at the wet end of the paper machine to improve the bonding strength. Sodium hydroxide is used during repulping to promote fiber swelling which helps to reverse hornification. Through fractionating screens, two fiber fractions, one longer fiber and one shorter, are used in separate grades or in different plies of the same paper.

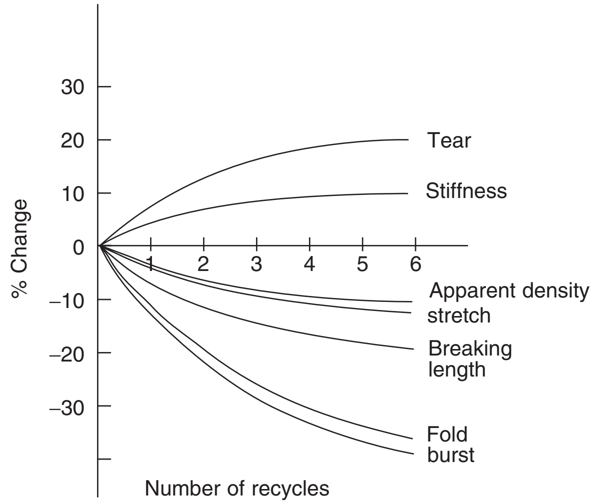

Figure 6 The general effect of recycling on the properties of paper made from refined chemical pulps. Reproduced with permission from McKee RC (1971) *Paper Trade Journal* 155(21): 34.

Summary

During the recycling process, fibers are separated from recovered paper and reused in the manufacture of new products. The practice of recycling paper is expected to grow as the worldwide demand for fiber increases. The percentage of recovered paper used worldwide in the production of paper and paperboard increased from 45.3% in 2000 to 45.9% in 2001.

Recycled fiber processing begins with pulping, during which the recovered paper is defibered. In subsequent steps, which include cleaning and screening, contaminants are removed. Depending upon the final product requirements, flotation and washing may be used to remove ink from the pulp. Bleaching is applied to remove color and increase the brightness of the fibers.

The use of recycled fibers in making paper and board poses an interesting challenge from the perspective of overall economics, removal of contaminants, and strength properties of the recycled product.

Printing

P D Fleming, III, Western Michigan University, Kalamazoo, MI, USA

Introduction

Printing has been called the single most significant technical development of human history. Prior to the invention of printing, virtually all communication was verbal. It was difficult to communicate to a large number of people. Printing provided the ability to record ideas in a manner that can be passed through generations. Paper is still the most utilized substrate for printing.

As early as 35 000 BC, people were drawing messages on cave walls. Pictographs were used to represent real objects. Pictographs evolved to ideographs, which were developed by the Phoenicians. By 900 BC, the Phoenicians had also assigned sounds to the symbols.

The Greeks adopted and expanded the Phonetic system. The Romans borrowed 13 Greek letters, revised eight, and added two more in order to write in Latin. Three additional letters were added later for a total of 26, as we know the Roman alphabet today.

Printing Processes

All printing processes produce lines and/or dots to form an image. Printing has made possible the production of multiple copies of graphic images. There are five types of processes, which can be used for graphic reproduction. They are all used to print on paper as well as other substrates. These processes are:

1. Relief printing
2. Intaglio printing
3. Screen printing
4. Lithographic printing
5. Nonimpact printing

Relief Printing

Relief printing was the basis for the original printing press, as invented by Johann Gutenberg. This is based on raised letter type (**Figure 1**). Gutenberg's characters were molded out of lead, a metal, which was used until only recently. This process came to be known as Letterpress and was the basis for all newspaper printing until only recently.

The letterpress process is still used today for die cutting, numbering, perforation, scoring, hot-foil stamping, and embossing. Letterpress inks are relatively high in viscosity to assure its even distribution as it passes through the multiple rolls (**Figure 2**) of the inking system. To distribute the ink better, some or all of the rolls oscillate.

Letterpress has evolved into flexography (flexo), which uses a flexible plate, which contains a raised image area of a cured photopolymer. The plate is wrapped around a cylinder and is used to put ink on the substrate. A typical flexo print station is illustrated in **Figure 3**.

Flexo is the fastest-growing conventional printing process, especially in packaging, such as corrugated containers and flexible films. It has also made significant advances in publication printing, particularly newspapers. Because the quality of flexo printing has improved so much, it is now used extensively for process color printing, as well as spot color, on a wide variety of substrates. It is used extensively for printing tags and labels, many in full process color.

Flexography was originally called 'aniline' printing because of the aniline dye inks originally used in the process. These were made from coal tar and were banned from food packaging by the Food and Drug

Administration because of their toxicity. Other coloring agents were developed that were safer, but the name aniline printing persisted. Because the name carried bad connotations, the name was changed to flexography in 1951.

Flexo plates are flexible and imaged in relief, a natural outgrowth of letterpress printing. The origin of these plates was in rubber stamps, which were formed in Bakelite molds that had been pressed with lead type. Thus, the original plates for aniline printing were made of molded rubber.

The first aniline press was built in 1890 by Bibby, Baron and Sons in Liverpool, UK. It used water-based dye inks, which were not chemically bleed-proof. In 1905 C.A. Holweg built an aniline press as a tail-end unit on a bag machine and patented it in 1908. The ink metering on these presses was crude until 1938, when the anilox roll was introduced. This employed a mechanically engraved copper-coated roll with controlled cell sizes (**Figure 4**). The idea grew out of gravure printers laying down coating from a uniform cell-engraved roll. The anilox uses this process to coat the raised surfaces on the plate.

Anilox rolls are coated with chrome to prevent corrosion and wear. The original aniline inks gave way to ones based on polyamide resins. These stable, fast-drying inks enabled web speeds to increase from 45–230 $\mathrm{m\,min^{-1}}$.

The 1980 Clean Air Act led to more extensive use of water-based inks in flexo. Water-based inks are now used extensively for printing on paper-based substrates. The quality is now approaching that of lithography and is even impinging on gravure.

Intaglio Printing

Intaglio (engraved or cut in) printing is the reverse of relief printing. As used in commercial printing, it is called gravure or rotogravure. The process utilizes an engraved image consisting of a series of recessed cells, which hold a liquid ink. The ink is transferred to the substrate from these cells with an image based on the cell pattern. A gravure press generally employs a rotating metal cylinder consisting of these cells, and hence the roto in rotogravure. A typical gravure print station is illustrated in **Figure 5**.

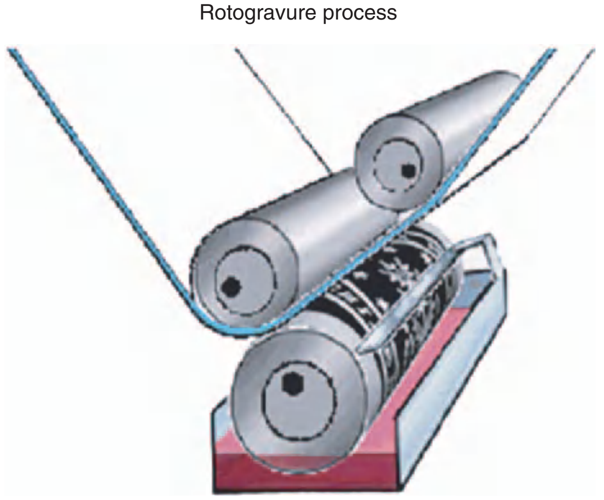

Figure 5 A rotogravure printing unit.

Rotogravure printing has a significant advantage relative to other printing processes for medium to long runs. Gravure can produce very-high-quality multicolor printing on a variety of substrates. Its success results from the simplicity of the process. Having fewer variables to control ensures consistent print quality throughout a run. Each print unit has four basic components: an engraved cylinder, the ink fountain, the doctor blade, and the impression roller.

The origins of gravure printing were with the creative artists of the Italian Renaissance in the 1300s. Fine engravings and etchings were cut by hand into soft copper.

Considerable force or pressure is needed to press the entire surface of paper against an image carrier evenly. Early presses were made entirely of wood. Thus, it was possible to print only small images without cracking. The first metal intaglio plate was used for printing in Germany in 1446, about the same time as Gutenberg. Unfortunately, the intaglio process was not compatible with Gutenberg's letterpress, so it was not adopted by early printers. The first metal printing press was built in 1550. This allowed larger sheets, but was still difficult to operate.

The modern gravure printing press resulted from the invention of photography and the adoption of rotary printing from cylinders. Auguste Godchaux received a patent for a reel-fed rotary gravure perfector press in 1860. This press was still in use in 1940! The process was refined by the German Karl Klic (Klietsch) and Samuel Fawcett. They did not have patents on their process, so they tried to keep the process secret. They sold prints from their press as 'heliogravure' prints, even though they were really rotogravure, as we know it today. Their process remained a trade secret, until an employee emigrated to the USA and made it public.

The process continued to improve and gravure presses were used to print Jell-O cartons, starting in 1938. Engraving continued to improve with electromechanical engravers being introduced in 1968, with digital controls added in 1983.

Screen Printing

This process transfers an image by allowing ink to pass through openings in a stencil that has been applied to a screen mesh. The process is often called silk screen printing, because silk was originally used to make the screens. Silk is not used industrially any more. Screen printing is commonly used to print on textiles.

Screen printing has two characteristics that make it distinctive from other forms of printing.

1. Versatility – screen printing can be adapted to print on almost any shape or object. It has been called 'the print-anything' process.
2. Variable ink thickness – screen printing can vary the ink film deposit from 25 to 130 μm.

This is the widest range of ink deposit of all the forms of printing.

The origins of screen printing are unknown. Evidence dates the process back to the Orient with links to China and to ancient Egypt. They used a simple open-stencil process. The stencil was pressed against the substrate surface. To hold the stencil in place, they brushed or painted the natural pigmented color on to the object.

Using this simple open-stencil process the Japanese devised a way to hold small stencil areas in place. A long piece of hair or silk thread was used to 'glue' an open spot on the stencil. This stencil process was also used to adorn fine silk fabric. Hence, the term 'silk screen' came into use.

In the 1830s silk was woven into a mesh and used for sifting purposes in the flour-milling industry. It was not until about 1870 that silk was used for 'silk screen' printing in Germany, France, and England. In 1907, John Pilsworth, an American, started using the screen method to make banners and short-run signs.

The basic concept of screen printing is based on a stencil. A stencil must be open or permeable in the image area and impermeable in the nonimage area. It is well suited for low-cost production of high-quality, short-run printed materials. It is versatile, capable of printing on nearly any surface, texture, or shape. The process is limited only by the size of the screen frame. Very high ink densities can be obtained.

Lithography

This process is based on a process discovered by Alois Senfelder in 1789. It literally means 'stone writing,' because it was originally based on images created on limestone plates. The plates are neither raised nor recessed and the process is often referred to as planographic.

Lithographic printing is based on wettability of different areas of the plate. The image area is oil (ink)-wet and the nonimage area is water-wet. The process makes use of the nonmixing of the oily ink and water (actually aqueous fountain solution). Lithography is the most chemical of the printing processes and Senfelder preferred the designation 'chemical printing.'

Because the transfer was made directly to the substrate, it was necessary to generate a mirror image on the plate. This was changed by the invention of the offset press, attributed to Ira Rubel in 1904. In this process, a set of three rotating cylinders is used and the image is first transferred from the plate (on a plate cylinder) to a rubber blanket (on a blanket cylinder) from which it transfers (offsets) to the substrate. A schematic of the cylinder arrangement of an offset press is shown in **Figure 6**.

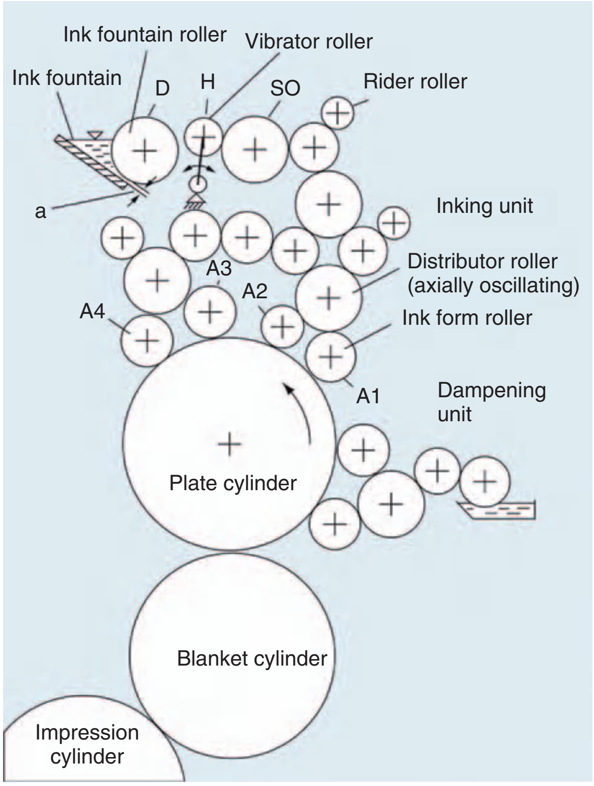

Figure 6 Complicated roller arrangement of an offset lithographic press.

On this we see the master, or plate, cylinder, the blanket cylinder, and the impression cylinder. The substrate passes between the blanket cylinder and the impression cylinder. The other rollers are part of the inking and dampening systems.

The advent of the offset press did not change the basic printing process; the image area needs to be oleophilic (oil-liking) or hydrophobic (water-hating), while the nonimage area must be hydrophilic (water-liking) or oleophobic (oil-hating).

Originally, when stone lithography was employed, letterpress was good for text, but poor for images, while lithography was good for images but poor for text. Books were often printed by a combination of the methods.

Stone lithography was primarily a picture-printing process. This changed and the printing industry was revolutionized by the advent of photography. It created demand for a totally new kind of printed picture. It became possible to combine pictures, including photographs, with text, on a single printing plate.

The relationship between lithography and photography was very strong from the beginning. Joseph Nicephore Niepce, a pioneer in photography, experimented with lithography. Lithography was the first printing process to make its whole plate, graphics and text together, photographically and photomechanically.

Nonimpact Printing

All of the conventional printing processes are impact methods. The plate and/or image carrier comes in direct contact with the substrate. Nonimpact printing refers to series of computer-driven devices that have evolved in a revolutionary fashion over the past 15–20 years. The developments in these devices have followed the dramatic improvement price and performance in desktop computers and the rapid reduction in cost of microelectronic devices. Because of the association with digital computers, nonimpact printing is often referred to as digital printing. These printing devices include laser printers, ink-jet printers, dye sublimation printers, thermal transfer printers, and others.

Because all these devices print directly from digital files, it is just as easy to print a single copy as many. This has made possible on-demand and variable data printing. Some concepts of on-demand ('I want it now') printing can be applied to conventional printing, but they are most appropriate for digital printing. A more rigorous difference between nonimpact printing devices and conventional presses is that nonimpact devices do not have 'permanent image carriers' (e.g., plates). On-demand printing provides many opportunities for printers and publishers to expand their capabilities.

On-demand printing is defined as short-notice, quick turnaround of short, economical print runs. When used efficiently, this can result in lower inventory costs, less risk of obsolescence, lower production costs, and reduced distribution costs.

This definition is not satisfied by traditional printing, where 31% of output is discarded before obsolescence. This includes 11% of all publications, 41% of promotional literature, and 35% of other material. Approximately one-third of magazines displayed on a newsstand are discarded.

Digital printing is defined as any printing completed via digital files. This includes all types of devices, from desktop printers to wide-format printers and digital 'presses.' These generally employ nonimpact printing processes as opposed to conventional impact printing. Digital printing also includes some of the devices used to make plates for conventional printing.

Variable printing is printing capable of incorporating data from a database to generate a short- to medium-length run of different but related pages. A traditional press may perform on-demand printing, but not variable printing.

Shorter runs comprise an increasing share of the total printing market. Short runs are usually defined as less than 5000 copies. Fifty-six percent of commercial, book, and office printing is between 500 and 5000 copies.

Digital color printing is the fastest-growing sector of printing, because of its suitability for short-run and variable printing. Unlike conventional printing devices, digital printers are falling in price and improving in performance.

Digital color printing currently supports the following:

1. Just-in-time production – printed items often have an unpredictable demand. With shorter runs, a purchaser can buy smaller lots more frequently.
2. Individual or variable output – it is just as easy to print every copy differently as the same. An advertiser can tailor a communication to different readers.
3. In-house production – simple color document production can be accomplished through in-house reprographics, as devices get cheaper and better.
4. Distributed information – reference items such as encyclopedias, manuals, and catalogs are now distributed more efficiently in electronic forms. High-quality digital printers at business locations allow use of the distribute-and-print model, rather than the traditional print-and-distribute model that has been in use since Gutenberg.
5. Visualization and prototyping – it is easy to produce single copies or short runs to test and approve visual concepts. The customer can view a printed copy on a local printer or soft-proof it on a monitor.
6. Compilation and offprints – if journal or magazine articles are stored in a digital database, then individual articles (or even bound custom collections) can be printed and distributed (or distributed and printed) easily.
7. Short-run printing – reports, manuals, posters, and specialty books can be produced with on-demand digital printing.

All digital printing systems have three basic components:

1. raster image processor (RIP) – converts image into device-specific bitmap.
2. A buffer to store rasterized data for printing.
3. A marking engine, which forms the image on the substrate.

Some of the marking engines are reviewed here.

Laser (or electrophotographic) printers use the same imaging method as office copiers. Indeed, modern color copiers have a direct computer and/or network interface, so they can be printed using the appropriate printer driver. A color copier is really a color laser printer with a built-in scanner. These devices can be versatile and may sustain high throughputs. The printing process is also known as xerography (literally, 'dry' writing) and has formed the basis for the success of the Xerox Company.

Electrophotographic printing also includes high-speed digital presses from Xeikon (now Punch) and Indigo (now Hewlett Packard). The Xeikon uses fixed light-emitting diodes (LEDs) instead of lasers, while the Indigo uses liquid toners. The process is illustrated in **Figure 7**, where a charged photoconducting drum is selectively discharged by the laser or LED. The drum is toned by charged pigment particles and the image is transferred and fused to the substrate with heat and pressure.

Inkjet printers use tiny nozzles to spray ink precisely on to the substrate. There are two broad classes of inkjet printers: continuous and drop-on-demand.

For continuous ink-jet printing, a thin stream of liquid is ejected from a container through a tiny orifice and is broken up into a steady stream of uniform droplets when subjected to a high-frequency vibration. After being electrically charged, the drops

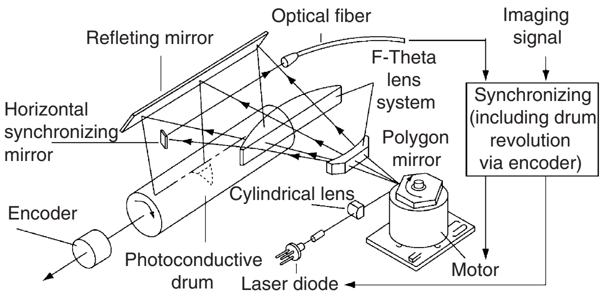

Figure 7 Mechanism of a laser or electrophotographic printer.

can be placed by an electrostatic deflector. Undeflected drops are recirculated. The Scitex 3600 digital press can print at 305 m min^{-1} in monochrome.

For drop-on-demand ink-jet printing, ink droplets are expelled from tiny orifices and directed immediately to the substrate. Most commonly, these devices use heat to vaporize a small amount of water-based ink in a chamber to form a gas bubble (bubble-jet). An illustration of the bubble jet process is shown in **Figure 8**.

The piezo drop-on-demand printer uses pressure pulses instead of heat to expel ink drops. The pressure pulses are generated by precisely charging a piezoelectric crystal. These are offered for desktop applications by Epson. An illustration of the piezo drop-on-demand process is shown in **Figure 9**.

Drop-on-demand inkjets are available in multiple formats, from letter size to 1.83 m-wide web. The wide-format versions can be used to proof imposition.

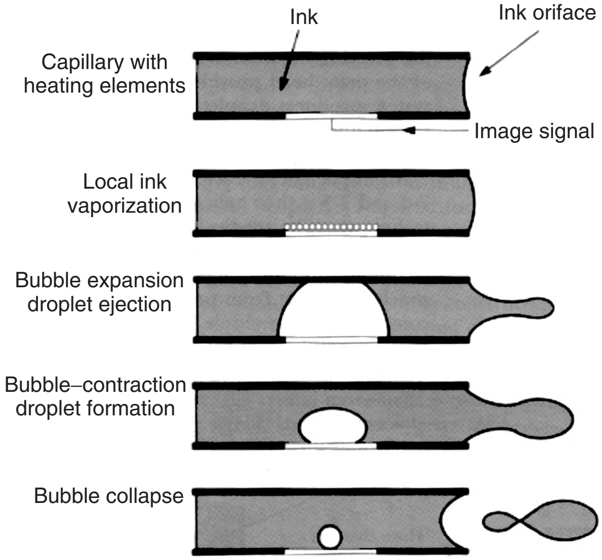

Figure 8 Illustration of thermal ink jet process.

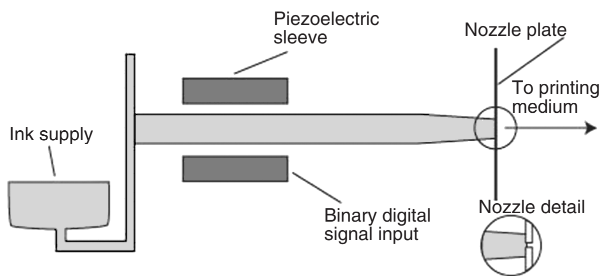

Figure 9 Illustration of piezo ink jet process.

The Printing Industry

Depending on the measure, the printing industry is between the fourth and seventh largest manufacturing industry in the world. Printing companies range from very large Fortune 500 organizations to small corner print shops. Because of the large number of small print shops and the large number of printing plants owned by the large companies, there are more printing manufacturing sites than for any other industry.

Types of Printers

Because of the diversity of the customer base, there are many different types of printing establishments. These are:

1. Commercial: commercial printers can vary greatly in size and can take on a wide variety of printing jobs. Their jobs can range from business cards to glossy color brochures.
2. Trade shops: trade shops provide services to the printing trade. They perform printing and finishing functions for printers who do not have all of the equipment for the job.
3. Special-purpose: special-purpose printing involves a limited type of job such as labels or forms.
4. Quick printing: quick printing includes copy centers such as Kinko's. These shops now employ direct digital printing devices as well as photocopying equipment. Many of these also still have small offset presses for larger numbers of copies.
5. In-plant: in-plant printing consists of any company which has its own print shop on site that performs printing functions for the organization.
6. Publishing: publishing involves printing of books, magazines, and newspapers. These usually employ very-high-speed web-fed printing presses.
7. Packaging: package printing involves printing on boxes, cans, and plastic films and foils.

There are also several related industries that provide services and materials to the printing industry. Related industries consist of ink companies and paper companies, along with film and plate material suppliers. Also included are the press and peripheral manufacturers.

Printing Inks

Printing inks are complicated mixtures of chemical compounds. The composition of printing inks varies by the printing process, by whether printing is sheet-fed or web-fed, and by the target substrate. The composition varies by the solvent base, be it oil or water. It varies by drying mechanism and by whether the drying is by primarily chemical, e.g., oxidation polymerization, ultraviolet cure, or physical processes, e.g., evaporation, absorption.

Inks are divided into liquid and paste inks. Gravure, flexo, inkjet, electrographic, and some electrophotographic inks (or toners) are liquid inks. Lithographic, screen, and letterpress inks are paste inks. The distinction between liquid and paste inks can be an arbitrary one, since it is based on apparent viscosity.

A printing ink consists of vehicle and pigment. Vehicle is all in the ink except the pigment. 'Varnish' is often used interchangeably with vehicle, but actually vehicle consists of varnish plus performance additives and solvent/diluent. As suggested by the name, the vehicle transports the pigment to the substrate. Varnishes must be chosen to wet the pigment. It they don't, suspension is virtually impossible and the ink will not have the desired rheological (flow) properties.

Pigments

Most pigments are used for all of the printing processes. Pigments are classified as carbon black, organic, white inorganic, and colored inorganic.

Carbon black is the major ingredient in black inks. Chemically it is mostly carbon, with small amounts of mineral matter and some volatile materials of the form C_xO_y. The typical particle size is 20–30 nm (10^{-9} m), the smallest of the pigments. Note that these may be truly nanoparticles. The smallest particles might be individual 'bucky balls' (single polymer molecules of carbon, possibly with other atoms encapsulated or bonded, e.g., C_{60}).

The C_xO_y improves the flow properties and serves as a natural wetting and dispersing agent. The amount of carbon varies between 90 and 99%, depending on the method of manufacture.

Organic pigments are used for process (photographic) color printing because they form transparent films. Most of these are derivatives of the aromatic hydrocarbons, benzene, naphthalene, or anthracene. The pigment molecules generally contain chromophoric groups such as $=C=NH$, $-CH=N-$, and $-N=N-$. The electrons in the double bonds selectively absorb some visible wavelengths and change energy levels. The color results from the wavelengths not absorbed. This is the subtractive color theory of colored objects.

The electrons in the chromophores are generally coupled to those in the conjugated aromatic rings. Dyes are soluble in the vehicle, while pigments are generally suspended in the vehicle. Pigments are preferred to prevent bleeding and fading. Dyes can be converted to pigments by reacting with phosphomolybdic and/or phosphotungstic acid.

Azo pigments, which have the $-N=N-$ group, include diarylide yellow, lithol rubine, red lake C, toluidine red, Hansa yellow, DNA orange, and napthol red. Phthalocyanine pigments are restricted to the blue and green regions of the spectrum. The phthalocyanine structure is given in **Figure 10**. Other pigments include pigment yellow 13, quinacridone magenta pigment, and pigment red 57, which are given in **Figures 11–13**.

White inorganic pigments include titanium dioxide (TiO_2), calcium carbonate ($CaCO_3$), and clay. (There are no white organic pigments.) The clay used is a hexagonal plate-like form of aluminosilicate called kaolin. It has low opacity and is used as an extender for letterpress and screen inks. Barium sulfate and fumed silica are also sometimes used as extenders in inks. These white pigments are all also used to whiten paper.

Colored inorganic pigments are mostly the iron blues, which are based on ferric ferrocyanide. These are formed by oxidizing ferrous ferrocyanide with a strong oxidizing agent such as sodium dichromate or sodium chlorate. Different shades of blue are

obtained by varying the pH, temperature, and time of heating during oxidation. These were used by printers for all printing inks through the mid nineteenth century, before the discovery of synthetic organic dyes.

Packaging Grades

G J F Ring, University of Wisconsin–Stevens Point, Stevens Point, WI, USA

Introduction

Nasiri Khosrau of Persia (now Iran) recorded the first use of paper as a packaging material in 1035 AD when he observed vendors in Cairo (Egypt) wrapping vegetables, spices, and dry goods in paper. Today, paper continues to be an important material used to transport, distribute, and market virtually every commodity and manufactured item. Paper competes very successfully with metals, glass, plastics, wood, and textiles, because it has many desirable properties including being biodegradable, recyclable, and renewable. Paper functions in many diverse packaging applications from heavyweight shipping containers to lightweight wrapping papers. This article will concentrate on lightweight specialty papers such as retail paper bags, food wrapping, gift wrapping, spiral-wound paper tubes, label stock, and other specialty items. The cut sheet size for wrapping papers is 24 in. by 36 in., giving a total ream area of 3000 ft^2. Types of paper used to manufacture boxes and containers are discussed elsewhere (*see* **Papermaking**: Paperboard Grades).

Retail Paper Bags

Retail bags are closed-bottom, flexible-walled containers that are capable of carrying many types of dry goods within them. Paper bags are manufactured from kraft paper due to the requirement for high strength. The paper may be bleached or unbleached depending upon the use. The grammage range for lightweight bags is 40–60 $g\,m^{-2}$. For heavier weight bags such as grocery bags that are required to carry as much as 12 kg the grammage range extends to 110 $g\,m^{-2}$.

Historically, bags were fabricated from textiles or animal skins with sewn bottoms. During the early nineteenth century, powdered goods such as flour or medicines were sold in hand-rolled paper sacks called 'pokes.' These early paper bags were actually inverted cones that required only folding to close the bottom. By 1877, paper bags were produced by machines that cut, folded, and either glued or sewed the sides from rolls of paper. Today, paper bags come in four basic shapes: flat, square, satchel-bottom, and self-opening.

Flat paper bags are made from kraft paper that has been glued with a starch-based adhesive to form a tube with its bottom folded and glued. This type of bag is commonly used for candy, greeting cards and many retail items that are small and lightweight. The square-bottom bag is similar to the flat bag except that the paper tube is first folded inwards along the sides to form an expanding gusset before the bottom is folded. When the square bag is opened or filled, the bag has a square or rectangular cross section. In this manner, the square bag can hold thicker and heavier items such as books and newspapers. The satchel-bottom bag also forms a square shape when opened but the bottom is folded into triangles and glued together to form a block bottom that is ideal for packaging flour, rice, sugar, and other dry food items. The satchel-bottom bags, when filled, can stand upright. Finally, self-opening bags have gussets to form square bags and specially folded bottoms that form flat-bottom squares or rectangles. These bags are folded flat but are designed to open with a snap of the wrist and stand by themselves for filling. Grocery bags and sandwich lunch bags are examples of self-opening bags.

Wet strength is an important paper additive for retail bags. Grocery bags in particular must be able to maintain a substantial portion of their strength when brought into contact with wet food and other products.

Multiwall Paper Sacks

Multiwall paper sacks are designed to be exceptionally strong and carry heavy and bulky materials for the building, food, and chemical industries. In essence, multiwall sacks are two or more separate sacks nested together to form a stronger and tougher sack. Five or six total plies of paper (60–110 $g\,m^{-2}$) may be necessary. For paper sacks, kraft paper is used; however, stretch and porosity as well as strength are critical performance criteria.

Stretch or extensibility is important because multiwall sacks are required to withstand numerous impacts during shipping and warehousing without rupturing and spilling their contents. Sack paper's ability to absorb shock during impact is measured by tensile energy absorption (TEA), which is a paper property that combines both strength and stretch. TEA can be thought of as a measure of 'work to burst.' Special extensible sack paper that has been produced through the 'clupak' process greatly enhances TEA and permits the use of lower grammage ranges (50–100 $g\,m^{-2}$) thus saving about 20% fiber by weight. The clupak process, invented by Sanford Cluett, produces extensible paper that is difficult to tear by passing wet paper through a steel and rubber nip that causes fiber crimping in the machine direction. Additional extensibility in the machine direction is produced on the paper machine through using slack draws in the dryer section. Slack draws prevent the sheet from developing dried-in drains leading to limited stretch.

Porosity is important for multiwall paper sacks because air needs to escape through the wall of the bag to permit rapid filling. Sack filling machines are able to fill a 25–50 kg sack in 1 second at temperatures that can exceed 100°C. Sewn-bottom and pasted bottom open-mouthed sacks are used for low pressure gravity-filling systems. Valve sacks are required when materials must be filled under pressure.

Multilayer sacks may be constructed with plastic liners to prevent moisture contamination. Plastic linings are important for foods and chemicals where the ingredients have to maintain a certain moisture level. Wet-strength resins are also used to control moisture penetration through the paper.

Food Wrapping Paper

Paper intended for the wrapping and serving of food must be manufactured from ingredients that do not adulterate food. This requirement necessitates the use of virgin chemically processed pulps along with paper additives and coatings that are recognized as safe to human consumption. These papers must have some form of wet strength and grease resistance as well as have reasonable printing properties. The basis weight range for food wrapping paper is 28–65 $g\,m^{-2}$. General categories of food wrapping paper include: greaseproof, metallized, and foil-backed papers. Special fruit wrapping papers impregnated with preservatives can also be found.

Greaseproof papers are papers that resist the penetration of grease and oils, and are also called moisture resistant papers. Vegetable parchment is a nonporous, homogeneous sheet of cellulose formed from sulfuric acid treating pulp. This material is the traditional form of greaseproof paper but is very expensive by present standards. Surface coating or sizing with wax or synthetic materials is now a more common method of manufacturing greaseproof paper from standard, bleached kraft paper. Food-safe paraffin wax is lightly applied to one side of the sheet. Thicker coatings of wax are also applied when a shiny surface is desirable. Synthetic surface treatments include silicone or polyvinyl alcohol based materials. Highly refined and supercalendered glassine, coated or uncoated, may also serve in this category. Grease or moisture resistance refers to surface treatments that have intermediate grease resistance between uncoated paper and greaseproof paper.

Metallized paper is an excellent packaging material for foods that are sensitive to moisture and light. The metal, usually aluminum, is applied in a very thin layer (0.02–0.05 μm) onto the paper sheet through vacuum deposition that involves vaporizing high purity metal. Due to the high surface free energy of paper, the vaporized metal bonds to the paper surface forming a moisture and gas impenetrable layer. The gloss of a metallized paper sheet is a function of the roughness of the paper. Rough paper surfaces produce matte or dull appearing metal layers, while smooth paper surfaces produce glossy metal layers. High-gloss metal layers are manufactured via indirect or transfer metallizing. In transfer metallizing a polypropylene web is initial metallized. Because the metal does not bond to the polypropylene, the entire metal layer can be transferred to the surface of an adhesive-coated paper sheet. The transferred metal layer has the surface smoothness of the polypropylene sheet. Thus, a high gloss metallized sheet is produced regardless of the original surface of the paper. Before printing, metallized paper is coated with a special primer layer to enhance adherence of the printing inks. Metallized paper is used as packaging materials for a number of food products that include chocolate bars, oily snack foods, candies, and chewing gums.

Foil-backed paper is produced by laminating aluminum foil to paper with an aqueous adhesive. The resultant sheet is attractive, easily printed upon, and has similar barrier properties to metallized paper. However, additional properties such as dead fold and heat retention capabilities that make it ideal for wrapping fast-food items such as hamburgers and other hot sandwiches. Dead fold is a direct property of the aluminum foil. Aluminum metal is very malleable and can be greatly deformed without cracking or losing its barrier capability. When fully annealed, aluminum maintains no 'temper' and retains its shape when deformed. Thus, dead fold gives foil-backed paper an ability to wrap around and temporarily seal a fast-food product from the time of purchase to the time of consumption.

Twisting paper is a novel food wrapping paper that is used primarily for personal-sized confections and cough drops. It has a high machine direction fiber orientation and a grammage range of 25–40 $g\,m^{-2}$. Some twisting papers may be metallized with aluminum to improve product attractiveness. Furnish additives include: titanium dioxide for enhanced opacity, and wet strength agents. Twisting papers are slit into very narrow widths to match the size of the confection. A heavier weight, non-food twisting paper is sometimes found making up the handles of paper bags used for shopping though it is now virtually obsolete.

An interesting paper grade that is frequently excluded as a packaging or wrapping grade is tea bag paper. Tea bag paper is a lightweight (grammage range 12–17 $g\,m^{-2}$) tissue paper made from very durable and long-fibered pulp such as abaca (banana leaf). This paper has to be porous yet hold the fine-sized tea leaves within the fabricated product.

Synthetic fibers such as polypropylene are frequently mixed into the furnish to produce a heat sealable bag.

Wrapping Papers

Wrapping papers are produced for a variety of purposes. Three major types include kraft wrapping paper, tissue paper, and gift-wrap paper. Kraft wrapping paper is sold in roll widths from 400 to 1200 mm with a grammage range of 50–90 $g\,m^{-2}$. It is produced from either unbleached or bleached pulp and is similar to kraft sack paper. When recycled pulp is used, it is sometimes called 'imitation' kraft paper and is dyed brown. Kraft wrapping paper is frequently used in retail transactions involving items that are not prepackaged or as an outer wrapping for food items that have flimsy, easily damaged food-grade packages.

Tissue wrapping paper is a lightweight paper sheet having a grammage range of 14–40 $g\,m^{-2}$. The standard tissue wrapping paper has a machine glazed finish due to the use of a high-temperature Yankee dryer that produces high gloss on the bottom side of the sheet. Unglazed tissue may also be produced using lower drier temperatures. Tissue wrapping paper is used to protect fragile or expensive gift items such as glass trinkets, ornaments, and jewelry. Wrapping tissue is made in colors running the spectrum from white to black. White wrapping tissue may have a brightness as high as 80. Special acid-free tissue is available to wrap items that are prone to tarnish, such as silver metal.

Gift-wrap paper is produced in grammages above 36 $g\,m^{-2}$, and is coated and calendered to maximize the attractiveness of the printed pattern. The paper's gloss is improved through the lamination of metal foil or the extrusion of a polymer coating. Rolls of gift-wrap are sold in widths of 500–800 mm and lengths of 1–5 m.

Paper Tubes

Spirally wound paper tubes are used in a myriad of packaging products. Some examples include: mailing tubes, snack food cans, and cores for paper roll products. The paper used is made from either virgin kraft or recycled fiber and has a grammage range of 35–95 $g\,m^{-2}$.

The process of producing a paper tube begins with slitting paper into narrow (minimally 2 inch) strips from a 50-inch roll. The strips of paper are then coated with a glue and several layers are wrapped into a spiral having an angle of approximately 45°. The final tubes can have typical diameters as great as 48 inches and wall thicknesses as much as 1/2 inch. Depending upon the final dimensions, the tube can be referred to as a tube, a can, or a drum. After gluing, the tubes are first rough cut, then cleaned, and precisely cut. Inside and outside layers can incorporate separate specialty papers that are optimized for barrier and printing properties. When tubes are used as cans or closed packages, the tube ends can be sealed by a variety of methods. In general, a paper top can be glued over the ends, the ends can be sealed by crimping and gluing, or a metal or plastic cap can be inserted.

Paper Cups

Paper cups are essentially single-wrap paper tubes with only one end sealed. The cup is sealed down the side similar to paper bags. The cup bottom may be sealed by either gluing a separate paper end cap or rolling the cup into a cone or convolute tube. Bleached, food-grade quality kraft paper similar to milk carton stock is required. The paper needs to have a high tensile strength, a low cross-machine stretch, and a low ash content. The top edge of a paper cup is rolled under to provide a smooth edge. This cup feature requires that paper cup stock have the ability to delaminate internally and hold the rolled edge.

Paper cup stock also needs to have a high moisture resistance for cold drinks. Wax coatings provide adequate moisture resistance as well as provide good sealing on the seam. However, wax coatings are likely to melt with hot drinks such as coffee and permit liquid leakage. Polymer laminations or extruded coatings are used on cups intended for hot beverages. The polymer coating is used only on one side to provide the moisture barrier and a sealable seam, while the outside of the cup is usually uncoated to provide better heat insulation. Clay coatings are frequently applied to increase printability and opacity. Miscellaneous paperboard items related to the use of paper cups in restaurants are insulating sleeves made from unbleached or recycled fiber and carrier trays. Many paper cups intended for hot drinks have paperboard handles glued to their sides.

Label Papers

Paper is an important method of labeling packages and containers that are nonprintable such as metal tins or cans and bottles. Paper is also an important method of labeling items in the office and at home with pressure sensitive labels. Paper designed for labels has one surface optimized for printing and the other optimized for the application of an adhesive. Flexographic, gravure, and offset printing are the most important commercial processes used for labeling retail products; however, blank labels used in the office and in the home must be receptive to pen inks and ink-jet printing. Paper label stock may also be clay coated, extrusion coated with plastic or laminated with metal.

Label stock intended for bottles and other liquid packages needs to be water resistant so that the label neither washes off the bottle nor losses its printing during normal usage. The label must also have wet strength sufficient to keep it intact if it is intended for use in recycled bottles where the label must be washed off with strong cleansing alkali. Paper used for these applications is white with ISO brightness above 80%, a gloss above 80%, and a high smoothness. The paper also needs to be stiff, dimensionally stable, and absorbent to adhesives. The paper furnish is derived from hardwood and softwood chemical pulps with a grammage range of 70–75 $g\,m^{-2}$.

Pressure sensitive labels are produced by laminating a printable face sheet on top of a 'release' liner using a suitable adhesive that completely peels away with the label allowing the label to be applied and adhered to another surface. Also known as 'peel and stick,' pressure sensitive labels come in either preprinted or blank forms that are die-cut to form individual labels on a roll or sheet. Pressure sensitive labels are used for: packages, cartons, mailing labels, computer disks, office labeling, and even postage stamps.

The release liner, also known as backing paper, is frequently silicone coated to create a smooth, pinhole-free surface that will not permanently bond with the adhesive of the face stock. The release liner can be either glassine or bleached kraft. Glassine is inferior to bleached kraft in regards to curl and dimensional stability, but its transparency makes it suitable where machine scanners are used to bring die-cut labels into position for printing and automatic labeling of packages. Glassine used for release liners has a grammage range of 30–80 $g\,m^{-2}$ and a caliper of up to 65 μm. Release liners made from bleached kraft have a grammage range of 30–130 $g\,m^{-2}$ with maximum caliper of 100 μm. The extra stiffness, dimensional stability, and bulk of the bleached kraft liners are required for high quality printing requirements. The need for high smoothness often necessitates supercalendering at about 20% moisture content. Silicone in the form of silicone acrylate is off-machine coated using a roll coater and then cured using either electron beam, ultraviolet or oven techniques. Solvent silicone systems are still used but flammability and environmental concerns are making newer aqueous systems more preferable. Modern machines that produce pressure sensitive labels coat and cure the backing paper and then apply the pressure sensitive adhesive directly to the silicone treated side. Simultaneously, the face stock is coated with an adhesive-receptive primer that is then dried. Both sheets are then laminated together to form the final product.

Face stocks can come in a variety of grades from lightweight (65 $g\,m^{-2}$) supercalendered paper to relatively heavy tag-grade paperboard (230 $g\,m^{-2}$). Face stocks may be either bleached or unbleached depending upon the application. Recycled fiber percentages as high as 100% may occur with post consumer waste percentages reaching as high as 50%. Face stocks are printed using a variety of methods including flexographic, letterpress and on-demand printing methods, such as direct thermal, thermal transfer, and laser/ink jet technologies.

PAPERMAKING

Contents

The History of Paper and Papermaking

S AbuBakr, Western Michigan University, Kalamazoo, MI, USA
J R Thompson, Talo Analytic International, Inc., Duluth, GA 30096, USA

Introduction

It is difficult to imagine life without paper today. Paper has been a key factor in the progress of our civilization. The pulp and paper industry is nearly as old as civilization itself. Originating in the papyrus manufacturing discoveries of Egypt and the bonding of cellulose fibers in China, the industry has steadily marched forward. By the early part of the nineteenth century, paper manufacturing had stripped the supply of available cotton rags, the only known raw material. Serendipitously, the French, examining hornets' nests, leaped to the conclusion that paper could be made from wood, an event that happened shortly after the Fourdrinier brothers developed the continuous papermaking process. To this day, wood and continuous processes are used. The transformations in the past 200 years have evolved into an increased understanding of the sciences of forestry management, machinery foundations and dynamics, wood and papermaking chemistries, motive systems, computer control, logistics, and business finance and management. Thus we have moved from paper machines commonly as wide as the standard office desk using raw materials gathered within 1–5 km to machines one-third the width of the Panama Canal selling finished products around the world. We also have moved from the concept of print-and-distribute to distribute-and-print using the Internet.

Up to 1900

The oldest extant document, the 40-m long Prisse Manuscript written on papyrus was made by the Egyptians in about 2000 BC.

In AD 105, Ts'ai Lun proclaimed his great invention of true paper – a thin, felted material formed on a flat porous mold from macerated vegetable fiber. In AD 400, the Chinese invented ink from lamp-black and used it for writing on paper. Gypsum and starch flour were used as sizing agents in about AD 700 in China.

Paper was first made the Chinese way in Samarkand in AD 751 and in Baghdad in 793, during the era of Harun Al-Rasid. In about AD 900 paper was made in Egypt and by AD 950 was already being transferred and made in Spain. Paper for packaging and wrapping was reported in Egypt in about AD 1035.

Papermaking appeared in Sicily (1102), in Constantinople (1100), in France (1189), and in Germany (1228). The Fabriano paper mills were established in 1276 in Italy and by 1282 the first watermarks were introduced in Italy. The first paper money was issued in Tabriz, Iran in both Chinese and Arabic texts. The first use of paper in England was reported in 1309 and by 1495 the first paper mill was established there.

In 1440, Johannes Gutenberg introduced to the world his invention of printing with ink on paper, combining movable cast metal type, ink, paper and press to produce printing that very much changed the world. The first newspaper with regular publication dates was published in Germany in 1609; a similar one appeared in England in 1622.

The first English patent pertaining to papermaking was granted to Charles Hildeyerd in 1665, for 'The way and art of making paper used by sugar-bakers and others.' In 1680, the 'Hollander' or beater used in the maceration of materials for making into paper was invented in the Netherlands. In 1798, the paper machine for producing a continuous web of paper utilizing a wire mesh screen to form the paper was invented by Nicholas-Louis Robert in France.

A patent dated 24 July 1806 was taken out by Henry Fourdrinier under the following specifications:

> A number of molds, of the description called laid and wove, are hooked together to form one long mold. A platform to hold the said molds in such manner that the molds shall slide along backwards or forwards, but in no other direction. A vessel or trough from which the paper stuff or material is caused to flow upon the molds through holes, each provided with one or more registers to limit or mark the flow of stuff. A set of cylinders, upon which is passed, in the manner of a jack towel, an endless web of felting. There is a third cylinder in contact with one of these cylinders, and this third cylinder communicates by means of another web of felt with an additional pair of pressing cylinders. When the molds arrive at the first cylinder, the felt web takes off the paper and conveys it to the first pair of pressing cylinders, whence it proceeds to the second pair, and afterwards to any fit place of reception, so that continuing the process, paper of any length may be made, and with separate molds.

Other important examples of inventions and discoveries during this period include:

- The cylinder paper machine was first introduced by John Dickinson in 1809 and by 1817, he was the first scientist to introduce steam-heated drying cylinders.
- The first dandy roll was patented by John and Christopher Phipps in 1825.
- Papermaking from mechanical groundwood pulp was first introduced in 1840.
- Chemical pulping using caustic soda was introduced in about 1854.
- The first use of toilet paper in roll form in America was introduced in 1871.
- The first coating of paper on both sides was first introduced in 1875 by S.D. Warren.
- The largest and fastest paper machine by 1900 was in Rumford, Maine, with a wire 4.1 m (162 inches) in width and 18 m (60 feet) long running at about 150 m (500 feet) min^{-1}.

The total paper production in the USA at the end of the nineteenth century was about 2 million tonnes $year^{-1}$.

1900–1925

In the first quarter century of the twentieth century, the organization and development of the paper industry looked little different than that of the nineteenth century. Electricity was still a novelty and forestry practices had not become widespread. Hence paper was manufactured from either rags or locally harvested natural growth forests. Most likely, the mill was operated with a water wheel. As an aside, the Finnish suffix ‘koski’ means rapids and many Finnish mills were located in towns with names such as Kylmäkoski, Valkeakoski and so forth, as these were places on rivers and streams where water wheels could be built to power machinery.

In the USA, forestry management grew out of the keen interest of Gifford Pinchot (1856–1946) in the subject. His interest in Forestry Management led Pinchot to L’Ecole Nationale Forestière in Nancy, France for education on the subject, as academic work was not available at that time in the USA. Later President Theodore Roosevelt appointed Pinchot Chief Forester of the US Forest Service. Pinchot did much work in North Carolina, and in commemoration of his visionary work, the US Forestry Service, in cooperation with others, maintains the Cradle of Forestry Historic Site on US Highway 276 just outside of Pisgah Forest, North Carolina.

In this same time period, electric motors began to make an appearance in paper manufacturing. Along with light bulbs, which had been introduced in the later part of the nineteenth century, electric motors went a long way towards moving papermaking into the modern age. At last, papermills did not have to be sitting literally on top of a stream. It appears that electric motors first made their debut in paper mills in the USA, as that country was an early adopter of electric power. Additionally, at the same time, development had stalled in Europe due to World War I (except in Finland, where the Finnish Forest Research Institute was established in 1917). Interestingly, in those days, because there was no national power grid in the USA, there were few electrical standards, hence mills had voltages and alternating current frequencies of their own choosing. As late as the 1990s some older mills in the USA were still using their own power standards.

1926–1950

Paper Manufacturing moved forward on many fronts in this period. Professionals around the world were beginning to think of papermaking as a scientific endeavor rather than the ‘black art’ that it had been. In the USA, the Institute of Paper Chemistry was founded in Appleton, Wisconsin, for the study of wood and papermaking chemistry, and the granting of graduate degrees.

The malaise of nearly worldwide depression seriously affected development from 1929 until World War II. However, in the southern USA, a precursor to post-World War II paper industry expansion was developed. This was the Tennessee Valley Authority (TVA) project instituted by President Franklin Roosevelt. This project harnessed the power of the Tennessee River for the production of electricity and the establishment, coupled with developments elsewhere, of a national power grid.

During World War II, paper recycling became important nearly everywhere. The survival of cylinder board paper machines to this day is highly dependent on the recycling infrastructure developed during World War II in Europe and North America.

Following World War II, there was an explosion in paper demand in the civilized countries of the world. In most of Scandinavia, this started soon after the war, but in Finland and mainland Europe, it came along slightly later due to extensive infrastructure rebuilding efforts. In the USA, big (for the time) southern mills sprouted to take advantage of the forestry work that had been done with southern pine and the electrical grid infrastructure of the TVA.

1951–1975

The 1950s saw an explosion in paper usage throughout North America and Europe. As standards of living rose, paper goods were consumed by people experiencing higher levels of disposable income. The widespread introduction of flush toilets in small towns, another US government program of the 1930s, increased people's awareness of appropriate sanitation measures, driving the use of paper products specifically designed for this service.

In the late 1950s, Procter & Gamble, the consumer goods giant from Cincinnati, Ohio, purchased a small paper company headquartered in Cheboygan, Michigan named Charmin. Although the pundits of the day thought this would be the end of Procter & Gamble, the marketers in Cincinnati had a different idea. First, they began researching the taboo subject of what attributes made a toilet tissue desirable to the discriminating user. Next, they found a way, once such products had been developed, to market them to a public still firmly rooted in Victorian mores. An explosion in the demand for high-quality sanitary goods was the result.

Also in the 1950s and early 1960s other universities, especially in the USA, founded undergraduate and graduate programs of study in pulp and paper. By the 1990s, there were 11 such programs in the USA, with many more in Scandinavia, Canada, New Zealand, the UK, and Australia. Real pulp and paper scientists with a firm understanding of cellulose chemical and physical properties were being trained in substantial quantities.

At nearly the same time, precipitous events were happening in Finland and the United Nations. By the mid 1950s, Finland succeeded in completion of payment of war reparations to Russia. It was time to turn to repairing and renovating their own industry. A young engineer by the name of Jaakko Pöyry became head of engineering for the first renovation project. It was immediately followed by another, then another. Finland, even though a small country, has always been driven to being a major contributor to the United Nations. The United Nations, from its beginning, looked to development of natural resources, such as forests, to aid undeveloped countries in their move from the Third World. At nearly the same time Jaakko Pöyry was looking to expand his business, Max Jakobson was appointed Finnish Ambassador to the United Nations. Max Jakobson and Jaakko Pöyry had been in the same unit of the Finnish Army in World War II, fortuitous events indeed. The Jaakko Pöyry firm was engaged to do many studies for the United Nations around the world. Some of these studies led to the realization of actual projects, such as the Aracruz manufacturing and forestry site in Brazil, one of the world's largest producers of eucalyptus market pulp.

In 1962, Rachel Carson's book *Silent Spring* gained attention and had an impact on the pulp and paper industry, the degree of which no one could have imagined. This book turned the conservation movement into the environmental movement. Starting about 1970, environmental laws were implemented on a nearly worldwide basis. Although of little impact in the balance of this quarter century, this time closed with another event critical to the paper industry: the rise of the power of the Organization of Petroleum Exporting Countries (OPEC). Several oil shocks caused the industry to spend time and money on basic power generation sources, such as bark boilers, detracting scarce resources from improving the products which the industry made.

1976–2000

By The last quarter of the twentieth century, papermaking had clearly become science. Many aspects of the microscopic and atomic-level processes were well established. The development of other basic engineering disciplines and sciences, such as dynamics, metallurgy, process control, and so forth, developed to the level that many formerly misunderstood parameters became routine to manage and control.

New and unfamiliar challenges, however, strained the industry in ways not seen before. The industry responded slowly to growing environmental pressures, giving its detractors plenty of reason to seek control of it.

Plastics began to make serious inroads, along with reformulations of products formerly contained by paper (such as liquid detergents replacing powders). At the same time the Internet and the electronification of the office seemed to be a two-edged sword. No doubt more printers were making more copies than ever before, but it seemed as though certain paper grades were quickly obsolescing. No longer were printed stock certificates required, and interest in daily newspapers was waining. The impact of writing a letter on high cotton content paper was lost. Conversely, computers and associated software, coupled with changes in printing processes, led to many new and specialized magazines, as layout was easier and runs could be shorter. Overall, papermakers seemed lost as to how to distinguish their products and avoid falling into a commodity-only business. How to go from a production orientation to one of marketing?

By the end of the twentieth century, it can be said that the science of papermaking was firmly established. High-speed equipment operated by skilled professionals, using massive computing capacity, tamed the process. Today, we know how to make paper at high speed, efficiently and consistently, in an environmentally sound way.

World Paper Industry Overview

S AbuBakr, Western Michigan University, Kalamazoo, MI, USA

Introduction

Paper is one of our most important materials. It has been a key to the growth in human communications and commerce since invented by T'sai Lun in China. Various historians rank the Gutenberg Bible and the invention of the printing press as among the most important developments in history.

Changes in society have had a major impact on the use of paper around the world. However, despite predictions in the 1980s and 1990s that some combinations of technology would eliminate the use of paper for common uses such as the daily newspaper, there is little doubt that it will continue to have a key role in the future. Nevertheless, the paper industry must maintain its competitiveness and viability by continuing to develop new products that can compete cost-effectively with alternate means of information dissemination and alternate packaging materials, as well as seek out new end-use applications. Paper must also be produced economically and in an environmentally responsible manner. There are many challenges to paper that could reduce its use in some applications. Conversely, as the economies of Second- and Third-World nations continue to develop, paper consumption and growth will grow, driven by established uses and new and innovative applications. A driving force for its sustainability is a renewable and relatively low cost principal raw material, namely wood.

The following major areas are discussed in this overview:

- raw materials and major products
- demand and consumption
- long-term growth trends

- global trade
- major industry structural trends
- challenges to growth.

Raw Materials and Major Products

Paper for the most part is manufactured using softwood and hardwood trees to supply the fiber used in its manufacture. Globally, fibers from trees provide about half of the material used to make paper and paperboard, while recycled fiber provides about 20%. Most of the remainder is accounted for by various minerals and chemical additives used to impart optical and printing characteristics, water resistance, and strength characteristics to paper and paperboard grades. The remainder of the raw material used by the industry is composed of non-wood fibers, which are mainly used in parts of Asia and Africa.

Many grades are manufactured using recycled fiber, i.e., fiber that has already been used in a paper product, such as a box or as office papers, which is then recycled to provide the fiber for a paper or paperboard grade. As discussed later, trees are a renewable resource and this provides an advantage over many competitive materials. However, it also presents an environmental challenge due to society's perceptions of the pros and cons of the widespread cutting of trees to fuel the demand for fiber by the paper- and wood-consuming industries.

Common grades of paper and paperboard are used by people all over the world for a wide array of uses. Most major uses can be categorized as one of two applications: (1) communicating information or protecting and packaging products for shipment and end-use applications; (2) personal hygiene applications where a range of sanitary tissue grades is used for products such as toilet paper, paper towels, napkins, and facial tissues. Nonsanitary grades include products such as tissues for interleaving and electrical applications.

Common examples of paper used to store or communicate information range from the ubiquitous sheet of cut-size copy paper to the daily newspaper, direct mail, magazines, catalogs, promotional brochures, and books.

Paperboard grades are used to package food and to protect products for shipment. There are two major forms of packaging: folding cartons and corrugating containers. Frozen food, dry foods, milk products, and many other foods are packaged in paperboard folding cartons. Food is the largest use for folding cartons. Major folding carton applications include:

- bottled and canned beverages
- candy, biscuits, and crackers
- cosmetics
- carry-out food
- soaps and detergents
- hardware and household supplies
- tobacco
- bakery
- paper goods.

A wide array of products are packaged in corrugated containers, which is a paperboard box made of three plies, with the middle ply comprised of a wavy or fluted sheet called corrugating medium. The use of this fluted ply enhances its bending stiffness.

Among the major uses for corrugated containers (in order of the volume of boxes used) are:

- paper products
- electronics
- food
- hardware, tools, etc.
- consumer soft goods (e.g., clothes).

There is also a large and varied converting industry that uses paper and board as one of its key raw materials to produce a wide array of products. Some segments are based mainly on paper or paperboard, such as business forms converting, envelope converting, and box and corrugated container converting. An equally large and even more diverse segment is flexible package converting, where, for example, a plastic film may be used to cover an item for sale and is affixed to a backing sheet composed of recycled or bleached paperboard. Other examples include combinations of paper, film, and foil to manufacture bags or sacks with various barrier properties. Common examples include pet food packaging and aseptic juice containers.

The other major paper industry product is pulp. Many mills around the world do not make paper or paperboard: they simply make pulp. Pulp is the first product phase from the pulping of wood, and is the basic raw material for paper and paperboard. This market pulp is then shipped to paper mills that do not make their own pulp or those that only make part of their pulp requirements.

Demand and Consumption

The amount of paper consumed in the world is driven by a complex set of social and economic factors and the amount of paper products consumed or used by an individual, or on a per capita basis, varies widely around the world. However, as a general rule, consumption tracks fairly closely with per capita income and general economic levels. Persons having higher income buy more processed foods, consumer electronics, and toys. They also tend to be better educated and thus consume more newspapers, magazines, and books.

In more developed economies, such as in Europe and North America, large amounts of paper products are used. In developing countries, such as in Asia and Africa, very low levels of paper products are consumed. For example, per capita paper and paperboard consumption in North America approaches 330 kg, in Europe it varies from less than 200 kg to over 340 kg, and might average 230 kg, while in Asia and Africa it is less than 35 kg.

Consumption is also highly cyclical due to its close correlation with economic activity. Thus during periods of high economic growth, paper demand typically expands, while during slow economic growth, or during recessions, demand growth slows or demand can decrease.

Total world demand for paper and paperboard exceeds 300 million metric tons, based on data for 2001, the most recent year for which world data are available. The largest consumers are the USA, followed by China, Japan, Canada, and the major economies in Europe. Global demand contracted in 2001 versus the 2000 level due to weak economic conditions that prevailed in key economies, notably, the weakness in the huge US market, and the decline in Asian growth rates. At this writing, demand continues to be weak due to the ongoing weakness in the major world economies. For example, total US demand for paper and board fell 0.1% in 2002, a much more modest decline than the 6.1% drop in demand in 2001 and the 2.5% decline posted in 2000. The 3-year decline is one of the largest ever posted in the US market.

The Asian market, with the exception of Japan, has historically been a modest consumer of paper despite its large population due to its general lack of economic growth. However, this has changed somewhat in recent years as various countries have seen economic growth, and in some cases, removal or at least easing of restrictions on the dissemination of information. **Tables 1–3** give more detailed global information regarding growth and consumption.

In particular, change in China has been noteworthy. While currently the second largest individual market, demand is growing rapidly owing to strong economic growth in the last decade. It is projected that China may eventually become the largest market for paper products in the world due to its enormous population and movement toward a less controlled economy. Twenty years ago China was ranked sixth

in total consumption; 10 years ago, it only ranked behind the USA and Japan, and today it is number 2.

Long-Term Growth Trends

Demand for paper and paperboard products typically mirrors economic changes as measured by gross domestic product (GDP) or gross national product (GNP). Thus, as economic growth occurs, more paperboard packaging is required to ship industrial and consumer goods, more books and magazines are sold, and more paper is used in offices for copying, printing, and mailing.

Global paper and paperboard demand has typically expanded at about the same rates as world GDP, or about 2–3% annually. However, growth rates vary widely by grade as well as widely by region and country.

Based on two examples of growth in the future, **Table 4** outlines the growth in world paper and paperboard demand.

During the 1980s, rapid growth occurred throughout the world and in particular the huge North American market as the US economy expanded, and

Table 4 Increase in world demand at various growth rates (000 tons)

Annual demand growth (%)	*Growth in world demand per year*
2	6000
3	9000

Based on base consumption of 300 million tons per year. Source: PPI Annual Review Issue, July 2002.

throughout much of Asia, with Korea and China's consumption more than doubling. During this period, US growth was particularly strong for printing and writing grades due to enormous growth in the use of direct mail – referred to as junk mail by its opponents – which includes catalogs, as well as strong growth in newspaper inserts (also called free-standing inserts). In addition, demand for grades such as coated paper, uncoated free sheet, and uncoated groundwood grew at nearly twice the rate in growth of the general economy, i.e., at rates of 5–8% annually. Demand for packaging also posted strong gains, but not at rates matching printing and writing paper growth.

Growth continued into the 1990s but during the latter part of the decade the rapid growth in the use of computers began to have an impact on consumption patterns in the USA (for much of the 1990s growth in white papers was spurred on by computer printers and fax machines – in the later part of the 1990s paper consumption changed, but it is difficult to differentiate between the impact of computers and the internet and the general decline in the economy). In particular, the explosion in the use of the internet began to have a negative impact on various communication papers. During the 1990s printing and writing paper demand continued to grow rapidly in Europe.

During the last two decades, many people have spoken of the paperless office, where a wide array of computer and internet-based devices would essentially eliminate the use of paper. This remains a myth, and printing and communication paper demand continues to be large.

However, while the paperless office has never materialized, electronic information dissemination has had a major impact on the use of paper. This impact is caused by a wide array of forces, including direct substitution where paper is eliminated because another means of conveying information has replaced it. A good example is the reduction in the use of first-class mail correspondence, which has been caused by two factors. Initially, the use of the facsimile machine replaced the mailing of letters, but more recently, the explosion in the use of e-mail has had a much larger impact, as has the low cost of telecommunications.

Table 5 Total US advertising expenditure by medium

Medium	*%*
Daily newspapers[a]	19.2
Television	23.5
Direct mail[a]	19.3
Radio	7.7
Yellow pages[a]	5.9
Magazines[a]	4.8
Other	17.1

[a] Paper-related.

In other cases, the impact was more indirect. For example, advertising expenditure is a major driver behind the use of printing papers. When more money is spent on print advertising, more paper is used to print magazines, catalogs, and flyers. However, advertising dollars are spent on a variety of media, including print and electronic media such as television, radio, and more recently, internet-based advertising, and thus will potentially impact paper consumption.

Table 5 provides insight into the use of various advertising methods in the USA, based on 2001 data.

Printing and writing paper demand continues to grow strongly in areas such as in Europe, which have historically had various controls in place that limited the use of various media such as television, and where the use of sophisticated marketing approaches such as direct mail and catalogs is not yet as advanced as in more developed markets. Growth will continue to be strong in Asia where both literacy and economic rates continue to show rapid growth.

US demand is expected to continue to expand, but at much lower rates than during the 1980s and early 1990s. Projections by various forecasting experts peg growth at 1–3% annually over the next 5 years.

Global Trade

Paper and paperboard grades may be consumed in the country in which they are produced, or they may be exported to other countries. While the level of income, affluence, and lifestyle influences demand for paper, the production of paper products is often driven by a different set of parameters. Traditionally paper was produced in regions with abundant forest resources such as Scandinavia, Canada, and the USA, and appropriate economic resources (South America, Asia, and Russia all have large forest resources, but limited financial resources).

Historically, trade between various regions of the world was modest. Initially trade between countries began in areas such as North America and Europe when regions possessing abundant natural resources in terms of wide tracts of forestland and low-cost hydropower began to make paper and ship it to areas that lacked such resources. Thus, in the early parts of the twentieth century, Canada, which had huge tracts of virgin forest and numerous rivers, began to make paper to sell to the huge US market located to its south. In fact, this trend was encouraged by major consumers of paper in the USA that built mills in Canada. A prime example is the Tribune Company, which founded the first newsprint mill in Canada to supply paper to the large Chicago newspapers.

However, as noted below, paper trade has expanded due to the availability of low-cost wood in the southern hemisphere. In regions such as South America, and more recently in South-East Asia in countries such as Indonesia, the warmer climate and wide tracts of unused land have led to large growth in the use of 'forest plantations.'

Production has increased considerably in the last 10 years in Southeast Asia, notably in China, Indonesia, and Korea. Production is growing rapidly in China as the country attempts to meet its growing demand for paper and paperboard. Most of this is targeted at meeting domestic demand growth in these countries. However, considerable tonnage is also currently being exported to the USA and Europe, which is having the effect of displacing higher-cost locally produced paper. The growth in capacity in these countries has also to some extent replaced grades such as paperboard that were previously exported by the USA and Europe to the region.

Major Industry Structural Trends

Two fundamental changes, both economically driven, have radically altered the global forest products business in the last decade. They are: (1) huge growth in the use of plantations in warm climate areas of the world such as South America and South-East Asia to supply fiber; and (2) the huge growth in the economies of Asia, notably China, and in turn the rapid growth in the demand for paper and paperboard in these regions.

The global pulp and paper industry has been strongly affected by several key macroeconomic trends. Among the major ones are industry consolidation and shifting regional competition due to exchange rates.

One key trend that has been underway for some time in many industries, such as the automotive industry, has been a trend towards consolidation. Big companies buy up other companies as a method of increasing their market share, and for strategic reasons such as to extend their reach to other markets. Being large also provides the capital needed for investments and to ride out the notoriously cyclical nature of the industry.

Over the last 20–30 years exchange rates have played a major role in many industries, including the pulp and paper industry. During the early 1980s, the devaluation of Scandinavian currencies radically changed the competitive landscape of the world pulp and paper industry. The US industry, which for years had enjoyed a favorable competitive position due to the dollar, was suddenly at a disadvantage. This devaluation led to the initial expansion of exports of paper and board grades to the US market. The devaluation had effectively made a high-cost industry either a low-cost one, or at the very least, a competitive paper industry that was able to ship product to North America.

Similarly, in recent years, the weak Canadian dollar versus the US dollar has been a boon for the large Canadian forest products industry by allowing it to ship competitively priced products to the USA.

During the period 2002–2003, a large-scale change in the value of the dollar against the euro has begun to change the competitive position of the European and US industries. For much of the latter part of the 1990s, a strong US dollar has meant that it was difficult for US mills to compete globally and to export paper products. In contrast, it has meant a boon for European and, to some extent, Asian countries. As a result, US imports have risen considerably while exports have fallen. The decline in the value of the euro vs. the dollar which has occurred since 2002 is likely to slow the growth of imports to the US, although it is not likely that imports for certain grades will actually decrease.

Environmental Issues

One major factor impacting the availability of timber for industrial use has been environmental considerations. The largest and most notable example to date has been the withdrawal of millions of acres of federal land in the western USA due to environmental concerns. Environmentalists argued that the spotted owl was being damaged by excessive logging in national forests and were successful in getting the government to ban, or severely reduce logging in the region, which was traditionally one of the world's largest suppliers of fiber to the pulp and paper industry.

Other environmentally related issues include huge sums of capital spent by North American and European producers to meet stringent air and stream environmental standards.

Challenges to Growth

Most forecasts of growth in world paper and paperboard project that demand will continue to expand at modest rates of 2–3% annually for the foreseeable future. However, in some of the more developed economies of the world, notably in the USA, a wide array of forces have led to slower demand for certain grades. In fact, demand for a number of grades, such as newsprint and packaging papers, has either stagnated or has posted major declines due to competitive factors such as the growth in electronic media and electronic information dissemination and due to losses to competitive materials, notably plastics used for packaging.

Much has also been written about the impact of information technology on the use of and demand for communication papers. It presently appears that while demand for some products may decline, the negative impact of technology on paper use in the next 5–10 years will be limited to merely slowing the growth in demand, not actually causing it to decrease. And this negative impact is most likely to be the largest in high paper-consuming markets, such as Europe and North America, and less important in other markets.

There are several other challenges to the long-term growth and success of the pulp and paper industry worldwide. They include:

- The paper industry's image as a smokestack industry
- The image that the industry destroys old-growth forest and rainforests
- Competition for traditional paper uses from competitive information means and alternate packaging materials

The industry's record on the environment is beyond the scope of this article. However, what is important to recognize is the importance of how the public perceives these issues. In recent years, environmental groups have waged campaigns urging consumers to stop the use of paper and forest products due to various environmental reasons. They include the charge that forestry companies are cutting down old-growth northern forests as well as destroying tropical rainforests. The threat to the industry is that consumers will cease to buy and use paper products due to these concerns. While these groups have achieved some success, the global industry has met these challenges and others with large capital expenditures for air and stream improvement and a prodigious effort to plant more trees than are being consumed. As noted earlier, environmental concerns have previously been used to limit the use of forests as a natural resource in the production of paper and lumber products.

Competitive packaging materials are another key threat to the paper and forest products industry. Among the most notable losses that paper products have endured are the large-scale replacement of the common paper grocery sack with plastic sacks, and the shift in packaging automotive oil from oilcans to bottles.

Food packaging is another prime area where product substitution has impacted and reduced the use of paperboard packaging. For example, folding cartons and paper bags are being increasingly replaced by plastic pouches and sacks in a variety of foods.

The driving force behind almost all of these cases of substitution is lower cost. Lower-cost plastic is replacing a higher-cost paper product. In some cases the replacement product is also a better product.

A final element that poses a challenge to the industry has been the relatively poor financial performance of the paper industry in recent years. This has been due to several factors, mainly the weak global economy in the 1990–1991 and 1999–2002 periods, in addition to the industry's tendency to overinvest in capacity when times are good. In turn, this means that new and frequently excess capacity typically comes online just when demand is plummeting. Among the biggest challenges posed by this weak performance is the limit it places on the industry's ability to attract investment capital and to attract employees.

Another factor impacting established mills is that new capacity is frequently produced more efficiently, and at lower cost. These cost factors include labor rates, employees required per unit of production, cost of raw materials and energy, not to mention possible differences in cost of environmental compliance.

In conclusion, despite numerous changers in the global pape]r industry over the past few years, paper and board production has grown and growth will continue for years to come as economy throughout the world continues to grow – bringing increased literacy rates, an educated populace, and business commerce use of paper.

Paper Raw Materials and Technology

P P Bhojvaid and A K Rai, Forest Research Institute, Dehradun, India

Introduction

Paper and paper products in today's world play a very important role in everyday life. One cannot think of any activity without the use of paper; in fact paper is almost synonymous with development in the contemporary world. Per capita annual paper consumption is one of the indicators of economic development and the literacy rate of a country. Consequently the pulp and paper industry is one of the most important industries of the world, which provides employment to a very large number of people in most of the countries of world. Furthermore, the rising population and the recent change in lifestyles necessitate that paper should be available in plenty and at a very cheap price. Consequently, significant research and development has taken place for finding different raw materials for the manufacture of pulp (the basic constituent of paper) and for developing efficient, environmentally friendly, and economical technologies for papermaking. These two aspects will be the focus of this article, with special emphasis on non-wood fibers.

Definition and History

'Paper' is defined as the sheet or web formed by the deposition of (vegetable, animal, or synthetic) fiber from a suspension (in water, vapor, or gas) with or without the addition of sizing chemicals and filtered over a fine screen in such a way that the fibers are bonded and intermeshed together after pressing and drying. The raw material for these fibers is pulp, which is commercial cellulose, fibrous in nature and derived from wood, bamboo, grasses, or any other raw material by mechanical or chemical means. The paper thus formed may be coated or impregnated with the use of different materials to make it suitable for various specific end uses such as writing paper, packing paper, currency paper, and so on.

The use of non-wood fiber (NWF) for making pulp and paper dates back more than 2000 years. The oldest surviving piece of paper, discovered in 1957 in a tomb in Sian, China has been dated to between 140 and 87 BC. This paper and similar pieces of ancient papers are all made up of pounded and disintegrated hemp fibers. Furthermore, paper historians argue that the earlier Egyptian papyrus sheets, being woven and not 'wet laid' should not be referred to as true paper. Until the late nineteenth century the only source of fiber for papermaking was rags, i.e., worn-out clothes. Since at the time clothing was made of hemp and flax (occasionally cotton), it would not be wrong to say that almost all paper in history was thus made from NWFs. However, an increased demand for paper coupled with a shortage of rags and a scarcity of hemp and flax compelled the paper industry to look for alternative sources and modifications in papermaking technology. This led to the use of the world's most abundant and cheap source of fibers: our forests. Consequently, the usage of NWF as paper pulp has been reduced to 5% of total pulp production and is restricted to developing countries and some parts of Europe.

Characteristics of Non-Wood Cellulosic Raw Material and Paper Properties

All lignocellulosic fibrous raw materials used for pulp and paper essentially consist of cellulose and lignin along with some extraneous material called extractives such as gums and resins (**Figure 1**). Cellulose, a polymer of carbohydrates $(C_6H_{10}O_5)_n$, is the main constituent of the cell wall of plants and its natural source in pure form is cotton. The length of cellulose fibers affects various physical strength properties of paper, such as tensile, burst, and tear indices, and surface and optical properties, such as smoothness and brightness. Furthermore, the degree of polymerization (DP) denoted by n in the formula varies with the source of raw material and is also affected by chemical treatment during pulping and bleaching. DP in papermaking fibers varies from 600 to 1800. Decrease in DP during pulping results in a decrease in the strength properties of paper. Hemicellulose is another constituent composed of short-chain polysaccharides, which is a polymer of five different sugars, namely glucose, mannose, galactose, xylose, and arabinose. The hemicelluloses are chemically bonded with cellulose and lignin in a plant cell wall (**Figure 1**). Thus the total carbohydrate part of the fiber is referred to as holocellulose.

Lignin

Lignocellulosic material contains a polymerized hydrophobic substance lignin, which is amorphous, highly branched, and three-dimensional. It acts as a cementing material in woody plant fibers and is mainly concentrated in the intercellular portion called the middle lamellae and to a lesser degree

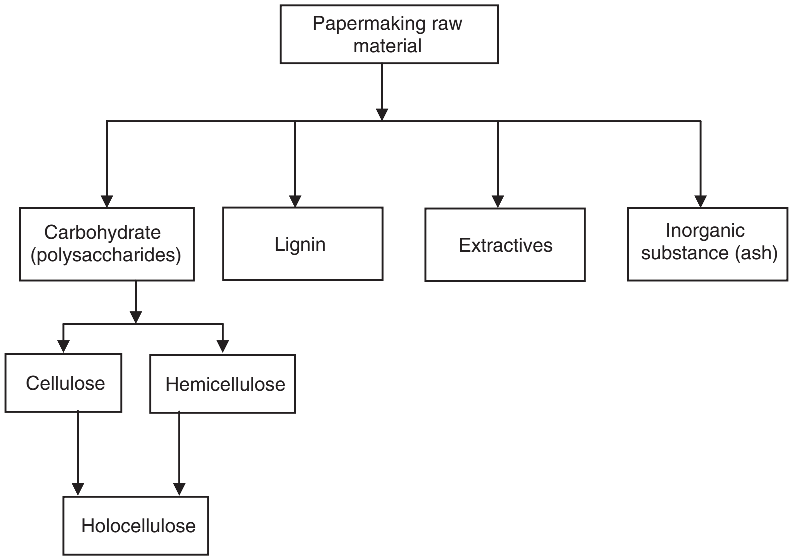

Figure 1 Components of cell wall of raw materials used for papermaking. The process of papermaking essentially comprises isolation of holocellulose and removal of lignin, extractives, and inorganic substances.

distributed in the cross-section of the cellulosic fiber. It imparts structural strength to wood but it is undesirable for papermaking as it inhibits interfiber bonding during the process of papermaking. Therefore, lignin is removed by treatment with acid or alkali, which results in its dissolution and facilitates fiber separation. The degree of lignin removal is dependent upon the desired quality and type of paper to be prepared.

In addition to cellulose, hemicelluloses, and lignin, the other group of chemical substances such as gum, resin, fatty acids, turpenes, and alcohols are also found in native fibers, depending upon the type of plant source. These substances, commonly referred to as extractives, are also undesirable for papermaking and are removed during pulping.

Most of the cellulosic raw materials due to their hydrophilic nature contain an appreciable amount of water either in green or air-dried conditions. It is, therefore, very essential to express the weight of raw material on a dry basis or wet basis. The common practice in paper mills is to express raw material weight on an oven-dried basis. This also helps in calculating the amount of various chemicals needed for wood or pulp processing. Further, wood specific gravity plays a very important role in the papermaking process and the properties of the end product. The specific gravity for softwood and hardwoods falls in the range of 0.29–0.57 and 0.30–0.70 respectively. High-density woods are harder to chip, require more energy for chipping, and are difficult for chemical penetration during pulping. Wood specific gravity strongly influences the fiber flexibility or collapse, which in turn influence the interfiber bonding and paper surface roughness. Low specific gravity wood will produce thin-walled, less coarse fibers, which collapse easily to give high physical strength properties with high paper sheet density. This makes softwoods suitable raw material for the manufacture of paper sheet of high density, low bulk, and higher physical strength. Therefore, it is clear that an ideal raw material for papermaking should have maximum holocellulose content, minimum lignin, and higher LD ratio, which is ratio of fiber length to fiber diameter. Accordingly softwoods are the best raw material for pulp making followed by hardwoods, bamboo, kenaf, and agricultural residues (**Table 1**).

Non-Wood Raw Materials for Pulp and Paper

Although any cellulose raw material can be used for the preparation of pulp and paper in the laboratory using the kraft pulping process, a proper selection of raw material is very important (from the vast source of vegetable kingdom) for commercial production. Wood, however, is the main source (60–70%) of raw material while non-woods such as bagasse, rice straw, wheat straw, reeds, bamboos and secondary fiber commonly known as recycled fiber (wastepaper) account for the rest of commercial production.

Bamboo

Apart from softwood and hardwood another most commonly used raw material for pulp is bamboo, which is used mainly in countries of the Asian

Table 1 Chemical composition, fiber dimensions, and global availability of wood and non-wood fibers for manufacture of various types of papers

Fiber source	*Cellulose (%)*	*Lignin (%)*	*Mean fiber dimension (mm)*		*Global availability in million tonnes (bone dry)*	*Types of papers*
			Length	*Width*		
Long fibers						
Cotton staple	85–90	0.7–1.6	25	0.02	18.3	Specialty papers, permanent document, banknotes, etc.
Seed flax	43–47	21–23	30	0.02	2.0	As reinforcement pulp to improve physical strength of paper, specialty papers
Hemp	57–77	9–13	20	0.022	0.12	Cigarette paper, tissue, lightweight paper, filter paper, greaseproof paper, security papers, tea bags, etc.
Abaca (manila)	56–63	7–9	6.0	0.024	0.08	Tissue and specialty papers
Medium long fibers						
Softwood	53–62	26–34	4.1	0.025	99.2	Almost all types of paper and board, and tissues of all grades
Sisal	47–62	7–9	3.3	0.02	0.50	Specialty papers
Bamboo	26–43	21–31	2.7	0.014	30.0	Printing and industrial grade papers
Kenaf	44–57	15–19	2.6	0.02	3.0[a]	Printing and industrial grade papers, tissues, etc.
Jute	45–63	21–26	2.5	0.02	13.7[b]	Most paper grades
Bagasse	32–37	18–26	1.7	0.02	120.20	Printing and industrial grade papers, greaseproof papers, and dissolving grade pulp
Short fibers						
Hardwood	54–61	23–30	1.2	0.03	41.6	Printing and industrial grades, tissues, etc.
Wheat straw	49–54	16–21	1.4	0.015	600.00	Printing and industrial grades of papers
Rice straw	43–49	12–16	1.4	0.008	360.00	Printing and industrial grades of paper
Esparto	33–38	17–19	1.2	0.013	-	Specialty papers
Rye straw	50–54	16–19	1.3	0.014	40.00	Printing and industrial grades of paper

[b] Whole stalk.

subcontinents such as India, China, Malaysia, Indonesia, Thailand, Myanmar, etc. Bamboo fiber is longer than that of hardwoods but shorter than softwood and has a high silica content, which poses some problems in chemical recovery and papermaking. This is overcome by using desilication of pulping spent liquor and improved paper technology. The bamboo species most widely used for pulp and paper manufacture are *Dendrocalamus strictus*, *D. hamiltonii*, *Bambusa tulda*, and *Melocanna baccifera*.

Agricultural Residues

Growing demand for pulp, shrinkage of forests, and the consequent shortage of pulpwood experienced by pulp and paper mills around the globe have led to the search for alternative sources of raw material from agricultural residues such as sugarcane bagasse, rice straw, wheat straw, and cotton stalks. These raw materials are used for the manufacture of pulp and paper in the countries where forest-based raw material, i.e., wood is not available due to environmental considerations and to dwindling forest cover. The use of these raw materials has increased considerably and is expected to raise further the pulp and paper manufacture capacity particularly in countries like India, Pakistan, China, Egypt, Turkey, Indonesia, Bangladesh, Mexico, and Taiwan. The major sources of NWF in agricultural residue category are as follows.

Bagasse Sugarcane is an important annual crop grown primarily for the manufacture of sugar on a very large area all over the globe particularly in Asian countries, South America, South Africa, the USA, and the UK. The fibrous residues left after the extraction of sugar juice is known as bagasse and is a very promising pulping material for paper.

The greatest advantage in using bagasse as NWF lies in the fact there is no additional cost involved in growing and harvesting, and only the collection cost is borne by the paper industry. However, bagasse is usually used as fuel in the sugar mill's boiler furnace. Therefore only the surplus bagasse is available for use as a pulp material in the vicinity of sugar mills. Bagasse contains 25–30% pith, a nonfibrous material unsuitable for pulping. It is, therefore, removed by a wet or dry depithing operation and subsequently pulped either by soda or kraft process. Recent advances in pulping and papermaking technology have made it possible to use bagasse for the manufacture of cultural, industrial, and greaseproof grades of paper. It is also used for the manufacture of dissolving grade pulp for the manufacture of viscose rayon.

Rice and wheat straw Rice and wheat, like sugarcane, are annual crops grown in major areas of the globe. Their straw is used for the manufacture of pulp which is then made into various grades of paper using the soda process in minimills in various parts of the world. These agricultural residues yield short fiber and due to its higher silica and ash content, wheat straw is favored over rice straw as pulp material. Papers made solely from straws can be recycled only a few times due to weak fibers, which loses its strength properties after one or two pulping cycles. Therefore, these short-fibered straw pulps are occasionally blended with long-fiber reinforcement pulp to produce various varieties of cultural and industrial grades of papers of higher strength. These straws represent a promising source of fiber and are being used primarily in countries where wood is in short supply.

Other Non-Wood Plant Fibers

Other non-wood plant fibers are esparto, elephant grass, reeds, sabai grass, bast fibers of jute, hemp, kenaf, flax, and leaf fibers of abaca and sisal. In this class also comes seed hairs, e.g., cotton linter. Cotton is an extensively used raw material in the textile industry, so its use in pulp and paper is very limited and used only in the manufacture of specialty paper like currency paper and permanent papers. Some of the most abundant and widely used NWF in this category are described in brief in the following section.

Kenaf Kenaf (*Hibiscus cannabinus* and *H. sabdariffa*) belongs to the same plant family as cotton, okra, the ornamental hibiscus, and hollyhocks. It is an annual crop, which is normally cultivated in the tropics and subtropics where temperatures are greater than 20°C. It is harvested for fiber soon after its flowering. Under good conditions kenaf will grow to a height of 5–6 m in 6–8 months and can yield up to 30-35 tonnes ha^{-1} of dry woody material. It is grown in Thailand, China, India, Australia, and the USA. Kenaf fiber is classified as medium long fiber similar to bagasse; however, it has a higher cellulose content and lower lignin content as compared to bagasse, and is preferred as a pulp material over bagasse. Kenaf crops are more susceptible than trees to abnormalities in seasonal weather changes, e.g., droughts and floods. Further, the harvested raw material needs storage for a number of months to sustain the supply of pulp material and it is prone to decay. Moreover, kenaf has a mixture of long bast fiber (57%) and short core fiber (41%), which need separation and subsequent pulping in separate lots. Kenaf is used for the manufacture of almost all varieties of paper including specialty papers.

Hemp Hemp (*Crotoleria juncea*) is an annual crop, which can be grown on normal to poor soils and yields three to four times more useful fiber per hectare per year than forests. It attains 2.5–3 m in height after 4 months of growth and is widely grown in Asia, Central America, and Africa. Hemp fiber is classified as a long fiber material and is considered as one of the best pulping materials for the manufacture of expensive specialty papers such as cigarette paper and others lightweight papers, and also in blending with weak pulps as a reinforcement pulp in certain grades of cultural, industrial papers.

Jute Jute (*Corchorus olitorius, C. capsularis*) is also an annual herbaceous plant mainly cultivated in South and Southeast Asia. The average dry yield of jute fiber varies from 1.6 to 2.0 tonnes ha^{-1} $year^{-1}$. After extraction of fibers, the remaining jute sticks (core) are usually used to make fences and as fuel. However, the core fibers, which are shorter than bark fibers, are utilized for many other value-added industrial purposes and cheap-grade pulp and paper manufacture. The five major jute producing countries (namely India, Bangladesh, China, Nepal, and Thailand) account for about 95% of world production. Jute fiber is used for the production of high-quality writing and printing papers and a variety of specialty papers. Like the other NWF, using jute for pulp and paper has many advantages; it requires less chemicals for pulping and consumes less energy due to its lower lignin content than woody fibers.

Waste Paper (Secondary Fiber)

Waste paper has become a very important secondary source of raw material for papermaking in recent years. However, collection and sorting of various grades of waste paper, such as mixed waste paper, corrugated waste paper, white paper cuttings (waste from printing presses), waste news print and its conversion into paper, is important in those regions where it is difficult to get a large amount of cheap raw material on a sustainable basis for papermaking. Further the cost of collection, sorting, and transportation are practical problems, which limit its wide-scale use in papermaking. But due to easy recycling and emerging new technologies for de-inking by biological and chemical treatments, the use of waste paper is likely to increase in future. The recycling of waste paper is further preferred due to environmental reasons as it facilitates conservation of trees and other cellulose raw material for future use.

Papermaking Process for Non-Wood Fibers

Essentially the process of papermaking involves the breaking up of the raw material into small pieces, pulping, bleaching, washing, stock preparation, and preparation of paper sheets (**Figure 2**). A brief account of various aspects of these processes is explained below.

Pulping (from Raw Material to Pulp)

- Cleaning: This involves elimination of all undesirable components such as dirt, sand, and other contaminants.
- Cutting/chipping: Most of the NWF are too long or big in size. Therefore, to facilitate homogeneous chemical treatment or mechanical treatment raw material is cut or chipped to uniform size.
- Screening/classification: Fibers are screened or classified by centrifugal and gravitational processes to get a uniform sized fibrous material for further processing.
- Fiber separation: Cellulose fibers are separated either by chemicals that dissolve the lignin, or by mechanically separating the fiber structure. The material thus prepared is referred to as pulp and this process of fiber separation is called the pulping operation.
- Bleaching: This is an optional operation to achieve a higher brightness or whiteness for a better appearing sheet of paper. For some grades of paper manufacture such as packaging paper and board, bleaching is not required. Traditional bleaching has been done by chlorine compounds, which are being replaced gradually due to environmental considerations, by the use of oxygen, hydrogen peroxide, and ozone. Non-woods can be bleached relatively easily by hydrogen peroxide.
- Refining/beating: In this process fibers are subjected to mechanical action for the modification of the fiber structure and to facilitate fiber-to-fiber bonding. This process adds to the strength of the paper in the finished paper sheet.

Papermaking (from Pulp to Paper)

- Dilution: The pulp is diluted with a large amount of water to convert pulp into a dilute fiber suspension to facilitate formation of a uniform sheet.
- Formation: The dilute fiber suspension is injected on to a fine-mesh wire screen. This results in drainage of excessive water and settling of the fiber networks into a flat sheet.
- Pressing: Sheet consolidation and dewatering results by mechanical pressing.
- Drying: The wet sheet is dried over a steam-heated dryer cylinder by the evaporation of water.
- Calendering (optional): The dried sheet is calendered for surface smoothness.
- Sheeting/reeling: Finally the formed dried paper sheet is cut to the required size.

Conclusions

Rising concern about the 'greenhouse effect' demands that wasteful disposal of fibrous material

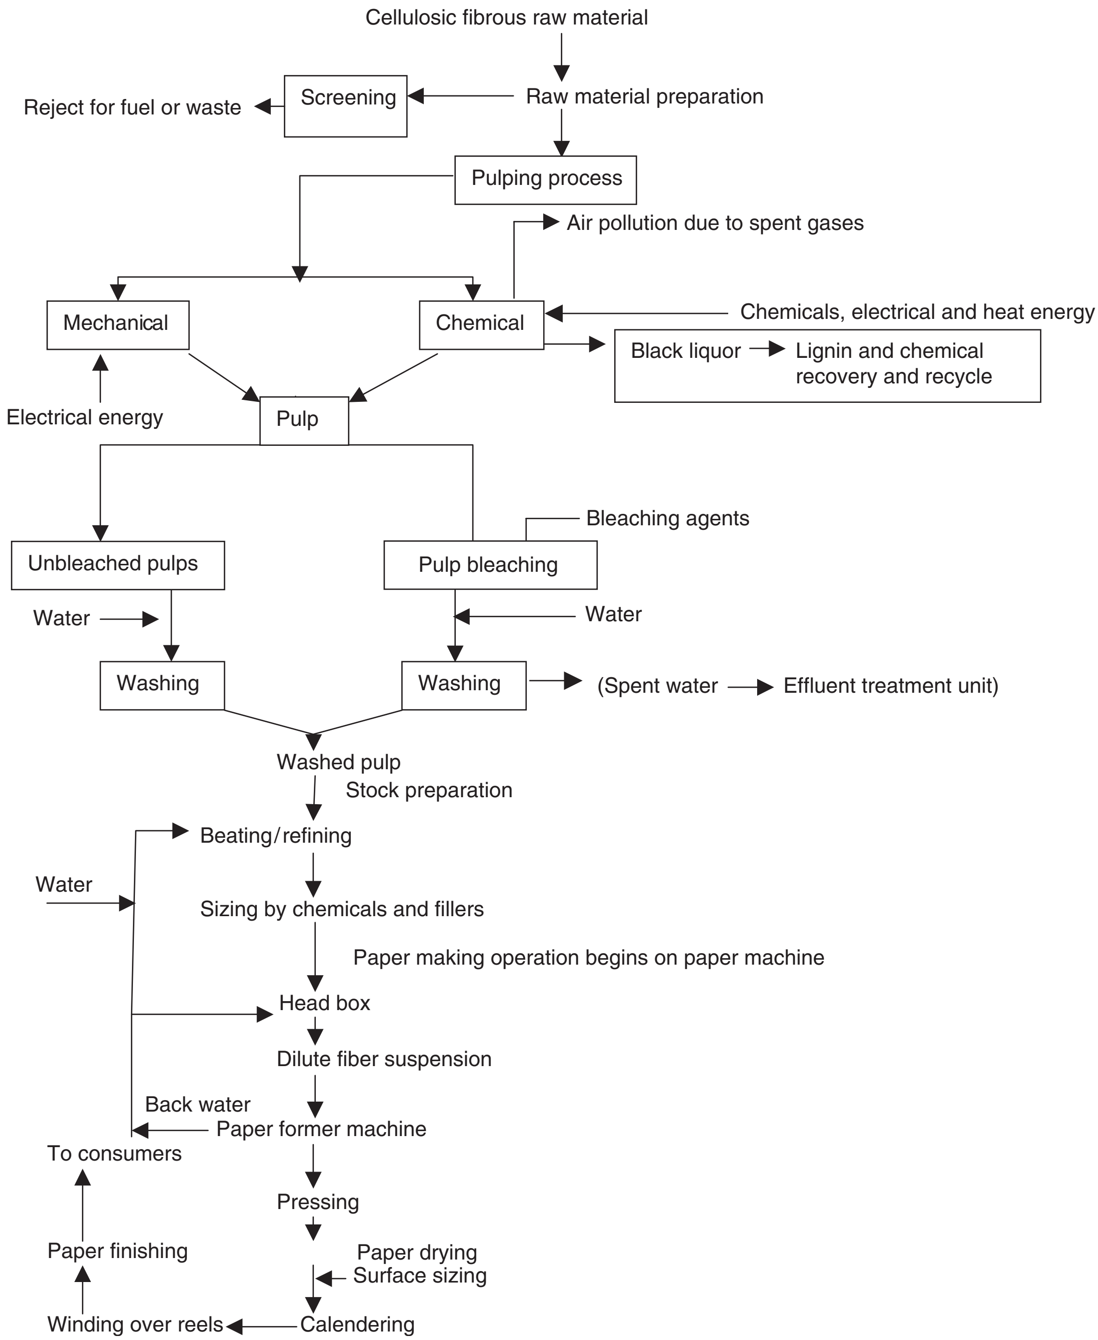

Figure 2 Flow diagram of pulping and papermaking process.

through carbon emission should be stopped. Consequently, efforts are being made to increase the use of non-wood fibers such as flax, hemp, rice, and wheat straw as valuable fiber supplements to the pulp and paper and allied industries. It has been suggested that such efforts will not only reduce demands on forest fiber supplies, but can also reduce greenhouse gas emissions. Further, carbon can be managed in a valuable material form as opposed to burning the agriculture residues as waste. Further, there is consensus all over the world that the non-wood fibers can be easily and quickly grown and are suitable for making paper of excellent quality. However, their usage is restricted to tropical developing countries due to the fact that contemporary papermaking in developed countries relies primarily on wood as the only significant source of paper fiber. The recent interest in using non-wood fibers, particularly hemp, in the Western world perhaps stems from strong environmental considerations.

Most of the forest resources in Europe, North America, Asia, and Australia have been utilized for paper production and other uses. So there seem to be valid reasons to look to NWF as a paper pulp source so that forests have sufficient time to rejuvenate and increase the forest cover. However, the research and development side of the papermaking industry has been focused on wood pulping technologies and equipment. Therefore, a lack of success and conservative attitudes with most non-wood initiatives stem from the application of wood pulping technology to non-wood fibers resulting in poor pulp quality and incorrect handling. This is generally true for digestion and refining operations, which tend to produce overcooked and over refined pulps due to the higher energy requirements of wood-based processes when they are used for non-wood fibers. Further, lack of will and financial support for the research and development wings of the paper industry, despite strong technical evidence of the potential of non-wood fibers, has resulted in the nonproliferation of this new concept. Nevertheless, there are many NWF-based paper mills already producing a wide range of paper grades. Finally, there is also a resurgence of initiatives for advancing the cause of the NWF paper industry to promote non-wood fiber as a cost-effective, high-quality competitive, and an environmentally friendly source for papermaking.

Overview

G M Scott, State University of New York, Syracuse, NY, USA

Introduction

There is no denying that paper is very important in today's world. We use it for money, record-keeping, communication, personal hygiene, and many other uses personally, commercially, and industrially. We often take paper for granted: it is ubiquitous but essential in our lives. However, very few of us think about how it is made beyond that it is made from trees. Paper can be an extremely complicated product, both in its components and in its manufacture. For example, printing and writing paper has distinctly different properties from tissue. It is often difficult to use one type of paper for another purpose. (How many of us has tried to draw on a dinner napkin?) **Table 1** is a selected list of the variety of paper grades that are produced today.

Papermaking is ever-evolving and developing. As the needs of society change, the types of paper being produced have also changed. The personal computer revolution was supposed to bring about the 'paperless office' and make printed newspapers obsolete. Paper consumption has not decreased, however, due to the increased use and popularity of computers. The types of paper demanded by consumers have changed significantly. In keeping up with computer technology, grades of paper for use in ink-jet printers and for the home-printing of digital photographs have been developed. Per capita consumption of paper has been increasing steadily over the past decade. Worldwide, paper consumption is increasing at an even greater rate as developing countries make

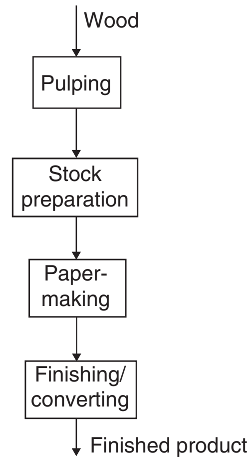

Figure 1 Overview of the papermaking process from wood to finished products. Pulping disassembles the wood into its component fibers while stock preparation prepares the fibers for papermaking. Papermaking reassembles the fibers into a sheet and finishing/converting makes that sheet into the final product.

increased use of paper. The paper industry is probably one of the most sustainable industries in the world. Its primary raw material, wood, is being replenished at a rate faster than consumption. Modern integrated paper mills are nearly energy self-sufficient. In addition, there is a well-established infrastructure for the recycling of paper.

Paper is typically defined as a 'felted sheet of fibers formed on a fine screen from a water suspension.' The key elements of this definition are that the raw material (pulp) has been previously reduced to individual fibers and suspended in water. This pulp is then treated and deposited on to a fine screen to remove the water, leaving a randomly oriented sheet that is subsequently consolidated and dried. In practice, modern paper also contains a variety of nonfibrous materials in order to give the paper its desired properties. These materials include clay, calcium carbonate, starch, and specialty chemicals that impart waterproofing, flameproofing, smoothness, and other properties. Paper thicker than 0.3 mm is often termed paperboard.

Figure 1 shows an overview of the papermaking process from wood to finished product. The wood is first pulped, or rendered into fibers, in one of two broad methods (*see* **Pulping**: Chemical Pulping; Mechanical Pulping). In stock preparation, mechanical action changes the surface properties of the fiber, allowing them to develop the papermaking properties that are desired. Different pulps (in terms of pulping methods and/or wood species) are blended with nonfibrous fillers and specialized chemicals. The papermaking process removes water from the sheet while forming and consolidating the sheet, which is dried to its final moisture content of approximately 5%. In the final step, finishing/converting, the final products of the process (e.g., envelopes, tablets, sheets, boxes) are produced from the large rolls of paper produced by the papermachine.

History of Papermaking

Given our definition of paper above, the first paper was reputedly made in China around AD 105 by Ts'ai Lun who was charged to find a new material for record-keeping. Papyrus, invented earlier by the Egyptians and not considered a true paper, was made by pounding strips of papyrus together to form a sheet. Ts'ai Lun pulverized the inner bark of mulberry tree, producing a pulp, and draining the fiber suspension using a fine screen. The resulting sheets were subsequently pressed and air-dried. For several centuries, China held a monopoly on papermaking, but eventually the technology traveled from China to Japan and Arabia, and into Europe by the eleventh century. By this time, cotton in the form of rags and linen was the primary source of raw materials for papermaking. A shortage of rags in the eighteenth century prompted papermakers to look towards other sources for fiber, especially wood. At this time, paper was still handmade one sheet at a time, using molds consisting of a fine wire screen (**Figure 2**). The invention in AD 1798 by Louis Robert of the papermachine, which could form a continuous sheet of paper, exacerbated the raw material shortage, prompting the development of the modern wood-pulping techniques in the nineteenth century. This century also saw many improvements in the continuous papermachine (**Figure 3**). While the basic concepts of papermaking remain unchanged since

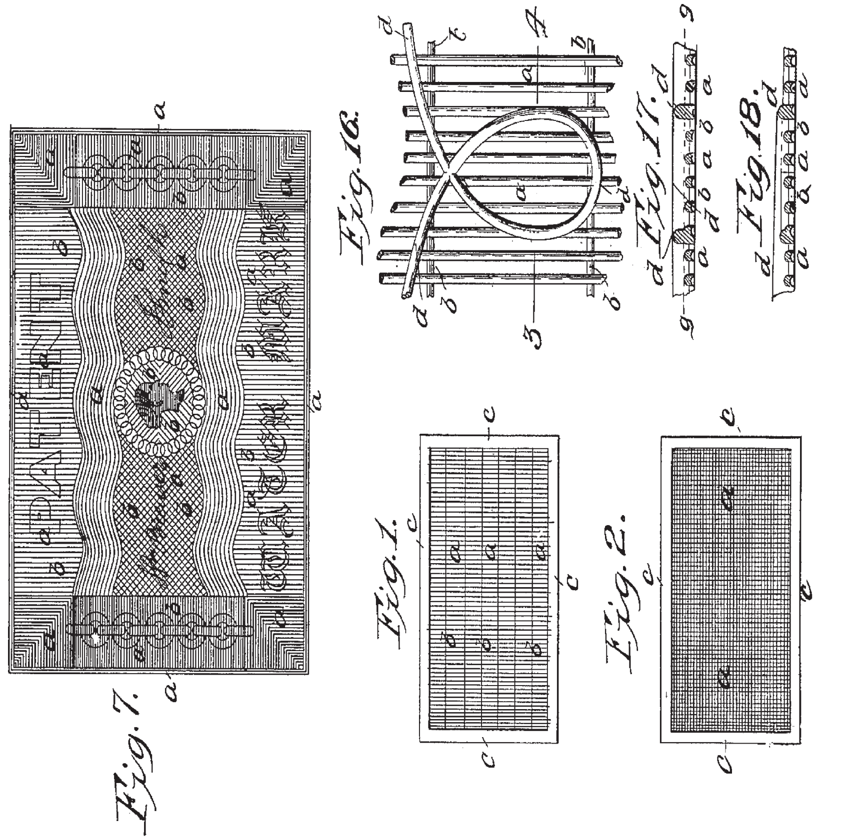

Figure 2 Patent drawing of mold for the handmaking of paper (US patent 7,979). This screen was hand-dipped into a slurry vat, drained, pressed, and removed for drying to produce paper one sheet at a time.

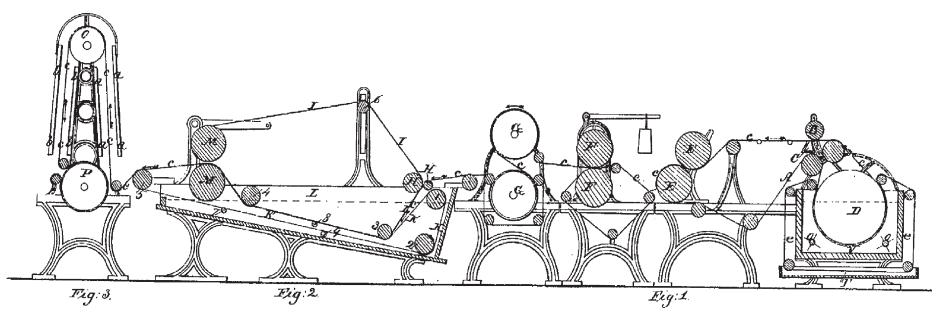

Figure 3 Patent drawing of early paper machine from the 1830s (US patent 8,698). All of the basic processes of a modern machine are present in this machine.

these developments, many refinements have led to the modern papermachine (**Figure 4**) that today operates at speeds of over 1800 m min^{-1}. **Table 2** summarizes the major historical milestones in the papermaking process.

Goals of Papermaking

Paper is an engineered product. The proper combination of raw materials and processing steps results in paper having the desired properties for a particular use. A large number of variables, from the raw materials to the type of equipment used, affect the final properties of the sheet (**Table 3**). It is the interaction of these variables that gives paper the properties needed for any particular grade. **Table 4** gives some of the desired properties of some common grades of paper as well as the typical pulp furnish used in that grade. As can be seen, different grades have significantly different properties, including printability, absorbency, and strength.

For example, newsprint must have excellent printability and opacity (so the writing on the back of the sheet does not show through). However,

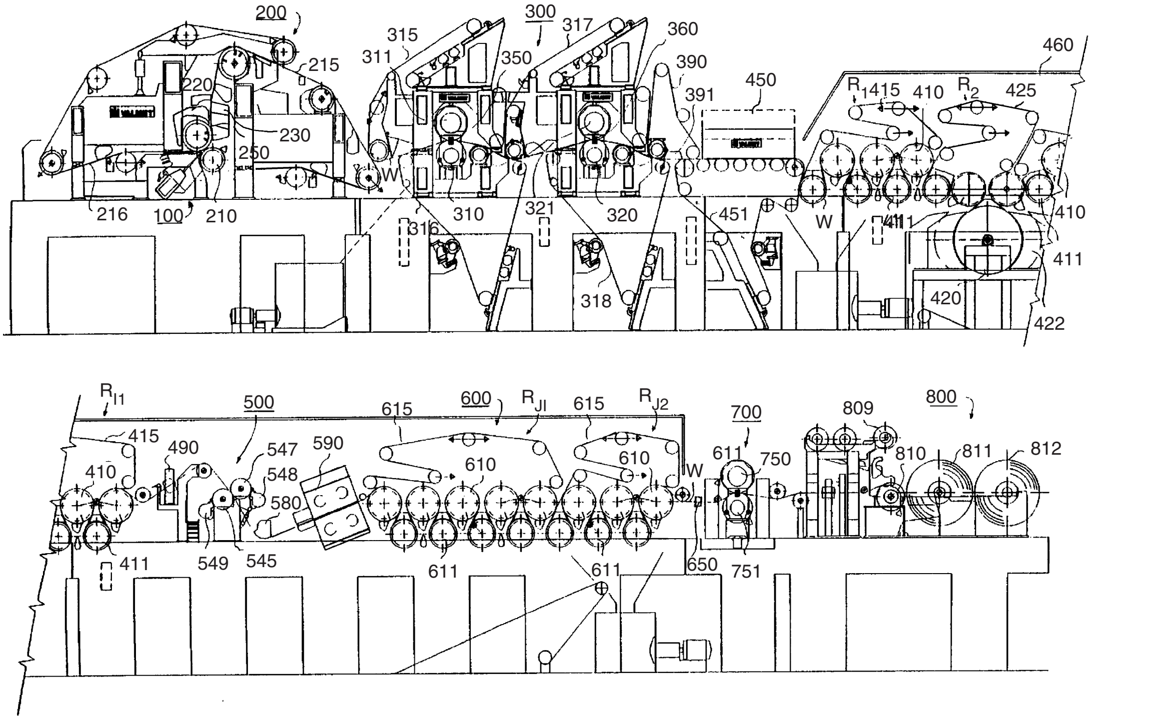

Figure 4 Patent drawing of modern paper machine (US patent 6,413,371). While much more complicated, this machine contains the basic operations of draining, pressing, and drying.

because of its limited life span of 1 day, it must be inexpensive. For newsprint, a thermomechanical pulp (TMP) is used. Printing and writing paper, having a much longer life span and higher brightness, uses more expensive bleached kraft pulp.

Papermakers use different raw materials for their furnish depending on the desired properties of the sheet. The different raw materials impart characteristic properties to the sheet (**Table 5**). While kraft (chemical) pulps are used for strength, they have relatively poor optical qualities. Mechanical pulps tend to be just the opposite. Fillers, such as calcium carbonate and clay, are inexpensive and impart excellent optical properties, but impart no strength to the sheet. Some specialty papers, such as paper for currency and bank notes, are made of nonwood fibers such as linen, flax, and cotton. Consumer demand has expanded the use of recycled fiber in many grades of paper. Some grades, such as tissue, toweling, and linerboard, are almost exclusively made from recycled fibers. Many other grades, such as printing and writing, have varying percentages of recycled fiber. Broke is internally recycled paper (e.g., off-specification paper) and is used in the furnish of most mills.

Paper Properties

The properties of paper can be divided into three main groups: physical, strength, and optical properties. **Table 6** summarizes the major tests that are performed on paper in these three categories. Physical properties are those that measure some structure of the paper such as grammage, thickness, and smoothness. Another physical property, density, ρ, is a function of the grammage, W, and thickness, t as $\rho = W/t$. Strength properties are those that measure the force or pressure needed to cause the paper to fail. Tensile, burst, tear, and folding endurance are all measurements of the ultimate failure of the paper in some prescribed manner. There are many more strength properties and measurement of paper; many of these are specific to certain grades of paper. Optical properties measure the paper's response to light, including brightness, color, and opacity. For some specialty grades of paper, some other properties are important, such as electrical properties. In other cases, the ability of the paper to resist water or oil penetration is very important. Each grade of paper has its own set of properties that must be met by the manufacturing process. The Technical Association of the Pulp and Paper Industry promulgates a complete set of testing methods for most of these paper properties.

Stock Preparation

Between pulping and the actual papermachine, the raw materials must be properly prepared. The

Table 2 Milestones in papermaking history

Year	*Milestone*
600 BC	Egyptians manufacture papyrus, which is not a true paper
440 BC	Greeks use parchment, the treated skins of sheep and goats
AD 105	Chinese invent the first true paper from the bark of the mulberry tree, reputedly by Ts'ai Lun in the court of Emperor Hedi
AD 610	Paper is made in Japan, where it becomes a part of the culture, being used for writing, fans, garments, and dolls
AD 704	Paper is made of cotton on the Arabian peninsula
AD 900	Paper (which was imported) used in Europe for papal proclamations
AD 1009	Papermaking introduced into Europe (Spain) and rags used as a raw material
AD 1330	Watermarked paper invented in Italy
AD 1411	First papermill constructed in Germany
AD 1453	Invention of the printing press greatly increases the demand for paper
AD 1588	Paper is made in England
AD 1680	Paper is made in Mexico
AD 1690	Paper is made in North America near Philadelphia
AD 1719	A shortage of rags for papermaking prompted investigations into other fiber sources, including wood
AD 1798	Invention of the continuous papermachine by Louis Robert
AD 1817	Development of the steam-heated dryer cylinders
AD 1840	Development of groundwood (mechanical) pulping process to allow paper to be made from wood
AD 1854	Development of soda process (chemical) which uses sodium hydroxide to digest wood
AD 1867	Development of sulfite process (chemical) which uses sulfites to digest wood
AD 1879	Development of kraft process (chemical) which adds sodium sulfate to the soda process
AD 1923	Development of twin-wire former
AD 1960	Development of the wet-end foil for dewatering
AD 1960s	Development of the synthetic press felts and nonmetallic wires

Table 3 Variables involved in papermaking from stock preparation to the paper machine

Raw materials	
Fiber furnish	
Type of wood	Softwood, hardwood
Time of harvest	Winter, summer
Location	Northern, southern, tropical
Pulping method	
Chemical	Kraft, sulfite
Semichemical	Chemimechanical pulp (CMP), chemithermomechanical pulp (CTMP), neutral sulfite semichemical (NSSC)
Mechanical	Groundwood, thermomechanical (TMP), refiner mechanical (RMP)
Recycled	Newsprint, old corrugated containers, mixed office waste, mixed paper
Fillers	Calcium carbonate, clay, titanium dioxide
Chemicals/ additives	Wet strength agents, dry strength agents, starch, retention aids, defoamers
Stock preparation	
Refining	Beaters, disk refiners, conical refiners
Cleaning	Hydrocyclones
Screening	Pressure screens, sidehill screens
Paper machine operations	
Headbox	Open, air-padded, hydraulic
Forming section	Fourdrinier, twin wire, multiply former, cylinder former
Press section	Solid roll, extended nip, suction roll
Dryer section	Two-tier run, single felt, single-tier run
Size press	Coating, surface treatment
Calender stack	Number of nips, heated nips
Finishing operations	Sheeting, converting, packaging

objective of the stock preparation step in papermaking is to process the fibers from the pulping step and combine them with the nonfibrous materials in a manner suitable for papermaking. Stock preparation consists of the processes summarized in **Table 7**. Consistency is a measure of the solids content of a sample of pulp. It is defined as the dry mass of the solid material over the original mass. In stock preparation, consistencies typically range from 0.5% or lower (in the final feed to the papermachine itself) up to 15% for high-density storage.

Repulping

For papermaking, the pulp fibers must be dispersed in water for pumping and the papermaking process. If a mill is integrated, the fibers will remain in a high-consistency slurry from the pulp mill. However, many paper mills do not have a pulp mill associated with them. So, these mills must take market pulp, often dried to 90% solids, and redisperse the fibers in water using a repulper. Repulpers or hydrapulpers are large mixing vessels with one or more revolving agitators to provide circulation and energy sufficient to disperse the fibers in the water.

Refining

The terms refining and beating are commonly used interchangeably in the paper industry and refer to the use of mechanical energy to develop papermaking properties of fibers. As with many processes, there are tradeoffs which depend on the products being made. In general, the strength properties, such as tensile and burst strength, increase with more refining. Tear strength tends to decrease with refining. Optical properties, such as opacity, tend to

Table 4 Properties and furnishes of common grades of paper

Grade	*Fiber furnish*	*Properties*
Newsprint	TMP	Printability, optical properties, inexpensive, short life
Printing/ writing	SWK, HWK, sulfite	Printability, whiteness, optical properties, ink holdout
Grocery sack	SWK	Strength
Tissue	Sulfite, recycled	Absorbency, strength, softness
Linerboard	SWK, recycled	Strength, printability
Corrugating medium	HWK, recycled	Stiffness, conformability
Paperboard	Recycled	Bulk, stiffness
Paper toweling	Recycled	Wet strength, absorbency

TMP, thermomechanical pulp; SWK, softwood kraft; HWK, hardwood kraft.

Table 5 Characteristics of various papermaking materials

Furnish	*Characteristics*
Softwood kraft (SWK)	Strength
Hardwood kraft (HWK)	Bleachability; optical properties
Sulfite	Bleachability; softer fiber
TMP/RMP	High yield; optical properties
Groundwood	Cheap filler; optical properties
Fillers	Good optical properties; inexpensive
Recycled	Consumer demand; mixed properties
Nonwood	Specialty products
Broke	Available; needs to be used; source of fiber

TMP, thermomechanical paper; RMP, refiner mechanical pulp.

decrease with refining as the fibers become more conformable and there are fewer fiber–air interfaces to scatter light. In all cases, the rate at which water drains from the fiber decreases. Slower drainage translates to lower production on the papermachine. Thus, it is necessary to refine such an amount that the necessary strength properties are achieved, while maintaining production rates on the papermachine.

The drainage rate of the pulp is often characterized by the Canadian Standard Freeness (CSF) measurement (Tappi test method T 227). In the test, water is drained from a known sample of pulp; freeness is the volume of water that overflows a calibrated orifice at the bottom of the collection cone. The greater the overflow, the faster the pulp drains. CSF is typically used in North American paper mills. Two other freeness tests used around the world include the Schopper Reigler and Williams. Typically, chemical pulps have a typical freeness of 400–700 ml CSF depending on the degree of refining. Mechanical pulps are much slower draining with freenesses in the range 100–200 ml CSF.

A variety of equipment is used for refining (or beating) in the paper industry. Early beating was done batchwise, using a Hollander beater or similar equipment (**Figure 5**). In this batch process, the pulp at 3–6% consistency circulates in an oval tank where it passes under a roller with bars against a bedplate. However, with the increasing production rates at many mills, the batch process became too slow, and mills changed over to conical and then to disk refiners. Both types of refiners operate similarly in

Table 6 Important paper properties and testing methods (Tappi)

Property	*Test method*[a]	*Description*
Physical properties		
Grammage	T 410	Mass per unit area of paper; also known as basis weight
Thickness	T 411	Single sheet thickness (caliper) of paper
Smoothness	T 538	Measurement of air flow between the surface of the sheet and two pressurized, concentric annular rings
Moisture content	T 412	Amount of water in paper
Strength properties		
Tensile	T 494	Force per unit width required to break a specimen in tension
Tear	T 414	Force perpendicular to the plane of the paper required to tear multiple sheets through a specified distance
Fold	T 423/T 511	Measures the ability of paper to withstand repeated bending, folding, and creasing
Burst	T 403	Pressure in a rubber diaphragm required to rupture a clamped sheet of paper
Optical properties		
Brightness	T 452/T 525	Measures the reflectance of paper
Color	T 524/T 527	Measures the color of paper with tristimulus filters (red, green, blue)
Opacity	T 425/T 519	Measures the ability of a sheet to obscure printing on a backing sheet

[a]Tappi test method published by the Technical Association of the Pulp and Paper Industry, Atlanta, GA, USA.

Table 7 Operations in stock preparation

Operation	*Description*
Repulping	Dispersion of the pulp fibers in water
Refining	Modification of the fibers and fiber surfaces through mechanical action
Cleaning and screening	Mechanical separation of undesirable materials in the pulp
Blending	Mixing of fibers and fillers to achieve desired sheet properties
Chemical addition	Use of specialized chemicals to achieve desired properties or operation

Figure 5 Jones–Bertram beater, which is similar to a Hollander beater. As the pulp circulates, it is refined in a batch process.

Figure 6 Small pilot disk refiner. Two facing rotating plates refine fibers in a continuous process.

Table 8 Effects of refining on papermaking fibers

Effect	*Description*
Fiber shortening	Cutting of fibers by the refining bars, producing shorter fibers
Fines production	Clipping and removal of fibrils from surface of fiber
External fibrillation	Increasing the fibrils on surface of fiber
Internal fibrillation	Increasing the swelling and hydration of the fiber

that the pulp passes between two surfaces that have bars over and between which the pulp must pass. In conical refiners (Jordan and Claflin refiners), the bars are on a tapered plug rotor which rotates inside the corresponding shell. In disk refiners, the pulp passes between two circular flat plates with bars. The two plates are either counterrotating or one plate is rotating while the other is fixed. Refiners operate with clearences of 0.1–1.0 mm between the bars on the two facing plates (**Figure 6**).

The passage of papermaking fibers through the close clearance of the refiners has several effects on the fibers, some beneficial to the development of the fiber properties and others that are detrimental. **Table 8** summarizes these effects on the fiber. In general, fiber cutting and fines (very short fibers) production are undesirable effects. One aspect of a fiber that determines the strength of a sheet of paper is the fiber length, especially tear strength. External fibrillation is the increase in the amount of fibrils raised from the surface. These fibrils, which look like 'hair' on the surface of the fiber, can interact and bond with similar fibrils on other fibers. The greater interaction between fibers leads to greater fiber-to-fiber bonding and greater-strength paper. Likewise, internal fibrillation, the delamination of the fiber structure, increases the flexibility of the fiber. Greater conformability also allows greater interaction between fibers and hence increased sheet strength. Refiners can be operated to favor internal and external fibrillation over fiber shortening and fines production by increasing the interaction between fibers in refining. With the greater consistency in the refiner, fibers tend to interact to a greater degree with each other rather than with the refiner plates. Gentler refining, using lower specific energies and wider plate separations, tends also to reduce the fiber cutting and fines production.

Different fibers refine at different rates. The degree of refining is typically measured through a drop in the CSF of the pulp. **Table 9** summarizes the energy needed per kilogram of pulp to drop the freeness by 100 ml CSF. Unbleached softwood kraft typically takes the most energy to refine. Bleaching the pulp weakens the fiber structure and makes it easier to refine. Hardwoods, which have shorter fibers than softwoods, also refine easier. Recycled paper, since it has already been refined at least once, also tends to require less energy to refine than the corresponding virgin fiber. Many paper grades are blends of different fibers. In the stock preparation step, it is usually necessary to refine these fibers separately as

Table 9 Energy required to change the freeness of the given furnish by 100 ml Canadian Standard Freeness (CSF)

Furnish	*Refining energy (kJ kg^{-1})*
Unbleached softwood kraft	280–360
Bleached softwood kraft	140–160
Bleached hardwood kraft	70–120
Mixed office paper	100–140
Old corrugated containers	100–180
Old newsprint	200–360

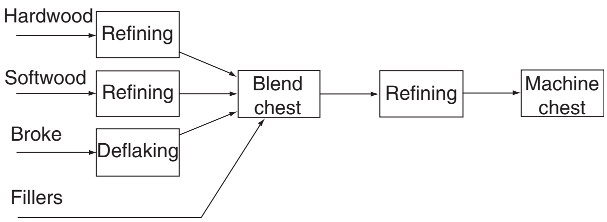

Figure 7 Overview of typical refining layout for stock preparation. Because of the different refining behavior of different fibers, they are often refined separately and then blended. A small amount of refining may be done after blending to 'fine-tune' the fiber properties.

they refine at different rates. For example, refining a blend of hardwood and softwood fibers together typically overrefines the hardwood and underrefines the softwood. As shown in **Figure 7**, the different furnishes are usually refined before blending. A small amount of refining ('tickler refining') based on feedback from the papermachine may be done after blending to meet the final requirements of the papermachine.

Cleaning and Screening

The cleanliness of the pulp going to the paper machine directly reflects on the quality of the final sheet. Most paper machines have one or more systems of screens and cleaners to remove contaminants that may affect the quality of the resulting sheet. While different fundamental processes are the basis for separation in different separation equipment, it is generally accepted that screens remove the relatively larger contaminants, while the various types of cleaners remove mid-sized contaminants. The smallest contaminants are generally removed in washing, thickening, and flotation operations, but these are not typically used on the approach flow to a papermachine.

Hydrocyclones Hydrocyclones, otherwise known as centrifugal cleaners, vortex cleaners, or centricleaners, came into widespread use in the paper industry in the 1950s. Prior to this, hydrocyclones were commonly used in the mining industry for separations. A hydrocyclone consists of a cylindrical-conical vessel with the inlet flow introduced tangentially at the top (**Figure 8**). The tangential inlet produces a helical flow of material in which centrifugal action and fluid shear force the denser material to the outside surface while the less dense material migrates to the center of the vortex. The outlet at the top of the hydrocyclone draws off the less dense material while the bottom nozzle removes the dense material that was thrown to the outside of the vortex. In the paper industry, the hydrocyclones tend to be 7.5–15 cm in diameter with the smaller-diameter cyclones developing the higher centrifugal forces.

Figure 8 Pilot plant hydrocyclone cleaners manufactured by Bird. Density differences allow the removal of the heavier contaminants.

As with any separation process, it is not a perfect separation. With hydrocyclones, there is a significant amount of fibers and other papermaking material in the reject stream to be recovered. **Figure 9** shows a three-stage system in which the accepts from the secondary and tertiary stages are returned to the previous stage while the rejects from each stage go to the subsequent stage. The primary purpose of the secondary and tertiary stages is not necessarily to

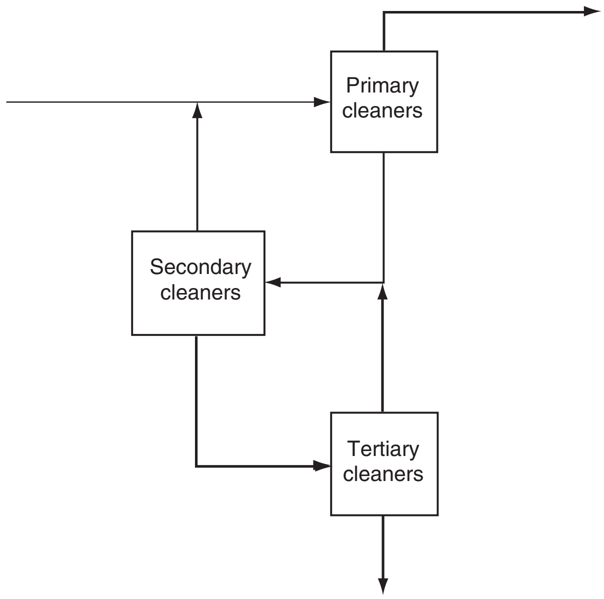

Figure 9 Three-stage cascade cleaner system. The accepts from each stage (top arrow) return to the previous stage, while the rejects (bottom arrow) go to the subsequent stage. The tertiary-stage rejects are removed from the system.

clean the pulp further. In fact, in most cases, a single stage produces cleaner pulp. However, the secondary and tertiary stages of cleaners recover usable pulp from the reject streams and return it to the primary screen. Some operations will even use four- and five-stage systems in order to recover the maximum amount of fiber.

Pressure screens Pulp is screened to remove oversized, unwanted particles before they can be incorporated in the sheet. While there are several types of screens, including vibratory and flat screens, most mills use primary pressure screens for the approach flow to a paper machine. Regardless of the type of screen, they all operate on the same principle: a barrier prevents the contaminants from passing through, while the pulp fibers and other desired papermaking materials pass through. **Figure 10** shows a pressure screen attached to a pilot paper machine. Depending on the type of contaminant that is being removed, the barrier screen can have either holes or slots. The slots in pressure screens typically have a width of 0.20–0.50 mm. As with hydrocyclones, pressure screens are usually arranged in a cascade arrangement (**Figure 9**).

Papermachine Operations

The most common basic form of the papermachine is the Fourdrinier machine, in which the paper is initally formed on an endless moving screen called

Figure 10 Pilot plant pressure screen manufactured by Black Clawson. The screen uses a slotted screen to remove contaminants from the pulp slurry.

a wire. There are a number of variations of the Fourdrinier machine in use today which use two wires with the sheet formed between them. After being formed on the wire, the sheet is conveyed through a series of presses to dewater the sheet further. Finally, the sheet is dried by evaporating the remaining water in the sheet (**Figure 11**). The papermachine has two main objectives: (1) to remove the water from the pulp, which is initially at approximately 0.5% solids to approximately 95% solids; and (2) to consolidate the sheet and form bonds, such that the sheet has the desired strength, optical, and other properties.

The following sections give an overview of the numerous processes that occur on a modern papermachine. Not all machines will have all the elements described, but most have many. In addition, the description of the approach flow, headbox, and wire section pertain to the most common form of the wet end of the paper machine: the Fourdrinier machine. A different type of former, the cylinder machine, is often used for heavier-weight paperboard grades.

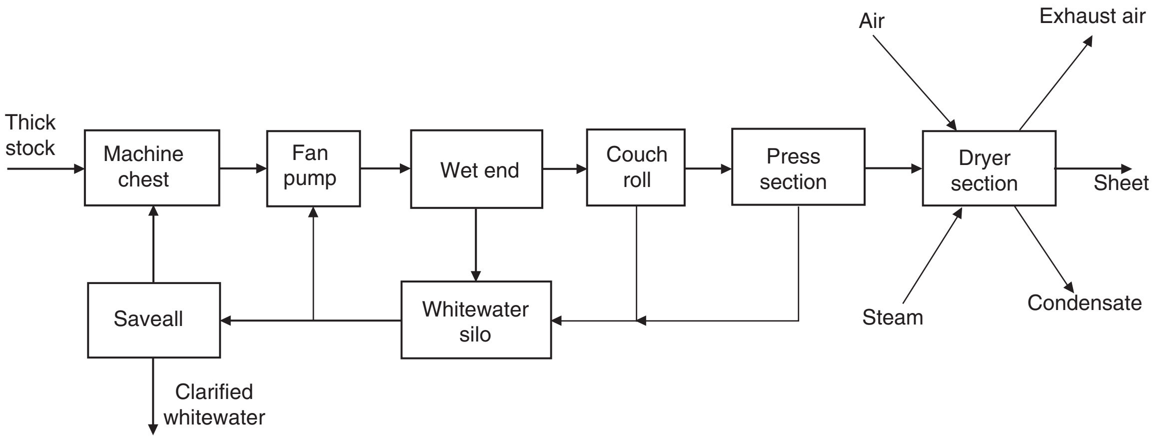

Figure 11 Flow diagram of typical papermachine. Note that the water drained from the wet end and press sections are used for dilution at the fan pump. Fiber from the excess water is recovered in the saveall.

For a description of this type of machine, the reader is directed to the further reading given at the end of the article.

Approach Flow and Headbox

The approach flow to the papermachine includes all the processes from the machine chest (where the pulp is held prior to use) to the headbox (which places the pulp suspension on to the wire). While every machine is different, most contain the hydrocyclones and screens described above, deaerators, and dilution to bring the stock to the headbox consistency. The fan pump, usually the largest pump in the papermachine, mixes the stock from the machine chest with the dilution whitewater returning from the wire, and delivers the stock to the headbox. Just prior to the headbox, the flow must be changed from a circular flow in a pipe to the flat flow evenly distributed across the machine. It is important for the uniformity of the final sheet that the pressure and flow pulsations be evened out. To accomplish this, a flow spreader, typically called a tapered header, distributes the flow evenly across the machine.

The headbox of the paper machine is the final element in the process before the pulp suspension is placed on the wire. The headbox, which can be either air-pressurized or completely hydraulic, accelerates the stock so that it hits the wire at approximately the same speed as the wire. In addition to accelerating the stock, the headbox also controls the flow rate of fiber on to the wire, thus ultimately affecting the weight of the sheet of paper. The headbox must also prevent flocculation of the fibers, which can cause nonuniformities in the final sheet. Baffles, internal mixing rolls, high stock velocities, and highly polished internal surfaces maintain the pulp dispersion.

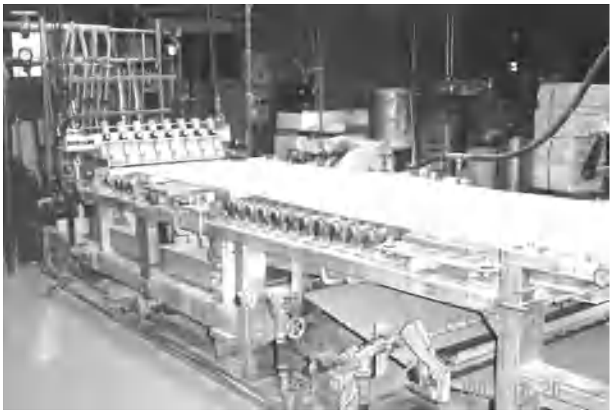

Figure 12 Wet end of the pilot papermachine at SUNY College of Environmental Science and Forestry. A hydraulic headbox is seen in the background and the forming sheet would move left to right while water drains through the wire.

Wire Section

The bulk of the water is removed at the wire section, or wet end of the papermachine (**Figure 12**). A good portion of this water is recycled for dilution of the incoming stock in the approach flow system. As the sheet moves with the wire, water is filtered through the wire, depositing the pulp fibers on the wire in a layered mat. However, as more and more fibers are deposited, the resistance to water flow is increased, thus retarding the drainage of water. With free drainage at the initial part of the wire, the only driving force of the height of the stock above the wire (on the order of 450 Pa) is quickly overwhelmed by the resistance. In some modern machines, multiple wires are used to dewater the stock from both sides of the sheet (**Figure 13**).

Table rolls and foils Table rolls and foils induce a vacuum under the wire, thus creating a greater

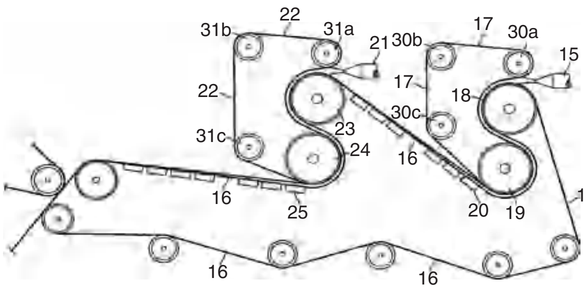

Figure 13 Patent drawing of a modern wet end of a papermachine using multiply, twin-wire forming (US patent 6,342,125). The pulp slurry is injected between two wires (15 and 21) and can be dewatered from both sides.

driving force to remove more water. Table rolls, originally used to support the wire, produce a vacuum that is proportional to the square of the velocity of the wire and related to the roll diameter and at moderate speeds on the order of 4500 Pa. Unfortunately, as speeds increased, a reverse pulse into the sheet at the front of the table rolls became too disruptive to the sheet. The foil was developed to address this drawback of the table roll. The foil is a stationary blade placed at an angle of 0.5–3° to the wire, with the larger angle causing a greater pressure drop. While the pressure driving force is approximately one-half that developed by the table roll, it does not have as great a leading pressure pulse into the sheet. Also, two to three foils can fit into the space of one table roll. However, since the foil is not rotating with the wire, they do tend to increase wear.

Vacuum boxes and vacuum couch At the final stages of the wire section, vacuum is applied to the underside of the wire to increase the driving force for water removal. As a series of vacuum boxes is often used, the vacuum level increases as one proceeds down the wire, with the highest vacuum being applied at the vacuum couch. The couch is the last roll before the sheet is removed from the wire and the wire is turned for its return. Vacuum levels can range from 20 000 to over 53 000 Pa of vacuum.

Forming fabric The fine screen on which the paper is formed is termed the wire, due to its originally being constructed of phosphor-bronze wire. Modern wires are basically a woven cloth of polyester monofilaments made into an endless loop. These fabrics are often woven into a double or triple layer construction in order to provide a wear surface on the bottom of the wire (for durability) and a smoother surface on the top on which the sheet is formed. In all cases, the wires are designed to maximize water flow from the sheet.

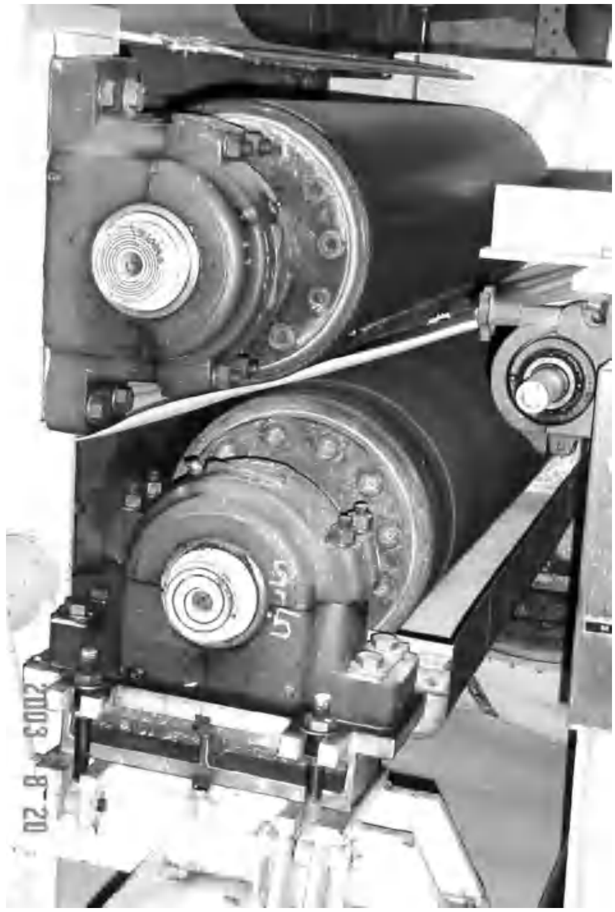

Figure 14 Press section of the pilot papermachine at SUNY College of Environmental Science and Forestry. The sheet together with its press felt would go through the nip, squeezing water from the sheet to the felt.

Press Section

The press section consists of a two to four press nips similar to the wringers on an old-fashioned washing machine (**Figure 14**). The objectives of press are to consolidate the sheet while removing water. Since the majority of the hydrogen bonding which gives paper its strength occurs at a solids content of 35–65%, pressing is key to the development of strength properties of the final sheet. Other properties that can be influenced in the press section include porosity, smoothness, and bulk. The sheet typically enters the press section at 20% solids and exits between 40 and 50%, depending on the grade of paper and pressing configuration.

In order to increase the amount of water removed, the sheet travels through the press together with a press felt, which also serves to support the weak sheet during pressing. The sheet and felt travel through the press nip in four distinct phases. In the first phase, the sheet and felt are compressed, removing air from both. When the air is removed and the sheet becomes saturated, water flows from the sheet to the felt. As the sheet passes mid-nip, the felt begins to expand and becomes unsaturated. However, hydraulic pressure still maintains water flow from the sheet to the felt. In the final phase the sheet is at maximum dryness and begins to expand and reabsorb moisture from the felt. It is important that the sheet and felt be separated as soon as possible after exiting the nip to prevent this reabsorption.

There are limits to the amount of pressure that can be applied to the sheet in the press section. In first presses in a section, the press is often 'flow-controlled.' That is, the limitation to pressing is the flow of water from the sheet to the felt. Overpressing under these conditions can lead to crushing the sheet, in which water flows backwards through the press nip, disrupting the incoming sheet. In 'compression-controlled' pressing, often found in the last press nips, the fiber web itself is the limiting factor in pressing. Under these conditions, increasing the nip pressure beyond a certain point has little effect on increasing the dewatering.

There are a number of ways of increasing the efficacy of the pressing operation; some are operational and require equipment changes. Increasing the nip pressure can increase dewatering in the early nips provided the sheet is not crushed. Double felting the nip can also increase the amount of water that can be removed. The press rolls themselves can be modified by grooving or drilling to allow water to pass through the felt. Suction press rolls can also increase water removal in the nip. Increasing the temperature of the sheet as it enters the nip reduces the viscosity of the water, making it flow easier. Finally, extending the length of the nip will increase the water removal of the nip (**Figure 15**).

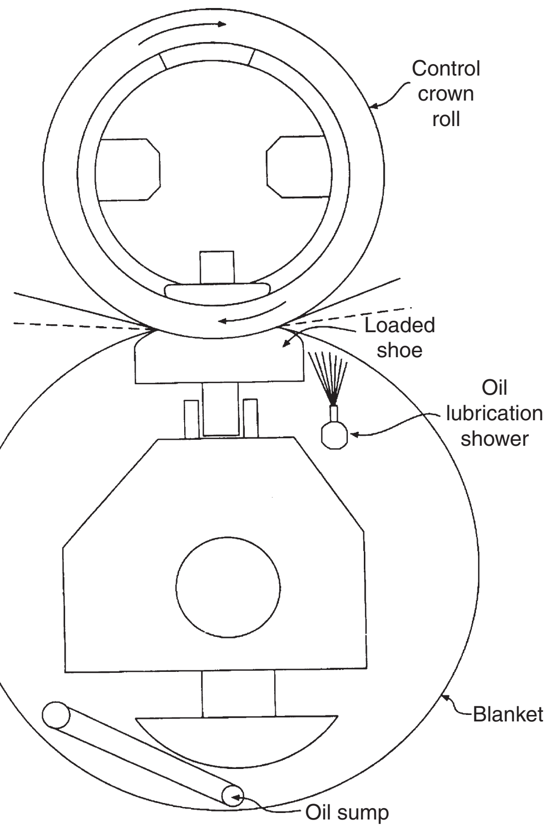

Figure 15 Patent drawing of prior art depicting shoe press used in many presses (US patent 6,458,248). Because of the loaded shoe, the sheet spends a much longer time in the press than with a nip produced by two rolls.

Dryers

The drying section is the most expensive part of the papermachine to run (**Figure 16**). About 78% of the energy used on a papermachine is used in the dryer section, with the remaining energy being split between the wet end and press sections. However, less than 1% of the water that enters with the stock at headbox is removed by drying. By contrast, pressing removes about 3% of the water, with the majority of the water being removed in the wet end. This last amount of water in the sheet is difficult to remove because of the fiber's strong affinity to water and the hydrogen bonds between cellulose and water that need to be broken. However, since this last water is so expensive to remove, small improvements in water removal at the wet end and press sections can translate into significant savings in the dryer section. Since the dryer section is also the most expensive part of the machine in terms of capital cost, paper machine production is often limited by dryer capacity.

Figure 16 Dryer section of the pilot papermachine at SUNY College of Environmental Science and Forestry. The sheet passes alternately over and under steam-heated cylinders in a serpentine pattern.

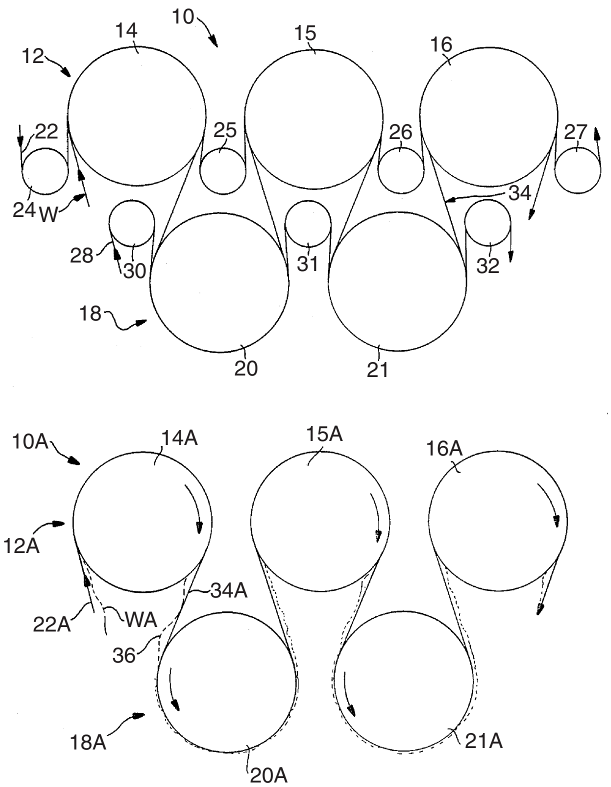

Figure 17 Patent drawing depicting prior art of dryer configuration. Top: double-felted dryer configuration; bottom: single-felted configuration (US patent 4,876,803).

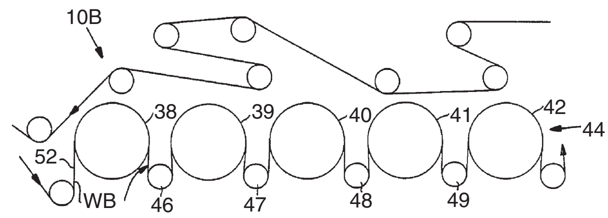

Figure 18 Patent drawing depicting modern dryer configuration. In this configuration, the sheet is completely supported by the felt through the entire run (US patent 4,876,803).

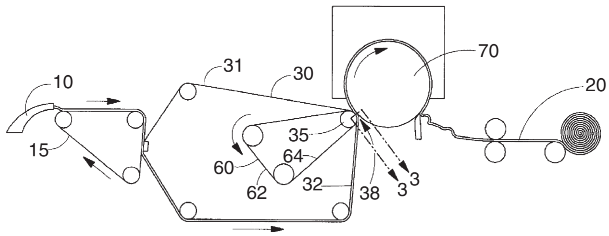

Figure 19 Patent drawing of modern tissue machine (US patent 6,447,642). Tissue machines, because of the light-weight sheet that they produce, tend to be smaller with a single, oversized dryer can (70).

The drying process consists of two main processes. First, heat is transferred from condensing steam in rotating cylinders to the paper sheet, evaporating the water in the sheet. Second, air is drawn through the dryer section to remove the evaporated moisture. The paper takes a serpentine path through the dryer section, passing alternatively over and under the steam-heated cylinders. Synthetic dryer felts hold the sheet in contact with the dryers which increases the heat transfer rate. A number of different configurations of dryers and felt are currently used in the industry. The top diagram in **Figure 17** shows the typical double-felted run in which the sheet transfers unsupported by the felt from one dryer can to the next. The bottom diagram shows a single-felted run in which the sheet is completely supported by the felt through the dryer section. However, in this case, the felt is between the sheet and the dryer can, retarding heat transfer. In **Figure 18**, the run is single-felted, so the sheet is supported and the rolls in which the felt is between the sheet and the roll have been reduced to unheated turning rolls. Tissue machines often use a single large dryer called a Yankee dryer to support and dry the sheet during the entire process (**Figure 19**).

Drying takes place in a number of stages. During the first part of drying, representing usually the first three or four dryer cans, the energy is mainly heating up the sheet. As the sheet proceeds down the machine, a constant-rate zone is entered that represents the bulk of the drying process. As the sheet nears complete dryness, the rate of drying decreases as the more difficult bound water is removed. In most paper machines, the paper is only dried to about 5% moisture, since this is the water content of paper in equilibrium with typical room air.

A size press is often located in the middle of the dryer section (**Figure 4**, item 500). The size press is used to put a surface coating or surface chemicals on to the sheet. Surface coatings can consist of clay, latex, and other materials depending on the grade of paper. Chemicals can also be added to retard moisture penetration or to provide fire resistance. After the application, which is often done as a slurry or solution, further drying is needed.

Calender

The final opportunity on the paper machine to change the paper properties is the calender stack (**Figure 20**). A calender stack consists of a loaded stack of steel rolls (or alternating steel and soft rolls) through which the paper takes a serpentine path. The paper thus passes through a number of nips depending on the number of rolls. The multiple nip passes tend to compact and densify the sheet. While some loss of strength is often evident in calendering, the process improves the smoothness and flatness of

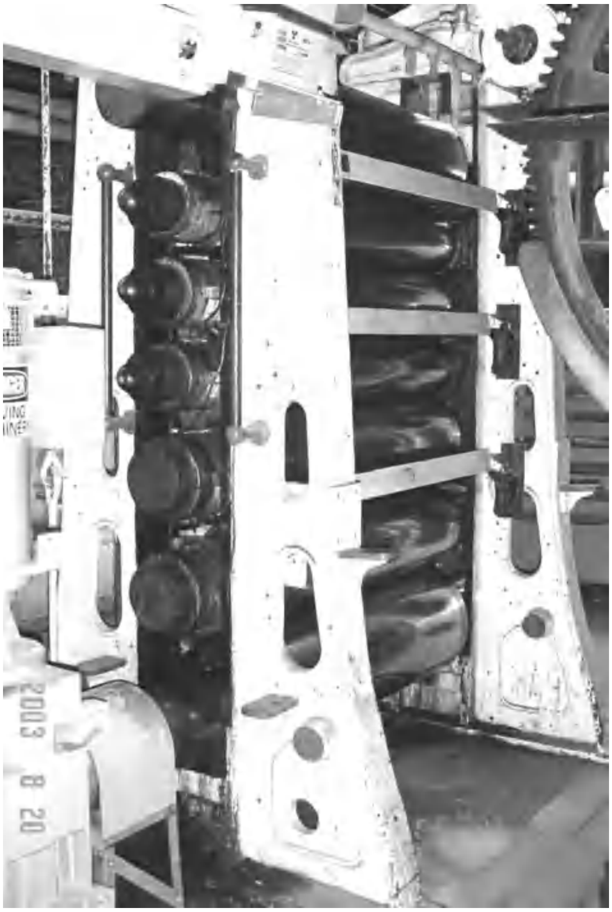

Figure 20 Calender of the pilot papermachine at SUNY College of Environmental Science and Forestry. The sheet passes through multiple nips to smooth the surface of the sheet.

the sheet and can correct some of the irregularities in the sheet. The effect of calendering on the sheet depends on a number of variables, including the sheet moisture, the type of coating applied at the size press, the calender stack loading, temperature, and number of nips.

Reel

The final step of the paper machine is to collect the paper that is produced on a reel (**Figure 4**, item 800). From here, the paper is rewound into smaller rolls needed for shipping or further processing in the finishing and converting operation. The type and amount of processing done after the reel depend on the grade of the paper and the customer specifications.

Paper Grades

G J F Ring, University of Wisconsin–Stevens Point, Stevens Point, WI, USA

Introduction

Paper is a sheet of dried cellulosic fibers and noncellulosic components formed from an aqueous suspension on a fine mesh screen. The ideal forming process deposits fibers on the screen in randomly oriented layers with a uniform mass distribution. Paper can make an enormous number of useful products. Approximately 2000 years ago, the Chinese invented paper as an inexpensive writing material. Because paper was also lightweight, flexible, and opaque, it became the material of choice for letters, manuscripts, and books, and it eventually replaced such writing materials as papyrus, parchment, and textiles. Paper later evolved to serve many other uses by changing the initial papermaking stock formulation, such as varying the type of fibers and additives, their relative proportion, and the total amount of these ingredients.

The term 'grade' signifies the manner in which one type of paper differs from another. Different papers can have different uses, appearances, qualities, and components. For example, paper can make books or boxes. Paper can be white or brown, smooth or rough, thin or thick, light or heavy. Virtually any plant can make paper, and virtually any noncellulosic material can be added to make specialty papers. Furthermore, different manufacturing processes can produce different grades of paper. This article will explore three typical categories of paper grades: printing, writing, and specialty grades.

Grade-Determining Paper Properties

Physical and strength properties of paper are important determiners of many paper grades. These properties include: grammage, caliper, density, strength, smoothness, porosity, lignin content, and pulp type. These properties are interrelated, and this section will describe the nature of this interrelationship and the fact that different stock formulations and production techniques can yield the same paper properties. For instance, uncoated supercalendered paper can successfully substitute for lightweight coated paper as long as the key material properties are identical.

A sheet of paper has dimensions of width and length dictated by its use. In general, the length is longer than the width. A common typewriter sheet size in North America is 8.5 inches × 11 inches (215.9 mm × 279.4 mm), while the equivalent size in Europe is ISO A4 (210 mm × 297 mm). The weight of a sheet determines the most basic physical measurement of paper: grammage or basis weight. Grammage is the ratio of sheet weight to area, and has units of grams per square meter ($g\,m^{-2}$). Basis weight is essentially the same measurement but uses English or United States Customary System (USCS) units. Basis weight is the weight in pounds of a ream or 500 sheets cut to a size specified by its ultimate use. A ream is an awkward and confusing measurement since the total area defined is different for many types of paper. Reporting basis weight in pounds per ream area (for example 34 pounds per 1000 square feet) can reduce potential confusion.

When all else is constant, changing the grammage of paper results in a change in thickness or caliper. Thicker paper will have correspondingly greater strength, bending stiffness and opaqueness. Paper having a grammage greater than 150 $g\,m^{-2}$ is usually termed paperboard. In the English system of units, paperboard is any sheet thicker than 12 points (1 point = 1 mil = 0.001 inch).

When caliper is held constant, changing the grammage of paper results in a denser sheet. Increasing density also results in increasing sheet strength with an accompanying loss in air volume. Sheet densification in papermaking occurs primarily through pulp refining, wet pressing, and calendering. Refining of pulp mechanically releases cellulose–cellulose hydrogen bonds inside the fiber walls by creating cellulose–water hydrogen bonds as water is drawn into the cell wall material. The net effect is a swollen fiber with a network of water-filled capillaries that exert considerable pressure inside the sheet during drying. The resulting surface tension pulls cellulose structures together both within and between fibers eliminating air spaces. As water in the capillary evaporates, the dimensions of the capillary decrease producing increasing surface tensions until the capillary disappears and the cellulose surfaces bond. Wet pressing enhances this bonding effect by mechanically reducing pore size before the dryer section thus increasing the average capillary pressure during drying. Calendering after drying collapses compressible air pores in the dry sheet without the same degree of hydrogen bonding and thus does not produce the same strength-enhancing effect. Calendered papers are smoother because of the reduced size of the surface pores. Calendered paper when compared to uncalendered paper at the same thickness will have a higher grammage or basis weight due to the increased density.

Paper has a surprisingly large percentage of air volume. Bulky groundwood paper has 63% air volume, while dense glassine (pergamyn) has only 13%. It is not surprising that glassine is the strongest class of paper since the underlying reason for the strength is maximally hydrogen-bonded cellulose. However, glassine is semitransparent and does not make good printing and writing paper. Transparency or its opposite, opacity, relates to the volume of air in paper. More precisely, opacity relates to the distribution of numerous small air pores with a large total surface area. Surprisingly, cellulose is a clear, transparent material, while paper composed of pure cellulose is a semiopaque white material. The appearance of whiteness comes from the visual effect of light scattering from the pore surfaces. This is identical to the visual appearance of either table salt or sugar: both appear white until microscopic examination reveals numerous clear crystals. Thus, paper is a matrix of transparent cellulose with a distribution of light-scattering pores.

For pure cellulose paper, increased opacity means a larger quantity of light scattered from the surfaces of numerous small pores. Correspondingly, increasing pore volume decreases the volume of cellulose thus reducing sheet strength. To produce equally strong yet more opaque papers, papermakers use inorganic fillers such as clays and calcium carbonates to increase the available light-scattering surface area inside the pores without sacrificing the volume and density of cellulose required for strength.

Pulp fibers play an important role in the structure of the paper sheet. The primary source of papermaking pulp fibers comes from wood because of its superior technical and economical factors when compared to other sources of plant fiber. Wood provides both short, fine fibers from hardwoods and long, coarse fibers from softwoods. Furthermore, wood fibers have lignin interpenetrating the cellulose material producing a controlled absorption of water. Different pulping methods yield different amounts of lignin. Chemical pulping has the least amount of lignin while mechanical pulping has the most. Lignin-free chemical pulps are pure pulps, free of biological contaminants, with quality high enough for food applications. Chemical pulps also have the highest absorption capacity.

Unrefined softwood chemical pulps (such as softwood kraft) by themselves do not make strong fine paper. These fibers floc excessively and produce bad formation with rough surfaces, high sheet porosity, and low sheet strength. Refining will increase sheet strength, reduce porosity, and reduce surface roughness, but only to a degree. Shorter, finer hardwood fibers are required to provide paper with superior properties. In paper, softwood fibers are the reinforcing elements producing adequate strength, while hardwood fibers fill in the spaces between the larger softwood fibers producing high-opacity, smooth paper.

Mechanical pulps with higher lignin contents produce inexpensive paper that has limited permanence. Lignin restricts the amount of fiber-to-fiber hydrogen bonding that can develop in the paper machine's dryer section. For this reason, mechanical pulps produce bulkier paper that has lower strength potential than refined chemical pulps. However, mechanical pulp produces paper that has greater porosity and opacity because of the greater number of pores left after drying. Smoothness is also a feature of mechanical pulps that results from the mechanical fracturing of wood yielding a large number of fines. These papers yield excellent surfaces for printing.

Lignin gives paper a yellow–brown color. Brightness is an optical test that measures the percentage of blue light reflected from the surface of paper. Brightness is sensitive to the presence of lignin in paper because the yellow color of lignin will absorb blue light. Chemical pulps tend to have dark brown colors due to the chemical modification of lignin even though the quantity of lignin may be very low when compared to brighter mechanical pulps. Bleaching of both mechanical pulps and chemical pulps is performed to increase brightness and improve the overall whiteness of paper.

Printing and Writing Grades

Printing and writing grades represent about 30% of the paper consumed in the world. The number of printing and writing grades is large and increasing due to both customer and technological demands. In general, where quality requirements are secondary to price mechanical pulps are used. Chemical pulps are used when higher quality is desirable and higher prices can be justified. Many grades are also coated and calendered to improve surface smoothness for higher printability. In general, printability can be defined as the combination of paper properties that result in a good printed image. Printability is a complex property related to the optical and strength properties of paper. It is also related to the manner in which ink chemically and physically interacts with the material substances of the paper. Furthermore, all printing grades have a high 'runnability' requirement, which refers to the efficiency with which the paper can run through the printing presses. Runnability is related to the strength properties of the paper sheet.

Uncoated Mechanical Grades

Newsprint is the grade used for the publication of newspapers, advertising supplements, magazines, telephone directories, and other similar publications. This type comprises uncoated papers with inorganic filler less than 8%, but may receive special calendering. Standard newsprint can range in grammage from 40–49 $g\,m^{-2}$ with a nominal caliper of 85 μm (3.3 mil or points). Lightweight newsprint may have a grammage as low as 28 $g\,m^{-2}$. The mechanical pulp used in this grade includes groundwood (SGW or GWD), pressurized groundwood (PGW), thermomechanical (TMP), and chemithermomechanical (CTMP). Recycled fiber (RCF) content may also be high depending upon region. Many manufacturers will add up to 30% chemical softwood pulp to ensure good runnability in printing presses. Newsprint needs to have good formation with a smooth, bright surface and be adequately thick for good opacity to avoid ink showthrough. Color printing in modern newspapers has necessitated one-stage chemical bleaching to improve brightness. Special grades such as those used for telephone directories may have dyes added to change the color of the sheet. The cut sheet size for newsprint grades is 24 inches × 36 inches (610 mm × 914 mm) giving a ream area of 3000 square feet (279 m^2).

Supercalendered (SC) papers are uncoated papers that have been supercalendered to achieve a high-gloss/nonglare finish and are used in magazines, catalogs, and other applications using rotogravure or offset printing. The amount of gloss is dependent upon the furnish ingredients. Filler content in these grades can reach as high as 35%. Fillers used include kaolin clay, talc, and calcium carbonate. Grammage can range from 39 to 80 $g\,m^{-2}$, but a range of 52–60 $g\,m^{-2}$ is typical. Furnish composition is 70–90% mechanical and 10–30% chemical pulp. Groundwood, pressurized groundwood, and thermomechanical pulps are the typical mechanical pulps used. Less premium grades of supercalendered paper have higher groundwood percentages and lower chemical pulp percentages. Recycled pulp may replace a portion of the mechanical pulp in these lower grades. Because these papers have exceptional brightness (68–70%), opacity (90–91%), smoothness, and strength they compete well with lightweight coated papers.

Coated Mechanical Grades

Coated mechanical grades are printing papers used for the production of magazines, catalogs, advertising flyers, and other printed materials that require high-quality four-color printing but still have a throwaway quality. The coating substance consists by weight: 80–95% pigment, 5–20% adhesive binder, and less than 2% miscellaneous additives that control the properties of the coating during and after application. Coating weights from 5 to 25 $g\,m^{-2}$ per side are applied with a thickness of 5–25 μm. Coating pigments may include: clay, calcium carbonate, titanium dioxide, aluminum hydroxide, barium sulfate, silicon dioxide, talc, zinc oxide, and plastic pigments. Sheet surface quality and production speed mandate the coating techniques used. Typical coating techniques include roll applicators with blade, rod, or air jet metering to control thickness.

Table 1 American Forest & Paper Association coated grades classification courtesy of the AF and PA

Quality	*Brightness*
Number 1	85.0–87.9
Number 2	83.0–84.9
Number 3	79.0–82.9
Number 4	73.0–78.9
Number 5	≤72.9

Coated papers are categorized primarily by brightness in the classification of the Technical Association of the Pulp and Paper Industry (TAPPI). **Table 1** lists the six American Forest & Paper Association (AF&PA) quality categories. Coated mechanical grades contain 50–70% mechanical pulp (GWD, PGW, TMP, or CTMP), and 30–50% chemical pulp. With 4–10% filler pigment content, these papers may have 24–36% total pigment content.

Coated mechanical grades are grouped into three main grammage classes: lightweight (LCW), medium weight (MWC), and high weight (HWC). LCW paper has a grammage range of 35–80 $g\,m^{-2}$, with a coating weight range 5–12 $g\,m^{-2}$ per side. MWC paper has a grammage range 70–130 $g\,m^{-2}$, with a coating weight range 12–25 $g\,m^{-2}$ per side. HWC paper has a grammage range 100–135 $g\,m^{-2}$ and may be double or triple coated. HWC are used in higher-quality publications and advertising. Other special grades exist such as ultralightweight coated (ULWC), machine finished coated (matte surface), and film coated offset (FCO). The cut sheet size for mechanical coated grades is 25 inches × 38 inches (635 mm × 965 mm) giving a ream area of 3300 square feet (306 m^2).

Uncoated Fine Printing Grades

Fine paper furnishes should have less than 10% mechanical pulp. Blends of chemical hardwood and softwood pulp with up to 25% filler are used. Papermakers sometimes apply the term ‘free sheet’ or the especially confusing term ‘wood free sheet’ to these grades to denote the absence of mechanical pulp, which gives the paper an archival quality. Alkaline or neutral papermaking conditions further enhance the permanence of these papers. High percentages of hardwood are necessary to achieve good formation in the paper, while fillers, such as calcium carbonate, are necessary for good opacity. On-machine calendering and soft-nip calendering provide surface smoothness. Size pressing may also enhance surface smoothness.

Another term for uncoated fine printing paper is uncoated offset paper used for book publishing, copy paper, and electronic printing. The important properties for offset papers are good internal bonding, high surface strength, dimensional stability, lack of curl, and low linting potential. Offset paper is surfaced sized with starch at 0.5–2 $g\,m^{-2}$ per side. The grammage range is from 32 to 300 $g\,m^{-2}$. The cut sheet size is 25 inches × 38 inches (635 mm × 965 mm) giving a ream area of 3300 square feet (306 m^2).

Uncoated book paper has a high requirement for appearance and printability. The brightness requirement is usually high. Color may run from blue–white to a natural yellow shade but must not change for the entire production run. Color may have to be consistent over several production runs so that different book printings will appear identical. Common surface finishes or textures are antique, eggshell, machine, English, and supercalendered. High opacity is crucial with low grammage sheets (i.e., $<75\,g\,m^{-2}$). Usually low gloss level is specified. High-quality book paper is known as text paper.

Bible paper is an example of a very low basis weight uncoated book paper (20–45 $g\,m^{-2}$). Because of its low weight, bible paper must be strong for good printability, but more importantly, it must be opaque. Highly refined chemical pulp is used to give excellent strength and high loadings of calcium carbonate are required for opacity. Frequently, non-wood pulps such as cotton, flax straw, and linen are used to provide superior strength.

Writing papers are a wide range of quality papers designed for pen and ink, typewriters, and personal printing uses. Some writing papers have well-identified brand names and watermarks. These papers may have very distinctive textures and colors. Many different types of pulps are used in this category for aesthetic reasons, and they may be made to simulate handmade papers. Tablet papers are part of this grouping. In general, they are hard sized for low-viscosity pen inks. The grammage range is from 48 to 90 $g\,m^{-2}$. The cut sheet size is 17 inches × 22 inches (431.8 mm × 558.8 mm) giving a ream area of 1300 square feet (120.7 m^2). Bond is a durable writing paper intended for stationery, legal documents, and other archival uses. Bond paper is manufactured from non-wood fibers such as cotton to increase its strength, durability, and permanence. Bond paper requires excellent printability. Onionskin paper is a lightweight (26–37 $g\,m^{-2}$) bond paper that has exceptionally low opacity and is used where low bulk is necessary. Other similar bond-type writing papers include: parchment, vellum, wedding, and ledger.

An important area for uncoated fine paper is copy paper and digital printing papers. These papers require good brightness (80–96%) and opacity, and must resist curling and cockling when subjected to heat from thermo-type printers. They must also be well sized to resist ink wicking in inkjet-type printers. Grammage range is 70–90 $g\,m^{-2}$.

Coated Fine Printing Grades

Coated fine paper grades are required for demanding printing applications. Products include magazines, books, and commercial printing. Grammage range is 55–170 $g\,m^{-2}$. General categories of coated fine papers include: low coat weight (55–135 $g\,m^{-2}$) with a total pigment content of 20–35%, standard coated (90–170 $g\,m^{-2}$) with a total pigment content of 35–45%, and art paper (100–230 $g\,m^{-2}$). Art paper has a highly finished and smooth surface with a coating weight of 20–40 $g\,m^{-2}$ per side or greater.

Specialty Grades

Specialty grade papers fit into a niche market where their enhanced value compensates for their low production volumes. All paper products begin as specialty grades until their production volumes make them commodity grades. Paper is extremely versatile and the number of paper products that fit into a specialty-grade category is prodigious making it difficult to completely describe the wide range of existing products. Paper's versatility is derived from the manner in which light, liquids, and air interact with it. Paper is also versatile because it is strong, yet light and flexible.

Paper's ability to carry an image led to its widespread use as a printing and writing material. However, the image carried need not be informational. Wallpaper is an example of this use. In practice, it is easier to create an image on paper using printing technologies and then apply the paper to surfaces that cannot be printed. Wallpaper is a decorative use of paper. High density laminates used for counter tops are another example of the decorative use of paper. Much like wallpaper, a sheet of paper with a color, pattern, or image is used in conjunction with other paper sheets that are saturated in resin polymers to form a waterproof veneer material that forms a very durable working surface. This technology is frequently used at lower densities in furniture-making to produce artificial woodgrain surfaces on top of compressed chipboard. Wallpaper is also an example of the use of paper as a carrier substrate. A carrier substrate can be defined as the employment of paper in a secondary role to assist the application of the primary product. In the case of wallpaper, the primary product is the decorative color, pattern, or image. It should also be mentioned that the backside of the wallpaper is coated with an adhesive glue to adhere the paper to the wall. Thus, the wallpaper acts not only as a carrier for the image, but as a carrier for the adhesive.

Many other materials can be carried on or in paper. Moist paper towels for hygienic purposes, household-cleaning tissues, and polish-saturated wipes are examples. It is also possible to imbed flower seeds in rolls of paper for planting purposes. Litmus paper is an example where paper carries chemicals for use in measuring pH. Medical test papers such as those used to determine blood sugar levels in urine are an extension of this principle.

An interesting use of paper as a carrier substrate is the manufacture of automobile brake pads. In this grade, paper is formed with a high loading of abrasive inorganic material and then saturated with phenolic resin. The sheet is glued to a metal backing and cured to form the brake pad surface that will provide the frictional forces to stop a moving automobile. A related range of products, where the abrasive is applied to the surface of the sheet rather than through the bulk, are sandpaper, finishing paper, and the base paper for grinder belts. Photographic paper carries the emulsion that forms a photograph when developed (before the acceptance of paper as the ideal carrier material, glass and metal plates were used). Release paper used as backing for self-adhesive labels is still another example. In many instances, the labels themselves are made of paper.

Because the porosity of paper can be controlled to a high degree by the selection of fiber type, additive, and processing, using paper as a filter material represents an important specialty grade sector. Paper filters are used to protect a wide range of automotive equipment as well as air handling, water purification, and electronic devices. Relative to the cost of the protected device, the paper filter is lowcost but can be sold for a premium. Coffee filters and tea bags are examples of these types of papers used daily by many people. Tea bags are made from a mixture of long banana leafstock (abaca) and synthetic fibers. The very open and thin sheet that is formed effectively filters the tea leaves from leaving the bag. It should be noted that air, water, and oil can all be filtered through paper because of the large quantity of surface area that provides ample surface free energy to adsorb and remove contaminants from the filtered fluid. Another home use for paper filters is the vacuum cleaner bag.

Food packaging at the wholesale and retail levels requires specialty grades. Cleanliness is very important to prevent tainting and spoilage. Recycled pulp, which may have significant contaminants, is not permitted to contact food. Generally, only chemical pulps are used. Sometimes the resulting paper is treated with fungicide to prevent molds as in fruit wrapping papers. Paper that contacts food often needs to be greaseproof. This property is provided by high density, low porosity paper such as glassine. Low opacity papers are used to wrap breads and bakery items to allow visual inspection of the product.

Many food products such as sugar and flour are packaged in bags made of sack kraft paper. These sacks need to be strong and resist rupture during handling. Sack paper also needs to be porous to permit air escape during rapid filling. Paper manufacturers will microcrepe sack kraft to increase elongation and enhance toughness. Square-bottomed kraft paper sacks are used as grocery bags. These bags are popular with consumers because they are recyclable. These bags need to have a high tensile strength to avoid rupture when filled with purchased items. A recent development to improve handling is the introduction of glued handles made of the same kraft paper.

Cigarette papers are required to be thin (16–24 $g\,m^{-2}$), strong, and porous. They are made from various textile fibers to ensure a white ash after burning. To achieve high opacities these papers are highly filled with calcium carbonate. Currency papers are also made from textile fibers for durability, but currency papers are also required to have high printability. Currency papers and related security papers must be refined enough to produce a good watermark. Many other security features are also incorporated to provide unique identification features.

Paperboard Grades

G J F Ring, University of Wisconsin–Stevens Point, Stevens Point, WI, USA

Introduction

Paperboard is a heavyweight paper that has a grammage or basis weight generally greater than 150 g m^{-2} and is thicker than 300 μm. The additional thickness results in a stiffer sheet that is ideal for boxes and containers providing protection for saleable products during transportation, handling, and storage. Paperboard grades include cartonboards, containerboards, and specialty boards, and are used in either food or non-food applications. The English units for paperboard are given in pounds per 1000 square feet (lb/1000 ft^2) and the thickness is measured in points or mils (thousands of an inch).

A box is a rectangular container with or without a top designed to transport and store a variety of goods and products in either liquid or solid form. A box must be strong enough to hold its contents not only during transportation and storage but also during the packaging operation. Because boxes are frequently stored in stacks, compression resistance in their vertical sides is required to avoid bulging and cracking that would result in loss or damage to the product contained within.

Boxes manufactured from paperboard are made to resist compressive forces by using stiff pulp fibers formed into thick sheets. Paperboard meeting these two requirements will have high levels of bending stiffness. Although the stiffness requirement for the pulp fiber is important, the greatest factor affecting bending stiffness is sheet thickness or caliper. Relatively small changes in thickness will result in large changes in bending stiffness since the effect of sheet thickness on stiffness is cubic rather than linear. Pulp selection for greater fiber stiffness leads papermakers to choose naturally thicker fibers such as softwood or hardwoods with noncollapsible, round cross-sections. High yield pulping processes such as thermomechanical pulp (TMP) or semichemical that produce pulp with high percentages of lignin are also desirable for paperboard because of their inherently stiffer fibers. High yield pulps are very desirable for the manufacture of paperboard because the fiber is not only stiff but produces bulky sheets that enhance bending stiffness through both fiber stiffness and sheet thickness. For these two reasons, recycled fiber is also used to a large degree in paperboard manufacture.

Manufacturing Multilayer Paperboard

The same basic paper machines used to produce writing and printing paper are also used to form paperboard. However, modern paper machines are limited in their ability to produce a single-layer paper sheet with a grammage above 150 g m^{-2}. There are a number of reasons for this limitation. Primarily, thicker single-layer sheets are more difficult to dewater requiring excessive reductions in machine speed. Furthermore, the increased drainage forces applied to thicker sheets in the forming section would cause greater fines removal from the bottom of the sheet resulting in a rougher surface. The topside of a very thick sheet would also be adversely affected since paper is formed on fourdrinier machines layer by layer from the wire side up, which would allow extra time for the fibers in the top layer to flock and produce a ‘hill and valley’ appearance. The combination of these two effects would produce an unacceptably two-sided product.

Manufacturing multilayered paperboard from separately formed sheets provides a solution to the above-mentioned problems. The forming section of paperboard machines are composed of two, three, or even four forming sections that bring individual sheets together at the wet press. Paperboard machines are for this reason large and complex having heights that are two to three times greater than single-former machines. Any one of the former sections in a multilayer machine can be either a traditional fourdrinier or a modified fourdrinier equipped with a top-wire unit for additional dewatering capacity. The use of different furnishes in each former produces a final sheet that is engineered for specific stiffness and smoothness requirements.

Although initially forming two to three separately formed sheets of paper, a multilayer machine forms a single sheet of paperboard when the individual sheets of paper are combined together in the wet press. The individual single-layered sheets prior to the wet press are 'vacuum dewatered' with a typical consistency of 20% (80% moisture) and are simply assemblages of fibers held together by capillary forces exerted by the continuous matrix of water surrounding the fibers. When the sheet continues it progress through the wet press and the dryers, this continuous matrix of water is decreased and the fibers are progressively drawn together through surface tension. Eventually, at the end of the drying process with a final moisture content of 4–8%, the surface tension forces between individual fibers will produce pressures sufficiently high enough to form fiber-to-fiber hydrogen bonds resulting in a mechanically strong sheet. During multilayer forming, a single sheet of paperboard is formed from the individual sheets of paper by merging the water matrices of each sheet into a single, hydraulically connected matrix in the wet press. The net result is that the multilayer sheet continues through the wet press and dryer section forming fiber-to-fiber bonds inside layers and between layers as if they were initially formed together. Theoretically, the fiber-to-fiber bonding between separately formed layers will be identical to fiber-to-fiber bonding within a single layer. Differences in interlayer bonding strength (measured by z-direction strength tests) will be found when the individual sheets are wet pressed at moisture contents lower than what is necessary to form a hydraulically connected matrix. (z-direction strength is the maximum tensile force per unit area which a paper or paperboard can withstand when applied perpendicularly to the plane of the test sample.)

The advantage of manufacturing a multilayer sheet is that key paper properties can be engineered into the paperboard that would not be obtainable by single-layer forming. Special top layers can be incorporated that are white and smooth, therefore, having excellent printing properties. Middle layers can be used that are bulky and thus inherently thicker producing the stiffest possible board. These middle layers can also contain recycle fibers or pulp fibers of lower quality that can be covered or masked by higher quality top and/or bottom layers.

Cartonboard Grades

Cartonboard produces consumer product packaging for food and retail items. The market for these grades is large and product development is great due to dynamic marketplace forces. Folding boxboard (FBB), white lined chipboard (WLC), solid bleached sulfate board (SBS), solid unbleached sulfate board (SUS), and liquid packaging board (LPB) are major types of cartonboard grades. Many of these grades will be pigment coated to produce a highly printable top surface. These paperboards need to be strong and stiff to form the walls of a carton. Because cartons are stacked during storage, compression resistance is also important. In particular, cross-machine direction (CD) stiffness is required to prevent carton bulging since the carton is manufactured with the CD parallel to its height. High-speed converting and mechanized packaging lines mandate excellent runnability; therefore, resistance to curl is also a necessity. Finally, folding these paperboards into containers must occur without cracking, which requires not only good strength, but also good stretch. The ream area for paperboard grades is 1000 ft^2.

Folded Boxboard

Folding boxboard grades are used to make packages for numerous products including: dry foods, liquid foods, frozen foods, confectionaries, cosmetics, detergents, and numerous other items. The grammage range for folding boxboard is 160–450 $g\,m^{-2}$. Folding boxboard is a multilayer sheet having three to four layers. The top and bottom layers are frequently made of bleached chemical pulp. The middle layers consist of either mechanical pulp or recycled fiber for stiffness enhancing bulk. The top layer is usually surface sized for good picking resistance in printing. Because the board must have a smooth top surface for good printability, yet have adequate thickness for good bending stiffness, smoothness is obtained through a combination of limited calendaring and coating. It is important for folding boxboard grades to also have good folding and scoring properties.

White Lined Chipboard

White lined chipboard (grammage range of 200–450 $g\,m^{-2}$) uses recycled fiber in its middle layers, and has many similar applications as folding boxboard except for certain food packaging applications where contaminants in the recycled pulp might spoil or taint the food. WLC grades may sometimes have four sheet layers. The fourth layer is actually an additional top layer used to maximize use of less bright recycled pulps, therefore minimizing the use of expensive highly bleached top layers. The top layer is frequently coated to increase printability and an optional bottom coating may be found.

Solid Bleached Sulfate Board

Solid bleached sulfate board is very similar to folding boxboard and white lined chipboard except that it is a single layer sheet (hence the term 'solid') made of virgin bleached kraft pulp. Hardwood is the predominant furnish but softwood is also used. Contamination and tainting of food and cigarette products is the primary reason for using virgin kraft pulp. SBS board may be coated on one or both sides with the topside receiving as many as three layers of coating.

Solid Unbleached Sulfate Board

Solid unbleached sulfate board is a heavier multilayer board (grammage $<500\,\mathrm{g\,m^{-2}}$) that uses unbleached pulps where extra board strength is required. For this reason, SUS boards are used in beverage and other packages intended specifically for carrying consumer items. Because SUS is not intended to come directly in contact with food, recycled pulps are frequently used in the middle layers. However, the high strength requirements (which includes tear strength) necessitate using kraft pulps in both the top and bottom layers. Sheet strength and surface smoothness are augmented through the application of surface size. Packaging applications for SUS require printing on the topside, which is accomplished by coating the topside two or three times to prevent 'show through' of the darker unbleached furnish. Where it is important to have high quality printing, high-whiteness pigments such as titanium dioxide (TiO_2) are used.

Liquid Packaging Board

Liquid packaging board is a multilayer board having a polyethylene-coated liquid barrier in conjunction with single or multiple layers of virgin chemical pulp. Milk, juice containers, microwave, and ovenable trays are typical uses for this grade. Polyethylene provides not only a liquid barrier, but also the ability to heat seal during container manufacture. The polyethylene is coated on only one side when a moisture vapor barrier is required for long shelf-life, but on both sides for liquid packaging such as milk. Aseptic packaging uses liquid packaging boards that have high cleanliness and purity standards.

Manufacturing Cartonboard Boxes

Cartonboard sheets or reels are converted into boxes through a process that involves cutting and creasing and then gluing the box into the final carton. Additional steps are frequently taken to produce a visually attractive box that may include printing, varnishing, film laminating, foil blocking, and embossing. Because cartonboard boxes are often an important part of the merchandizing of the contained product, rotogravure printing is necessary to provide the highest possible printed quality. Where self-advertising on store shelves is not critical, offset or flexography printing is used instead, or the box may be unprinted.

Printed boxes, unlike magazines and books, experience considerable abrasion during their use as a product package, which requires surface protection through either varnishing or plastic film lamination. Varnishing is accomplished through coating during the printing process. The varnishes of choice are usually aqueous dispersions that are cured on-line with ultraviolet light. Varnishing provides a gloss to the surface of the box further enhancing its attractiveness. When a more durable or glossier surface is required, off-line film lamination is also used.

Quality printing requires cartonboard grades to have a relatively high brightness from either the pulp or an applied surface coating. Printing also requires high smoothness, which is obtained from coating the sheet and using hardwood furnishes.

Cartonboard boxes are specifically designed for each product and have no standard sizes. Products such as cigarettes, camera film and software are sold in boxes that have unique sizes and designs, which may include intricate product-inspection windows or cutouts. These potentially complex designs are produced by die-cutting a cartonboard sheet in either a flat-bed or a rotary press that has cutting rules in the shape of the unfolded box mounted to a cutting die, which is then applied through the sheet against a counter die. The cutting rules or knives that are attached to the cutting die have compressible rubber gaskets on either side. These rubber gaskets hold the sheet motionless to produce an accurate cut and then expand to cleanly eject the sheet after the cutting compression stroke has taken place. Any cutouts are prevented from accumulating in the cutting die area by keeping them connected to the sheet through small 'nicks' or perforations that are produced with notched cutting rules. Cutouts are then removed in a stripping step that breaks the nicks and collects the waste material.

Die-cutting requires cartonboard sheets to have good strength properties to produce a clean cut. Poor fiber-to-fiber bonding, a function of low sheet strength, will result in fiber linting or dusting. Low-strength sheets are also more subject to tearing after cutting and exhibit poor runnability on converting machines. Moisture content is also important for converting machine runnability. Excessively dry sheets are harder and will wear out the die-cutting rules sooner. Drier sheets will also produce more cutter lint or dust.

Cartonboard sheets must also be creased to form folding boxes. Creasing is a step that occurs simultaneously with die-cutting on flat-bed machines, but after cutting on rotary machines. A folding crease is formed with a creasing rule that has a rounded edge rather than a cutting edge. Creasing rules are attached to the cutting die together with the cutting rules; however, the creasing rules work in conjunction with a creasing channel located directly opposite them on the counter die. A properly working creasing rule will form a sufficiently deep and narrow crease that will allow the cartonboard sheet to precisely fold where intended and produce a sharp attractive box corner. The creasing rule will be pressed against the side of the sheet that is intended to form the inside of the box.

Cartonboard grades that exhibit good creasing properties have good tensile strength and elasticity in order to survive the out-of-plane deformation during creasing. When a box is folded along its crease, the inside portion of the crease will undergo compression while the outside of the crease will undergo tension. Cracking will occur when the elastic limit is reached and the sheet fails in either tension or compression. In general, the compression limit is reached before the tension limit. Cartonboard sheets that resist cracking tend to have multilayered construction that delaminate around the crease with the inside layers buckling rather than undergoing compression failure.

Corrugated Containerboard Grades

Corrugated containerboard boxes are lightweight structures that can transport significant internal weight and withstand buckling and collapsing when multiple container units are stacked on top of each other. Corrugated containerboard boxes are manufactured by gluing a fluted corrugated medium between two strong outer linerboard faces. In this manner, maximum thickness is obtained with minimum weight to ensure high bending stiffness. Corrugated containerboard may also have two or even three corrugated layers sandwiched between alternating layers of linerboard when extra strength and rigidity is required.

Linerboard's primary characteristic is high bending stiffness and is usually produced with two or more plies from high-quality kraft or recycled pulp. To maximize bending stiffness, pulp fibers that will produce the highest tensile strength are placed in the outer or top layer that comprises about 30% of the total sheet. For example, the top layer will have the highest percentage of virgin fiber while the lower base layer will have a higher percentage of recycled pulp. As another example, the top layer may be a kraft pulp cooked to a lower degree of lignin content and refined to a higher degree than the bottom layer. Typically, compression testing such as the edge crush, flat crush, ring crush, and short-span compression is useful in predicting linerboard performance in the final containerboard product. Burst testing, which measures tensile strength in an empirical manner, has also been used to assess linerboard strength, but is now considered inferior to compression testing. Dry strength agents such as starch may be applied at a sizing press to increase linerboard's surface strength, and resin sizing may be applied in the headbox to enhance water resistance and wet strength. Printable top plies are made from bleached chemical pulps (either hardwood or softwood) that are sometimes pigment coated for more demanding printing requirements. The grammage range for linerboard is 125–350 $g\,m^{-2}$. Linerboard made from at least 85% virgin kraft pulp is called 'kraft linerboard.' Linerboard meeting the requirements of Rule 41 of the Consolidated Freight classification in the US is called 'test linerboard,' and meets either a minimum bursting strength or a minimum edge crush strength. Because kraft linerboard easily exceeds either minimum strength criteria, the term 'test linerboard' is usually applied to linerboard containing predominantly recycled pulp. Modern linerboard machines are multi-ply machines using twin-wire/gap-forming technology. Many new machines are being outfitted with the latest in shoe or extended nip wet presses.

Corrugating medium, used as the fluting between two linerboard layers, is a single-layer uncalendered sheet with a grammage range of 112–180 $g\,m^{-2}$. Compression resistance rather than tensile strength is particularly important for corrugated medium, because, as a composite structural material, corrugated containerboard boxes will fail at the box corners in an identical compression mode when either excessive external loads or excessive internal loads are present. In general, failure occurs in either condition because the containerboard is bending outwards and the linerboard on the inside of the bend is compressed to failure. The primary role of the corrugating medium in preventing containerboard failure is to provide adequate separation of the linerboard faces such that the degree of bending is minimized during loading. For this reason, the portion of the flute that spans from one linerboard face to the other must be stiff enough to resist compressive collapse. This particular property can be obtained in relatively low-cost, minimally refined, semichemical pulps where the fibers are naturally stiff due to the presence of lignin. Recycled pulps also having characteristically stiff fibers can be successfully used in this grade. These pulps produce sheets with bad formation and low tensile strengths. Handsheets made from these pulps are specified to be formed at 150 $g\,m^{-2}$ rather than

$60\,g\,m^{-2}$ to compensate for their lack of wet handling strength. Corrugating medium is also produced with a high machine-direction fiber alignment to enhance compression resistance in the direction of fluting.

Manufacturing Corrugated Containerboard

Producing corrugated containerboard requires converting machinery that combines separate rolls of linerboard and medium into a glued structure. The simplest structure is one sheet of linerboard glued to single sheet of corrugated medium and is known as single faced corrugated. Gluing an additional sheet of linerboard to the corrugated side of single face produces a single wall corrugated board. Gluing either two or three single faced corrugations together with a final linerboard face produces a double wall or triple wall corrugated board respectively.

During the production of single face corrugated, linerboard is unrolled and preheated to a temperature of 160–190°C in a unit known as a 'single facer.' In this unit, medium is also unrolled and preheated, but is passed over a corrugating roll to form the flutes or corrugations. During this operation, the medium must be held securely by either pressure or vacuum in the fluting roll to maintain the shape of the flutes. Glue, generally starch, is applied to one side of the flute tips, and then pressed firmly to the underside of the linerboard instantaneously bonding them together. The bond line formed by the glued tips is observable through the linerboard, and is preferably used as the inside surface of corrugated boxes. Single face is flexible, bending easily at the glue lines. As a material by itself, single face is used as a packing material due to its ability to wrap around items such as bottles providing them with excellent crush protection during shipping.

Single wall corrugated boards are produced in a converting machine where the single facer unit is coupled with a 'double facer' or 'double backer' unit. In this unit, the single face material is again preheated and glued to the remaining unbonded flute tips. The prepared single face is then pressed to another preheated linerboard sheet, which produces the rigid containerboard. Less pressure is applied in the double facer than in the single facer to avoid crushing the corrugations. However, because of the reduced pressure the linerboard glued in this manner does not have the same observable glue line as the single face material, and is more suitable for use as the printable outside surface of a containerboard box. Once the single wall board is produced, further heating to set the glue must take place over hot plates in order to convey the board flat through slitters and scorers before being cut into the final board sheet. Converting machines capable of producing double and triple wall container board operate in a similar manner to that just described with the exception that flutes on the corrugation side of a single face board can be glued to the linerboard side of a second single face board to form the final multilayer construction. Final boxes are manufactured using similar die-cutting, creasing, and printing techniques as described above for boxboard.

Tissue Grades

P Parker, Western Michigan University, Kalamazoo, MI, USA

Introduction

'Tissue' is a generic name for a variety of light-weight paper products. In normal use, the word refers to the hygienic or sanitary grades which collectively encompass products commonly known as bath or toilet tissue, facial tissue, napkin, and toweling. Other products in the tissue category include condenser paper, wrapping paper, and tea bags. The focus of this discussion will be on the sanitary grades, which account for the vast bulk of the production of tissue papers; the latter products will be discussed only briefly. In the remainder of this article, the word ‘tissue’ will refer to hygienic grades unless explicitly indicated otherwise.

Tissue use is very much driven by economic development. North America, western Europe, and Japan exhibit very high per capita consumption of tissue, while other regions have per capita consumptions that are small (**Figure 1**).

Growth rate data suggest that the North American market is close to saturation, as tissue growth is about the same as the population growth. Major tissue growth is expected in other regions (**Figure 2**).

Tissue production is dominated by two very large manufacturers (Kimberly-Clark and Georgia-Pacific), two medium-sized manufacturers (Procter & Gamble and SCA) and a host of smaller companies. Consolidation will continue to occur, as the four large companies have about 80% of the market in North America, 50% in western Europe, and 40% or less in other regions.

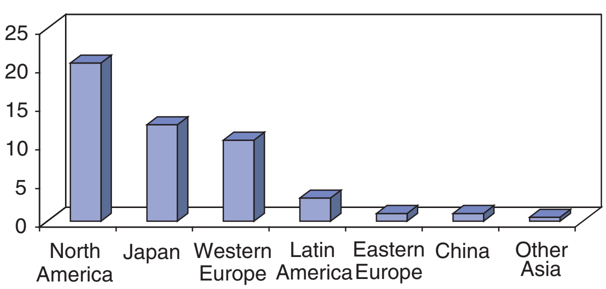

Figure 1 Per capita consumption of tissue products.

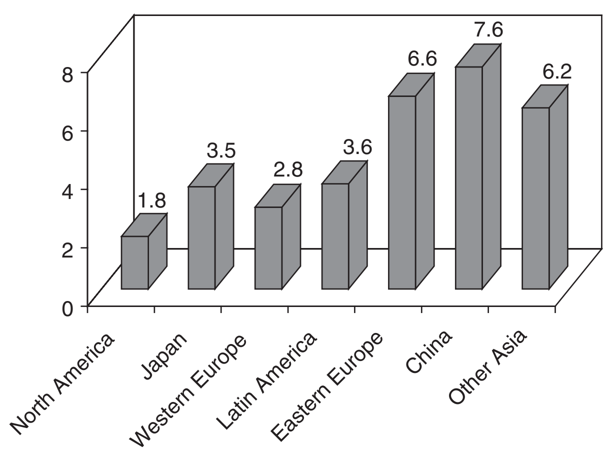

Figure 2 Forecast percentage per capita tissue growth (1994–2005).

In addition to categorization by use, the tissue market is often divided into two large distribution channel categories. Consumer tissue is that destined to the home user and brand-name recognition is critical to marketing success. Unlike most other paper products, manufacturers in the consumer tissue market channel product under their own names and do considerable marketing focused on brand-name recognition. The leading manufacturers (Georgia-Pacific, Kimberly-Clark, and Procter & Gamble) devote considerable resources to developing and protecting their brands (e.g., Brawny from Georgia-Pacific, Kleenex from Kimberly-Clark, or Charmin from Procter & Gamble.) The leading manufacturers, as well as the smaller producers, also supply products for private-label or ‘house’ brands. This latter market is growing substantially, especially in North America. While the consumer market is price-sensitive, product performance is paramount. The market can be segmented by performance/price expectations of the consumer as premium, value, or economy.

The away-from-home (AFH) channel distributes many of the same products as in the consumer channel, as well as some products made specifically for this distribution category. As indicated in the name, this category is for products not used in the home, and includes products distributed to hotels, food-service operations, health care, lodging, office, manufacturing, and institutions. Dispensing systems for product delivery with portion control and labor savings are an important factor. Specialty products in this channel include heavy-duty industrial wipes, heavy-duty napkins, and other specially treated products. This is a major channel for products made from recycled paper, as cost, rather than performance, may be the major selling characteristic. Performance is still important, but business owners who make the selection to service their business judge it. Tissue is generally a necessary cost and not a profit item for AFH.

Performance Characteristics

Performance of tissue products, in either the consumer or AFH segments, is critical. There are three major performance areas – softness, absorbency, and strength – that are common to virtually all tissue products. Visual appearance is an important characteristic, especially in the consumer channel. These four characteristics drive much of the manufacturing process. While the visual appearance can often be manipulated without affecting the other three to a significant extent, there are significant trade-offs in the other properties. Bulk is a key factor in product design as it signals to the user if there is enough product to do the job. Another key point is the bulk or absorbency per unit weight of fiber – getting the job done more efficiently.

Softness

Softness is a quality that is perceived by the user and, to date, has defied quantification. It is a critical property, especially for toilet and facial tissue in the consumer markets. It is becoming a more important characteristic for some toweling and for products in the AFH market where image is important. Softness has been studied extensively by the tissue manufacturers and they have drawn heavily on studies done in the fabric industry. There appear to be two components to softness as perceived by humans. A surface softness refers to the texture felt when the product is rubbed lightly across the skin (or vice versa). This characteristic appears to be related to the frequency, variability, and flexibility of the fiber ends that stick up from the surface of the tissue sheet. All three components are important. If there is no variability, then the user may perceive the product to be flat or smooth, but not soft. Similarly, if the flexibility is too low, then the product is rough. And if the frequency is too low, the product may be perceived as rough, even though the ends that stick up are very flexible. There is extensive work being done in this area, but to date the research work has not yielded quantitative models of human touch.

The other component of softness is bulk softness. This quality is related to the overall bulk and flexibility of the sheet and appears to be related to the tensile strength and modulus, tensile energy absorption (TEA), and thickness of the sheet. 'Hand' or 'drape' are similar terms from the fabric industry and the tissue industry has attempted to modify, with very limited success, test methods from the fabric industry. In general terms, bulk softness increases with the apparent thickness of the sheet and decreases with increasing tensile strength. Thus, manufacturers attempt to increase the thickness, or bulk, of the sheet while simultaneously decreasing the strength. Adding more fibers per unit area (that is, increasing the basis weight) will increase the bulk. Unless other steps are taken, however, this will also increase strength, as well as increasing cost. The goal, then, is to increase the bulk and decrease the strength at constant-basis weight. As fiber becomes more expensive, the goal becomes to reduce the basis weight without affecting other properties – a major challenge in the tissue industry.

Fiber type also plays a role in softness. Hardwood fibers tend to be short, thin, and flexible, contributing to a higher surface softness. Hardwoods also have a high number of fibers per unit weight, which contributes to a more uniform visual appearance. Softwood fibers tend to be long, bulkier, and somewhat less flexible, thus contributing more to the bulk softness component. Recycled fibers tend to be stiff, thus decreasing surface softness. However, their stiffness allows them to make a bulkier sheet, increasing the perception of bulk softness. The actual impact of recycled fibers on the tissue properties will depend upon their original source (e.g., high-yield pulp, bleached chemical pulp).

For the tissue industry, there are no agreed-upon, standardized tests for softness. Tissue manufacturers rely on human panels to measure softness and, while not truly quantitative, such tests do give relative rankings of products. Such tests can support advertising claims, but are not suitable for direct control of the process. A surrogate test that was rapid, accurate, and cheap would allow a tissue producer the ability to improve quality control of the process and lead to a competitive advantage. Such surrogate tests are under development by the major producers and hints of such work can be seen in the patent literature.

Absorbency

Absorbency is the ability of the product to absorb, or imbibe, a fluid. For most tissue products, the fluid of interest is water, and absorbency is normally measured with distilled or tap water. However, some products are required to absorb other fluids. Tampons, for example, must absorb catamenial fluids, while industrial wipes may need to absorb oils. Normal cellulose-based tissue products may need to be specially treated to meet these challenges.

For many products, the rate of absorption is of equal importance to the amount of absorption. The rate of absorption is, in general, related to the size and number of the surface pores. Relatively small pores give a high rate of absorption due to the high surface tension driving forces. Larger pores can hold more liquid. Multi-ply products attempt to deliver an optimal combination of both characteristics. The base paper of each ply can contain small pores to enhance the rate of absorption, while the space between the plies offers volume to hold the imbibed liquid.

Pore size is not directly controllable (or measured) by the tissue-maker. It is a function of the fiber type and how they bond to each other in the papermaking process. In general, low-basis-weight paper will have larger pores due to the larger spacing between the fibers, while higher-basis-weight paper, with more densely packed fibers, will have smaller pores. Increasing the basis weight to increase absorbency also increases cost.

As with softness, there is no standardized test for absorbency. Absorbency rate is usually measured by dipping a vertical strip of the product in water and observing how fast the liquid interface rises up the strip. Another option is to put a drop of water on the product and time the disappearance of the drop. Most tissue products are sufficiently absorbent so that this test is very inaccurate.

Total absorption is usually measured by placing a weighed piece of the product in water, waiting a fixed amount of time, and then extracting and weighing the test piece.

Fiber type and fiber processing are also important for absorbency. Cellulose fibers are hygroscopic and thus absorption of water into the fiber pores and on to the fiber surface are important components of the total absorption process. For most products, the bulk of the absorption is due to the physical spaces between the fibers, not absorption into the fiber pores. Absorption on to and into the fiber are probably significant components of the rate of absorption, but there is little work in this area. Virgin fibers have a much higher rate of absorption than recycled fibers due primarily to the hornification of the recycled fiber during repeated drying. Recycled fibers must be extensively treated, usually by refining, to make their absorption properties similar to that of virgin fibers. Unless recycled fibers are specially treated, products made from them will have relatively low rates of absorption. The total amount of water taken up may be equivalent to that of products made from virgin fibers as the total amount is related to the overall structure of the sheet, but they will require significantly more time to reach this final amount.

Strength

The importance of sheet strength depends upon the product. Bath tissue can be relatively weak, whereas toweling and napkin must be relatively strong. Sheet strength is primarily governed by the fiber-to-fiber bonding characteristics of the sheet. The more bonds that exist, the stronger the sheet. However, as indicated above, increasing the sheet strength generally leads to a stiffer, less soft sheet. The tissue manufacturer must balance the need for strength with the consumer's desire for softness.

Sheet strength is primarily controlled by the hydrogen bonds between the fibers. Fiber entanglement contributes in a minor way to sheet strength. As a result, when the sheet absorbs water, the hydrogen bonds are broken and sheet strength deteriorates rapidly. For bath tissue, this is not a serious problem, as it is generally used in the dry state and water absorption is not a major issue. For toweling and napkin, and facial tissue to a lesser extent, strength while wet is an important, consumer-driven property. Chemicals are added to the sheet during the manufacturing process to improve wet strength. These are normally long-chain polymers that bridge or cross-link between fibers during the drying process. Thus they impart additional dry strength as well as providing wet strength. Because they have significant wet strength, towel and napkin products are difficult to recycle as they will not break apart upon contact with water.

Visual Appearance

The visual appearance of the product, both in its roll form and as individual sheets, is an important marketing tool. This is especially true for the consumer distribution channel, but is playing an increasingly important role in the AFH distribution channel as well. The visual appearance can be affected in a number of ways. Until recently, the primary way was to treat the product during the converting process to impart a distinctive pattern on each sheet. Embossing, passing the sheet through a nip in which the opposing rolls contain a pattern, is a conventional way to impart a pattern on the sheet. This embossing could also be used to increase the bulk and absorbency of the sheet. Recently, manufacturers have developed ways to put patterns directly on the fabric used in the forming and/or drying processes.

Tissue products can also be printed to provide a distinctive visual appearance as well. Since the products are designed to absorb water (and other materials), high-resolution printing is difficult, as the ink tends to spread on the surface and creped tissue is not flat, thus destroying a crisp print pattern. Printed products tend to be slightly higher in price and are used primarily for special occasions.

Manufacture

The forming of a tissue sheet is very similar to that of other paper products. Fiber stock is prepared much like all other paper products. Virgin fiber is lightly refined to increase fibrillation; recycled fiber is more heavily refined to obtain the necessary fiber properties. The stock is cleaned, screened, and diluted to 0.5–1.0% consistency before being deposited on to a forming wire by the headbox. Both Fourdrinier and twin-wire formers are used. Modern machines are generally of the twin-wire type as they permit much higher speeds due to the two-sided drainage of the sheet. One unique modification for tissue manufacture is the crescent-former. This is a twin-wire-type machine, but the bottom 'wire' is not a true wire, but is a felt, similar to that used in dryer sections of other machines. The advantage of the crescent former is that the light-weight sheet can be carried from the headbox to the dryer without transferring the sheet. This is a significant advantage, given the light weight and low strength of tissue sheets. The combination of light-weight sheets, high drainage, and continuous sheet support allow tissue machines to reach high running speeds. Typical light-weight tissue machines will operate in the 5000–6000 ft min^{-1} (25.4–30.5 m s^{-1}) range and it is speculated that tissue machines will approach 8000 ft min^{-1} (40.6 m s^{-1}) in the not too distant future.

While the forming sections of tissue machines are very similar to that of other paper grades, it is in the pressing and drying sections that these machines differ dramatically from the other paper grades. For most tissue grades, there is no press section. One of the goals of the tissue manufacturer is to have a high-bulk, relatively low-strength product, so it is desirable to prevent the sheet consolidation and bonding that occur in pressing. Sheets are conveyed directly from the forming section at 20–45% fiber content, depending upon the forming method, to a drying section.

There are two types of drying systems in use: the Yankee dryer and the through-air dryer (TAD). The Yankee dryer is normally combined with a creping system to impart the desired properties. The TAD can be used alone or in conjunction with some form of Yankee dryer and creping.

Yankee Dryer and Creping

The in-line Yankee creping dryer was first pioneered by the Scott Paper Company in the early part of the twentieth century. Prior to their work, drying and creping were two distinct operations. The Yankee dryer removes moisture from the sheet, while creping breaks bonds and imparts bulk and softness to the sheet.

The Yankee dryer (**Figure 3**) is a large, cast-iron, steam-heated cylinder. Typical diameter is 16 or 18 ft (4.88 or 5.89 m) and the wall thickness is around 2 in. (0.051 m) to contain the pressure of the steam. The cylinder is the full width of the machine, sometimes exceeding 20 ft (6.096 m) in width, so these are massive items of construction. Steam (100–150 psia) is condensed on the inside of the cylinder and hot air (700°F (644 K)) is blown against the surface of the sheet to remove evaporated water as well as provide additional drying energy. The sheet is pressed against the Yankee surface and some water is removed in this light pressing operation. The sheet leaving the press nip is typically about 40% fiber. The sheet is then dried to around 95–98% fiber in the roughly 0.5 s that it takes to travel from this press nip to the crepe blade.

Figure 3 Yankee dryer. From *Pulp and Paper* (1978).

It is imperative that this drying process be as efficient as possible. As the sheet dries, it tends to lose contact with the drying surface, thus decreasing the ability of the Yankee to transfer drying energy to the sheet. To aid in heat transfer, as well as assist the creping operation, a small amount of an adhesive-type material is normally sprayed on to the surface of the Yankee just prior to the sheet nip. Manufacturers, both tissue and supplier companies, devote considerable resources to developing new and improved adhesives. A wide variety of materials have been patented, including polyvinyl alcohol, poly methyl methacrylate, and several types of poly amino amides. Exact formulation and application levels are protected by patents or kept as trade secrets. Application levels are small and the patent literature reveals application rates in the 0.5–1.0 lb (0.25–0.5 kg) of adhesive per ton of fiber.

The dried sheet is then creped off from the Yankee. The crepe blade is a thin steel blade that is pressed against the Yankee dryer and it 'scrapes' the sheet from the dryer. In effect, the sheet, traveling at about 60 miles per hour (26.82 m s^{-1}) impacts a solid-steel wall in the form of the crepe blade. The sheet buckles and fiber–fiber bonds break, imparting both surface softness and bulk to the sheet. This process is not well understood, but micrographs of a creped sheet show a large number of fiber ends, indicating broken bonds. Surface photographs show a large number of 'corrugations' or crepe bars. These run in the cross-machine direction and are up to a half-inch (0.013 m) in length. On a well-creped sheet, there will be 50–100 crepe bars per inch (1970–3940 crepe bars per meter) in the machine direction. While there is no proven theory for crepe bar formation, it is generally believed that the bars result from sheet buckling at the crepe blade. Thus the crepe process can be envisioned as repeated buckling of the sheet as it impacts the crepe blade. These crepe bars impart bulk to the sheet and affect surface softness in at least two ways. They provide some of the variability the sense of touch registers and they also provide hills and valleys for the free fiber ends to stick up and provide a component of surface softness.

Control of the creping process is critical to machine efficiency as well as producing the correct sheet attributes. If the sheet adheres too tightly to the Yankee, then it will not crepe cleanly and there will be holes in the sheet (which is a problem for later converting processes) or the sheet will tear altogether, resulting in machine downtime. If the sheet is not adhered strongly enough, then it will tend to float off the crepe blade and not provide the desired properties. At present, there is no automatic way of determining the quality of the crepe, although there are several laser-based instruments that have been tried. The current control is one of manual operation, with the machine operator judging both the sheet characteristics and the operability of the machine.

The crepe blade also plays an important role in the creping process. The crepe blade is pressed against the Yankee with a small level of force (about 10 lb (44.5 N) force per lineal inch or pli). It is believed that the crepe adhesive provides a very thin coat of organic material on the dryer and that the crepe blade cuts through part of this coating and rides on the remainder of the coating, thus protecting the Yankee surface. Thus, the crepe blade does not actually ride on the metal surface of the dryer. A new crepe blade has a very sharp corner that cuts into this adhesive layer, as shown in **Figure 4a**. As time passes, the corner is worn away and the blade starts to conform to the Yankee surface, as shown in **Figure 4b**. As this corner wears away, the surface contact area increases and the pressure applied drops, as the force pressing the blade to the surface remains constant. At some point, the pressure is insufficient to cut through the adhesive coating and the blade (at a localized point across the width of the machine) no longer crepes the sheet. This leads to holes in the sheet and indicates that the blade must be replaced. Also, as the blade wears, the crepe quality decreases. Changing the blade causes machine downtime, so blade life is a trade-off between machine efficiency and product quality. Typical blade life is in the 4–8-hour range, depending upon product type and product quality demands.

The angle the crepe blade makes with the dryer is an important part of the machine set-up, as it is difficult to adjust this angle. The set-up angle (α in **Figure 5**) is typically between 12 and 22°, resulting in a crepe angle (δ in **Figure 5**) of between 88 and 78°. The face of the crepe blade can also be beveled to adjust the crepe angle. Current belief is that the crepe angle is the critical angle for the process, not the set-up or take-off (θ in **Figure 5**) angles.

Through-Air Drying and Uncreped Sheets

The Yankee dryer requires that the sheet be pressed against the dryer surface to assure good heat transfer for drying. The creping process is difficult to control and requires some downtime to change crepe blades. To overcome these issues and to provide a sheet with improved properties, the through-air-dried process was developed. This has recently led to a version in which the sheet is only through-air-dried (TAD) and is not creped.

The TAD is a large, open-type cylinder which is the full width of the machine. Hot air (400–500°F (477–533 K)) is blown through the sheet to dry it. Air can be blown from either the inside, with the sheet held against the TAD by a wire of some form, or it can be blown from the outside. This leads to two versions of TAD, commonly referred to as inside-out and outside-in. The main advantage of the TAD over the conventional creped Yankee dryer is that most, or all, of the water can be removed from the sheet by pressing the sheet. This leads to a bulkier sheet, as there is no press-related sheet consolidation.

In the early version of the TAD, the sheet was not completely dried on the TAD. Rather, it was taken to some intermediate dryness (around 60–70% solids) and drying was finished on a small, conventional-type Yankee dryer. The pressing necessary to adhere the sheet to the Yankee in this configuration was not damaging as the sheet was dry enough that the pressing did not consolidate the sheet. It did require a more complex machine, however, as now two drying cylinders (TAD and Yankee) were required and there was a need to transfer the sheet from the TAD to the Yankee. In addition to the drying, the Yankee was also needed to crepe the sheet to provide the desired surface characteristics.

A significant advance for the TAD process was the development of specialized forming and TAD fabrics. Conventional forming and early TAD fabrics were quite smooth, as the papermaking fabrics were designed to minimize the impression of the fabric design in the sheet itself. With TAD, it became possible, and even desirable, to leave some fabric impression in the sheet. These impressions can replace the crepe bars imparted by creping and contribute to desired bulk and surface characteristics. Operating the TAD at a slower speed than the forming section, called negative draw, can impart increased fabric impression in the sheet giving a surface with a visual texture similar to creping. This is commonly called fabric crepe and the negative draw may range from 3 to 15%. With the proper TAD fabric design, it is possible to eliminate the Yankee dryer altogether and impart surface characteristics with the fabric pattern, making full use of fabric crepe. This type of tissue making is called uncreped TAD.

While the uncreped TAD process eliminates the crepe dryer and the drawbacks associated with creping, it is not without some disadvantages. As currently practiced, it requires several fabrics and usually two TAD cylinders. This means that there are several sheet transfers, which increase the risk of sheet breakage. The additional wires are also an additional operating cost. The actual design and operation of an uncreped TAD machine is a closely held trade secret, as well as being protected by multiple patents.

Coating

M K Joyce, Western Michigan University, Kalamazoo, MI, USA

Introduction

Coatings are applied to paper and paperboard for two essential reasons: to create a uniform surface for printing or to impart certain functional properties to the surface such as, grease resistance, water resistance, etc. Paper contains a series of holes formed by the overlaying of the fibers during the papermaking process. Coatings are applied to fill these holes and smooth the surface (**Figure 1**). Smoothing the surface enables the image carrier of the printing process to make more intimate contact with the surface, which results in better transfer of the image to the surface, hence better image quality. Coatings also provide a more uniformly porous layer for receiving the inks. Paper suppliers can use the coatings as a means to provide a product that has the desired optical and ink receptive properties needed by the printer for a given print job. Since the characteristics of the inks, means of image transfer, and ink setting and drying mechanisms change from printing process to printing process, the characteristics of the coatings must also change. Coated paper and paperboard manufacturers must therefore first understand the requirements of the coating for each of the printing process, before developing a coating formulation. A review of the four major printing processes (offset, flexographic, rotogravure, and nonimpact) is given elsewhere (*see* **Packaging, Recycling and Printing**: Printing).

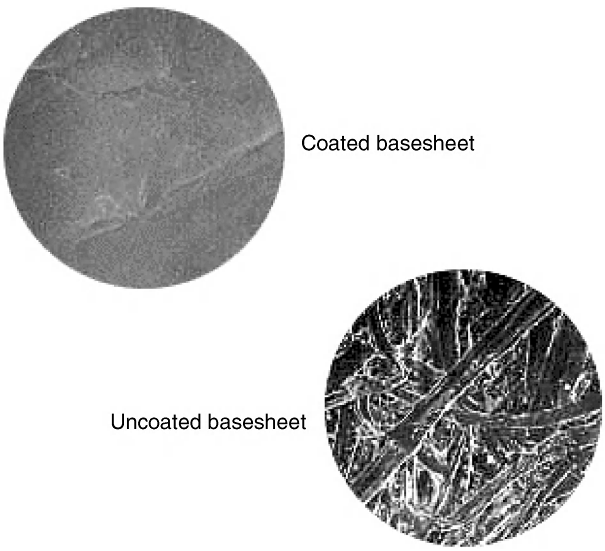

Figure 1 Microscopic views of a coated and an uncoated sheet of paper.

Ingredients and Properties of Coatings

Coating consists of three major components: pigment, binder, and water. It is the pigments that are used to fill the voids between the interlaying fibers. White pigments are chosen in order to provide the highest print contrast between the coating and printed image. The higher the print contrast, the more 'snap' the image will have. This is why high-quality photographic papers are now being sold with brightness values greater than 100%. How this is accomplished will be discussed in the upcoming section on coating additives. But for now, it is evident, that brightness is one property used to judge the quality of paper. Other important properties used to classify the grade of paper are furnish type, basis weight, smoothness, gloss, and opacity. A summary of the properties used in classifying coated North American paper and board grades are given in **Tables 1** and **2**.

Pigments

The optical properties, smoothness, and ink receptive properties of a coating are determined by the types of pigments used in the coating formulation. The most

commonly used pigments in North America are clays, while in Europe, carbonates are more commonly used. This is mostly because of availability. Europeans also tend to prefer more of a matte finish than a glossy finish, which is accomplished by using more carbonate in the formulation than clay.

The properties of the pigment that are most important to the papermaker are particle size and distribution, particle shape, index of refractivity, brightness, abraisivity, and of course cost. The particle size and distribution of the pigment(s) used influences the rheological qualities and runnability of the coating during application and metering and will influence the density of the coating layer after drying. The density of the coating layer influences the optical and ink receptive properties of the coating. The ink receptive properties of a coating are generally reduced when smaller particles, which pack more tightly, are used. However, the shape of the particle will also affect this property because it also influences the final packing density of the dry coating structure.

Gloss and smoothness generally increase with decreasing particle size. Smoothness tends to improve with decreasing particle size because the microdeviations on the surface decrease as the void spacing between the pigment particle decreases. There is some evidence that finer particle pigments require slightly more binder for sufficient adhesion and cohesion of the pigments to each other and the substrate.

Opacity will increase moderately with decreasing particle size, due to the increase in the number of air to pigment interfaces, which will refract more light. This holds true up to a particle size of about 0.3 μm. This has to do with the ability of light to see the pigment particle. For the most effective scattering of visible light, the diameter of the pigment particle should be about 40% of the light that is desired to be scattered. The visible light spectrum ranges 400 to 700 nm or 0.40 to 0.70 μm. Thus, a pigment particle diameter of 0.16–0.28 μm will scatter the incident light most effectively. The ability of a pigment to reflect light diminishes under 0.16 μm particle diameter.

So, as it may appear, the papermaker must balance the desired optical, smoothness, and ink receptive properties of the coating to the costs and processability requirements of the mill and customer.

Pigment Selection

Pigments are classified according to their brightness and weight percentage below 2 μm (**Table 3**). The particle size distribution and shape influence the ability of the particles to flow in the wet and to pack together in the dry state. So in the wet state, the rheological properties of the coating are greatly affected by the distribution and shape of the pigment particles.

The shape of a pigment is determined by the crystalline structure of the mineral from which it is obtained. The crystalline structure and chemical composition of the pigment are what also determines the refractive index and abrasitivity properties of the pigment. The surface finish characteristics of a sheet are heavily influenced by the shape of the pigment particle.

Clay

Clay is a naturally mined pigment. The most significant deposits of clay are found in Georgia (USA), Cornwall (UK), Jari River (Brazil), and southern and northeastern Australia. The major constituents of clay are koalinite and montmorillonite, hence the term kaolin clay. Chemically, clays are alumina silicates, Al_2O_3–$2SiO_2$–$2H_2O$, which have platy hexagonal structures (**Figure 2**). Its platy structure is what enables clays to develop gloss upon calendering. During calendering, the platelets align in the machine direction to improve the smoothness and gloss of the finished surface.

A perfect clay particle would be as shown in **Figure 2**. However, particles are rarely perfect and tend to be irregular six-sided platelets. Above 2 μm, they tend to exist as stacks of two to three platelets. By using a high shear extruding process (**Figure 3**), these platelets can be separated to produce a special grade of clay called delaminated clay. The individual platelets provide a smoother and more closed coating structure than standard clays upon calendering. For this reason, they are commonly used for solvent-based lightweight coated rotogravure printing grades.

Figure 2 Perfect rhombohexagonal clay platelets.

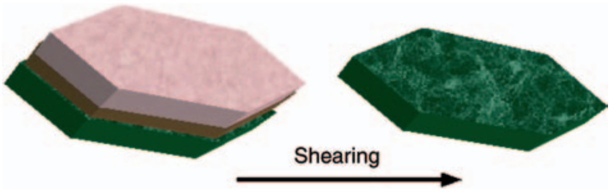

Figure 3 Shearing action to produce delaminated clay.

Selective fine clay particles can be structured into larger particles to enhance the light scattering and ink receptive properties of the particles. The structuring of clay can be performed by either a chemical or thermal treatment processes. The most commonly structured clay is called calcined clay. Calcined clay is obtained by calcifying the clay at temperatures above 1000°C. The high temperature treatment sinters the fine particles together and drives the hydroxyl groups from the chemical structure, which converts the clay to a noncrystalline aluminum silicate, Al_2O_3–$2SiO_2$. The new thermal structure can be described as a 'popcorn' type structure. Like popcorn, the structure contains many voids between the sintered particles. These voids improve the opacifying properties of the pigment, but rheologically make them more difficult to handle. Unlike standard clays, they can only be slurried up to 60% solids. Standard clays can be slurried up to 70% solids. The difference is significant to those wishing to apply high-solids coatings. Calcification also increases the abraisitivity of the pigment. They are most used in coated board grades where coverage is needed to cover the darker base sheet and to improve the absorption properties of grades to be printed with water-based inks.

Calcium Carbonate

Naturally ground calcium carbonate (GCC) is produced from chalk, limestone, or marble by either a wet or dry grinding process. The basic mineral of both chalk and marble is calcite, whose crystals are rhombic in structure. A rhombic structure is best described as a cube, which unlike the platelets of clay, do not produce gloss as readily during calendering. As a result, calcium carbonates are used more in the production of matte grades. However, fine ground and ultra fine ground calcium carbonates (UFGCC) are now available for gloss grades. Calcium carbonate reacts readily with acid and acid salts so carbonate coated broke can not be mixed with acid sized furnishes. They are therefore used in mills producing neutral or alkaline sized papers.

As a coating pigment, calcium carbonate produces a high brightness, high opacity coating. The rheological properties of calcium carbonate enables it to be supplied in slurry form at greater than 70% solids, which allows paper mills to run at higher solids. Unlike clays that have a yellow tint, carbonates have a bluish tint, which causes it to appear brighter in a coating. This property enables it to achieve a brighter coating more economically than clay. It is used significantly in wood free grades and matte grades. The rhombohedral particles pack more tightly than the two to three stacked platelets of standard clay. The resulting tight packing structure tends to dust more while printing. A blend of clay and carbonate is therefore more generally used for matte grades. Glossy grades are produced using little or no GCC or using an UFGCC with 90% finer particles less than 2 microns.

Another form of calcium carbonate that is being commercially sold in smaller quantities to the paper industry as a coating pigment is precipitated calcium carbonate (PCC). The switch from the acid to alkaline papermaking process has increased the usage of precipitated calcium carbonate in paper coatings, but its cost has limited its use. The conversion from acid to alkaline papermaking led to the development of satellite PCC mills next to the paper mills. PCC is produced from the limestone generated from the kraft chemical recovery process. The particle and shape of the PCC are determined by the precipitation conditions used, such as pH, temperature, degree of agitation, and use of additives. By controlling the conditions, either calcite or aragonite forms of PCC can be produced. The main advantage of PCC over GCC is the control of particle size, shape, and particle size distribution. They are mainly used for grades that can justify the increase in cost for the properties gained. The rheological properties of some of these grades also limits the ability to slurry them at high solids.

Specialty Pigments

Besides clay and calcium carbonate, there are many other types of pigments used in paper coatings that due to their lower usage levels are considered specialty pigments. These include titanium dioxide, plastic pigments, talc, alumina trihydrate, and silica, just to mention a few. The properties that prevent these materials from being used in larger quantities are one of cost and ease of application. Several of the above-mentioned pigments are difficult to disperse at high solids. They are therefore only used in applications where they have a special part to play.

Comparison of each pigment's properties in **Table 4** show the distinctive properties of some of these pigments. Besides differences in particle shape and refractive index, density is another distinguishing characteristic that can play an important role in the selection process for a coating. The density of a

Table 4 Summary of distinguishing pigment properties

Pigment	*Dry bright (%)*	*Refractive index*	*Specific gravity*	*Crystal form*
Clay	70–90	1.55	2.65	Rhombohexagonal

GCC, ground calcium carbonate; PCC, precipitated calcium carbonate; TiO_2, titanium dioxide.

pigment is especially important for lightweight coated grades of paper. In these grades, lower-density pigments are preferred to keep the weight of the coating down. For this reason, synthetic plastic pigments are often used for opacity and improved finishing and printing properties in these grades. Synthetic pigments are made from a variety of synthetic polymers, but styrene and copolymers that possess glass transition temperatures above 50°C dominate the commercial market.

The selection of pigment(s) for a coating will have a profound effect on the runnability, printability, and optical properties of the finished product. The right combination of pigments must be chosen to meet the end-use requirements and cost constraints of the customer. At the same time, it must be capable of being run on the manufacturer's available coating equipment. The same requirements must be met by the binder, which is the second largest component within any coating formulation (besides water).

Binders

The role of the binder is to provide the properties of cohesion and adhesion to the coating. Cohesion refers to the binding of two like surfaces, such as pigment-to-pigment bonds. Adhesion refers to the binding of two unlike surfaces, such as pigment-to-fiber bonds. The strength of the bond between any two surfaces strongly depends on the type of binder used and the amount of contact between the two surfaces. It is important to say that these are not the only factors, but since they are the two that can be controlled through the selection process, they are the only two that will be discussed at this time.

A summary of the different types of binders used in paper coatings is given in **Figure 4**. The bonding strength of the binder is to a large extent influenced by the length and flexibility of the polymer chain. The more flexible the polymer chain, the more flexible the bond. The chemical composition of the polymer and the amount and type of chemical conversions performed on the polymer control the flexibility and length of the binder's polymer chains.

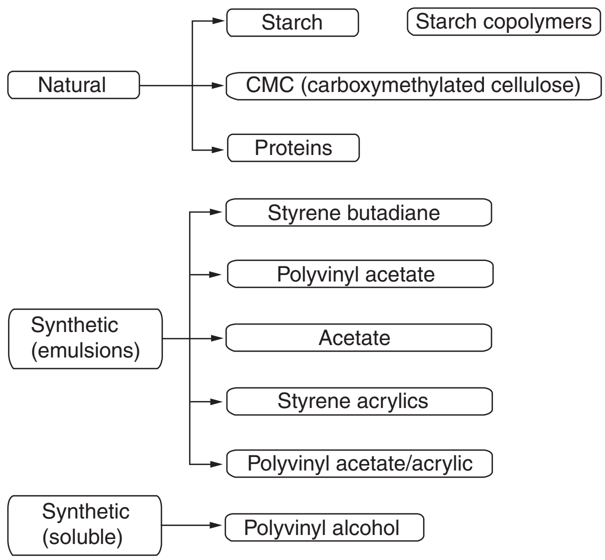

Figure 4 Summary of different paper coating binders.

A binder is a special kind of adhesive. Its role in a coating formulation is to adhere the pigments to one another and to the substrate. The binder also serves to control the porosity, and the water and solvent resistance of the coating. The gloss of the coating can also be greatly influenced by the type of binder used.

Binder Selection

When selecting a coating binder, the binding strength is not the only property that must be considered. The flexibility of the binder after drying is also very important as well as its film forming properties. A flexible binder will form a flexible, continuous film upon drying and flexible bonds between any two solid surfaces. A nonflexible binder will form a rigid film, resulting in rigid bonds that are nondeformable. A rigid structure that will not deform under the action of the calender will not attain a high level of gloss. On the other hand, a very flexible binder might become tacky and stick to the rolls of the calender. As a result, the two properties must be balanced to yield the final desirable coating properties.

The level of binder used depends on the 'binder demand' of the pigment. Binder demand means the amount of binder required to obtain the desired surface strength properties of a coating. Binding strength is very important, but it is very difficult to quantify because just as each binder has a particular strength, each pigment has its own binder demand. The binder demand of the pigment will depend on the shape of the pigment, particle size and particle size distribution.

So, when selecting a binder the formulator must consider the binder demand of the pigment, the bonding strength of the binder, the desired coating properties (optical and print properties), the demands of the printing process on the surface strength of the coating, and of course cost. Formulators seek to minimize the amount of binder needed not only for cost considerations, but also because the binder can interfere with the optical properties of the coating. The presence of excess binder reduces the number of air voids available to scatter light and receive the carrier solvents in the printing inks.

There are two major classes of binders used in paper coatings; natural and synthetic. The two predominant types of natural binders are starch and protein. Starch is composed of two high molecular weight polymers called amylose and amylopectin (**Figure 5**); it is easy to see that amylose is linear like cellulose while amylopectin is branched.

To enable the starches to be prepared at higher solids, the molecular weight of the starch can be reduced or the starch depolymerized. The depolymerization of starch involves the chain cleavage of the anhydroglucose units, which results in shorter, lower molecular weight polymer chains. Consequently, the viscosity of starch decreases and they can be prepared at higher solids.

Starches can be depolymerized (degraded) enzymatically with enzymes, or chemically using hypochlorite or hydrogen peroxide to oxidatively depolymerize the starch. Another chemical method is acid hydrolysis. The degradation can be made either on-site at the mill, or by the starch supplier. Hypochlorite, hydrogen peroxide, and acid hydrolysis are usually performed by the supplier. Starches can also be thermochemically modified. Thermochemical starches are prepared on-site by the mill using a continuous jet cooker. A starch slurry containing oxidizing agents, usually ammonium persulphate or hydrogen peroxide, is cooked in a jet cooker to a desired viscosity.

Another problem associated with using starch in comparison to synthetic binders is that it must be cooked to get it into solution and the temperature of the solution maintained at an elevated level to prevent retrogradation or gelling. To limit the effects of retrogradation and improve the solubility of starch, starches are chemically modified. The most commonly used derivatized starch in paper coatings

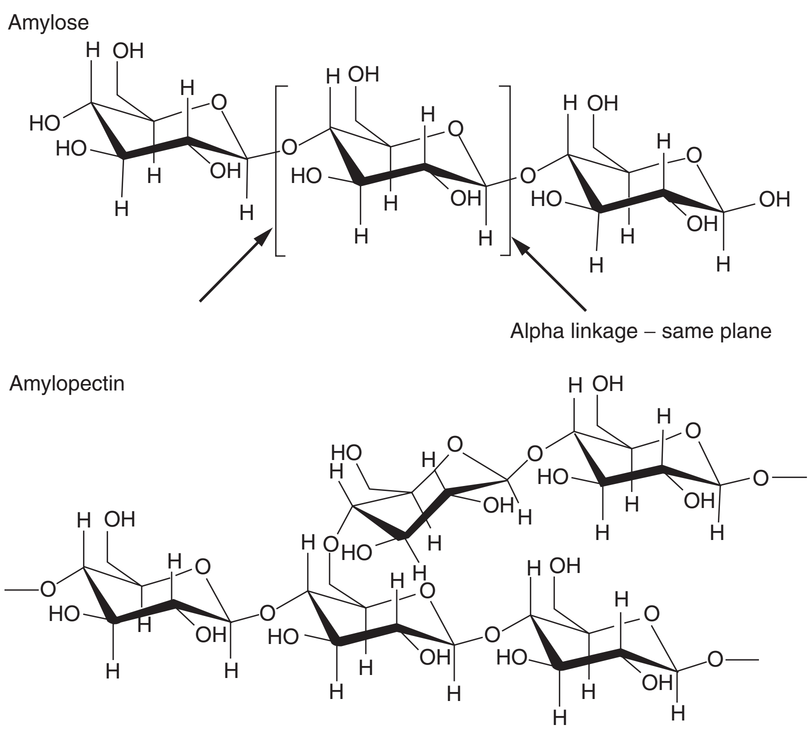

Figure 5 Structures of amylose and amylopectin.

is hydroxyethylated starch. Although more expensive, hydroxyethylated starch offers the advantages of more stable viscosity control, better film clarity and flexibility, and better water-holding properties.

Although these advantages come with a price, the economics are still better than that of synthetic binders. Unfortunately, regardless of the functionality added and the properties gained by the derivatization process, the solids at which these products can be made down are still limited to less than 30%. This limits the amount that can be used in high solids coatings.

Proteins

Proteins are obtained from natural sources such as milk casein and soybeans. But today almost all protein used by the paper industry is derived from soybeans.

The structure of protein is much more complex than starch. Protein contains 19 different amino acids, which are held together in a coiled structure by hydrogen and disulfide bonds. Proteins are amphoteric polymers. This means they contain positive (cationic) and negative (anionic) functional groups. Because most pigments are anionic, proteins interact strongly with pigments. This interaction causes a more open and bulkier coating to form.

Proteins can be modified to provide different bulking and viscosity characteristics. Like starch, they can be hydrolyzed to reduce the molecular weight, hence enabling them to be prepared at higher solids, due to less viscosity at given solids. They can also be carboxylated to improve their solubility and alter their degree of interactivity consequentially altering their bulking properties. They are mostly used in coatings for unbleached kraft board grades where bulk is needed to provide good coverage of the lower brightness base sheet.

Coating Additives

Additives are minor constituents that are added to a coating in relatively small amounts (less than 2% on weight of dry pigment) to improve the runnability of the coating on the machine or to enhance the final properties of the coatings. Some of the different types of coating additives used, just to name a few are defoamers, lubricants, rheology modifiers, crosslinkers, optical brightening agents, colorants, biocides, and dispersants. The name of the additive for the most part describes the role it plays within the coating. Although additives constitute only a minor part of the overall coating mix, their use is often critical to the overall performance of the coating in both the dry and wet state. A full discussion of their chemistry and application is too extensive to cover in this article.

Coating Processes

There are various methods for applying and metering a coating on to paper and board. Regardless of the method, the main objective is the same, to apply a uniform coating layer in a controlled manner.

All coating processes can be separated into three different operations: application, metering, and leveling. The type of application and metering devices used determine the stresses placed on the basesheet, the uniformity of the coating layer, the coat weight, range and possibility of operating problems such as scratching, ribbing, whiskering, misting, etc. Coatings can be applied on-machine and off-machine.

Size Press and Metered Size Press

The size press is the most common on-machine coater. It is mainly used to apply film forming materials such as starch and polyvinyl alcohol to the sheet to improve surface strength, alter the absorptive properties of the sheet, or impart a special functional property. When used to apply a pigmented coating, it is normally used to apply a low coat weight precoat. Three different flooded nip size press designs are shown in **Figure 6**.

The size press can be thought of as a simple roll coater or film transfer coater. Film transfer coaters all experience the same runnability problems at high speed, ribbing and misting. Both problems are influenced by the thickness of the wet coating layer as it is transferred from the roll to the paper. During the transfer process, the coating layer is split. As shown in **Figure 7**, part of the coating remains on the roll and part of the coating is transferred to the paper. The amount of ribbing and misting that occurs depends on the thickness of the wet coating layer before it splits, the rheological properties of the coating, absorptive properties of the base sheet and machine speed. Therefore to prevent the onset of ribbing and misting at higher speeds, it is desirable to minimize the thickness of the wet coating layer prior to the film transfer process. This understanding led to the evolution of the film transfer coater design from the flooded nip size press to the gate roll coater to the modern day premetered size press shown below in **Figure 8**. The premetered size press utilizes a short-dwell coating

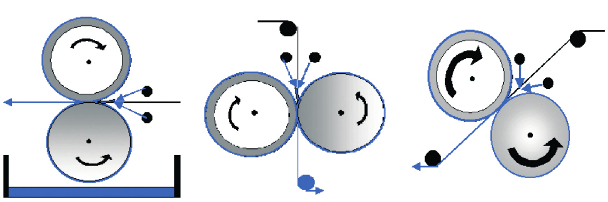

Figure 6 Three different size press designs: vertical, horizontal, and inclined.

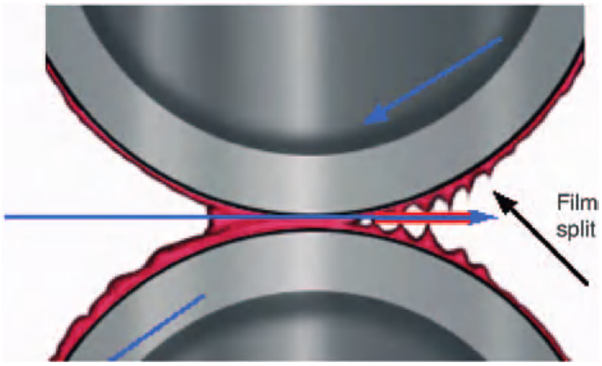

Figure 7 Film split between size press rolls and paper.

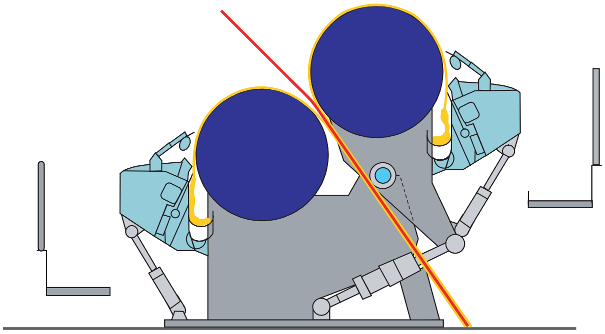

Figure 8 Modern metered size press.

head design, which holds a blade or rod metering device. In the short-dwell applicator, coating is pumped into a reservoir immediately upstream from the metering device. The pneumatic loading of the metering device controls the final coat weight.

Short-Dwell Coater

The short-dwell coater was originally designed as an off-machine coating method to coat lightweight grades of paper. The short contact time between the coating and paper surface reduced the number of sheet breaks experienced running these grades as a result of the loss in sheet strength due to the rewetting of the basesheet upon application of the coating. However, vortex flows in the low pressure reservoir have been linked to coating nonuniformities caused by the entrainment of air.

Blade Coaters

Although it provides the smoothest surface, the blade coater applies the greatest stress to the paper web. The stress applied to the web can cause web breaks, which results in costly machine down time. Scratches and streaks are also more prevalent with this method of coating.

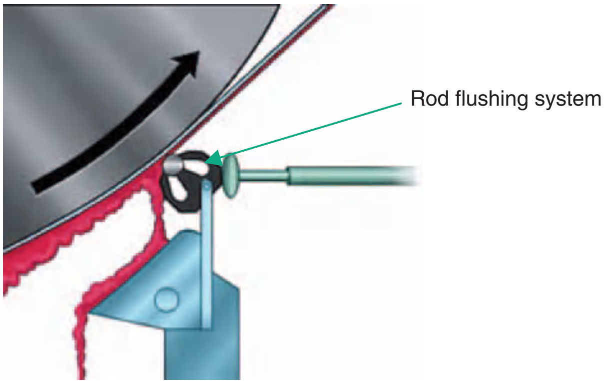

Figure 9 Example of rod holder and flushing system set-up.

Rod Coaters

Rod coaters are also rigid metering device coaters, but their cylindrical design stresses the base sheet less than a blade. It also enables the rod to be rotated against the web during its operation. This enabled a flushing system to be incorporated into the rod holder (**Figure 9**). This reduces the tendency for scratching and streaking which is especially beneficial to grades containing larger amounts of recycled fiber and lower surface strength, but the finished surface is not as smooth as a blade finished one.

Air Knife Coaters

Air knife coating is a noncontact coating application method, which uses a jet of air to meter the coating from the substrate. Since it is a noncontact coating method, it does not have the disadvantages of stressing the web and is not prone to scratching and streaking. The disadvantage to this coating method is in its limitation to applying low coat weights. It is mostly used to coat board. The smoothness of the coating layer is lower than that of a blade or rod coater.

New Coating Methods

Two new coating methods that are gaining industrial interest are curtain and spray coaters. Curtain coaters utilize a flow element, such as a die or extruder, to meter a coating onto the substrate. The coat weight is controlled by the slot width of the die and pressure drop in the coating line. New designs are currently being studied to reduce the problems associated with running these coaters at higher speeds and coating solids. The problems are mostly associated with the entrainment of air in the coating at higher web speeds. The advantage with this system is that good coating coverage can be achieved with little stress to the base sheet.

Spray coating is the newest commercially available coating method available. The method uses several spray nozzles that can be rotated during operation for cleaning to prevent down time. With spray coating, a wide range of coat weights are possible. Good coverage with minimal stress to the base sheet can be obtained. As with curtain coating, several issues remain with regard to formulation and uniformity of the final coating layer. However, each method shows promise as lower stress coating methods.

Concluding Remarks

The introduction of new coating technologies and new coating materials into the market place is increasing the level of competition between coated grades. Machines are running faster and more efficiently. Quality is improving and printers are reaping the benefits as they continue to demand and receive more from their suppliers. Advances in printing technology will continue to drive the coated paper markets as printers seek to print more colors using multiple printing technologies. To keep pace, the papermaker must stay knowledgeable of not only innovations in coating material and process technology, but also new printing technologies and trends.

Diseases of Forest Trees

M J Wingfield, University of Pretoria, Pretoria, Republic of South Africa

Introduction

Plant diseases have been recognized for as long as plants have been cultivated. There are many references to plant diseases in early Greek and Hebrew writings. In these early times, diseases were believed to result from the wrath of God and it is not surprising that the Bible contains many references to plant diseases.

The discovery that fungi could cause diseases of plants was made by the chemist Anton de Bary in 1853, when he showed that rust and smut fungi (Uredinales and Ustilaginales) were the causal agents of cereal diseases. De Bary was also responsible for showing that late blight of potato, a disease responsible for reducing the human population of Ireland by half in five years, was caused by the fungus *Phytophthora infestans*. This is perhaps the most famous (or infamous) of all plant diseases. De Bary is appropriately recognized as the 'father' of modern plant pathology.

Although understanding that plant diseases are caused by microbes might seem to be rather obvious to us today, the process of enforcing this understanding was by no means simple. During the first half of the nineteenth century, the doctrine of spontaneous generation was well established, with strong support for the view that microbes emerged from decaying plant and animal matter. Understanding that microbes were the cause and not the result of decomposition emerged relatively slowly. This was through substantial experimentation by scientists including De Bary and Pasteur.

Forest pathology and the study of diseases of trees followed relatively soon after the recognition that microbes can cause diseases of plants. The science of forestry had its origins in Europe and it is not surprising that the 'father' of forest pathology was German. Thus, Robert Hartig (1839–1901) produced the first textbook of forest pathology in 1874. The importance of this book was recognized rapidly as is evident from its rapid translation by the famous British plant pathologist Marshall Ward and the publication of an English edition in 1894.

Plant pathology is hugely important to human health and welfare, yet ironically it is not a subject that has attracted adequate support. It is difficult to know exactly how many active plant pathologists there are in the world but the International Society for Plant Pathology records approximately 6000 names. It is worrying to know that there are certainly no more than 300 active forest pathologists in the world today. These scientists are mostly specialists interested in particular groups of pathogens or aspects of forestry.

This article presents a brief overview of the role of pathogens in forests. This is clearly a very broad topic, which has been treated in various levels of detail and focus in a number of excellent textbooks. It is obviously impossible to provide detail concerning any particular disease. Rather, the aim is to present an introduction to other articles that deal more specifically with various categories of disease.

Diseases in Natural Forests and Plantations

Forest pathology generally treats three broad categories of trees:

- natural, generally undisturbed forests
- intensively managed plantations of native or exotic species
- amenity or ornamental trees.

Diseases tend to act differently in these distinct situations and their management is also generally different. This article specifically treats diseases of native trees, mostly in natural ecosystems or in managed woodlands or forests. Diseases in intensively managed plantations of exotic trees such as the millions of hectares of *Pinus*, *Acacia*, and *Eucalyptus* found in the tropics and the southern hemisphere are treated elsewhere (*see* **Pathology**: Diseases affecting Exotic Plantation Species).

Categories of Tree Disease and their Causal Agents

Virtually every treatment of tree diseases classifies them somewhat differently. If we use Manion's definition of diseases any 'disturbance in the normal physiological functioning of a plant,' then diseases include both those caused by biotic factors as well as those associated with abiotic factors. Biotic factors include microbes and other organisms that have the ability to spread and are thus considered to be infectious. Most forest pathologists study these diseases because they have the ability to cause devastating losses. Diseases caused by abiotic factors such as air pollution, soil contamination, and other environmental factors can also result in very substantial damage. Diseases associated with air pollution, for example, have grown in importance in recent years and this is a trend that is likely to continue as the world population grows.

Most biotic tree diseases are caused by fungi. These fungi include: (1) basidiomycetes such as the decay fungi with mushrooms and brackets as fruiting bodies and the rusts; (2) ascomycetes which are the most numerous causal agents of tree disease; and (3) the oomycetes or water molds such as species of *Phytophthora* and *Pythium* which are best known as root pathogens of forest trees. Tree diseases are also caused by many other biotic agents such as bacteria, phytoplasmas, viruses, nematodes, and parasitic plants.

Disease Epidemics

There are numerous examples of tree disease epidemics that have caused devastating losses to natural ecosystems. Most of these have occurred on trees in natural ecosystems into which pathogens have been introduced. Generally these pathogens occur on the same genera of trees in areas, separated geographically from those that are affected. Typical examples are Dutch elm disease caused by *Ophiostoma ulmi* and *O. novo-ulmi*, chestnut blight (*Cryphonectria parasitica*), white pine blister (*Cronartium ribicola*), and pine wilt caused by the pine wood nematode (*Bursaphelenchus xylophilus*).

The first recorded tree disease epidemics date back to the beginning of the twentieth century. That was also the time when worldwide trade in and movement of forest products began to increase. Today there are increasing numbers of tree disease epidemics appearing. This is likely to be a trend that will continue, with the increasing movement of people and products around the world.

Vascular Wilt Diseases

Vascular wilt diseases are broadly defined as those that result from a blockage of the vascular tissues. Symptoms generally include chlorosis of the foliage and a rapid wilt (*see* **Pathology**: Vascular Wilt Diseases). These diseases are best known in hardwood trees that have xylem vessels that are easily blocked, particularly in the case of ring porous trees where trees depend on large xylem vessels at the start of the growing season. Vascular wilt diseases are less clearly defined in the conifers that have tracheids, which are less easily colonized and blocked.

Blockage of the vascular tissues can be due to the physical presence of fungal structures. The production of tyloses in the xylem vessels is a typical response to infection by vascular wilt pathogens. Production of these structures represents an attempt to slow the movement of the invading pathogen and also blocks the vessels, giving rise to wilt symptoms. Some vascular wilt pathogens are known to produce toxins, which are also involved in the development of the wilt symptoms.

Vascular wilt diseases are caused by ascomycete fungi, nematodes, bacteria, and phytoplasmas. A large number of these disease agents are carried by insects and some are soilborne. Vascular wilt diseases tend not be caused by pathogens typically dispersed in water or via airborne inoculum.

Some of the best-known fungal vascular wilt pathogens are transmitted by insects. In this regard, there are two main categories of insects that carry these pathogens. Thus, the devastating Dutch elm disease pathogens *O. ulmi* and *O. novo-ulmi* are carried by bark beetles (Coleoptera: Scolytidae) which produce maturation feeding wounds in the branch crotches of healthy trees, enabling infection to occur. The same would be true for black stain root disease caused by *Leptographium wageneri*, which can be vectored by insects such as *Hylastes* spp. that undergo maturation feeding on healthy conifer roots. In contrast, various vascular wilt pathogens are carried by casual insects such as flies (various families of Diptera) and picnic beetles (Coleoptera: Nitidulidae) that are attracted to the sap produced by freshly made wounds on trees. Typical examples of this group of insect-vectored fungi causing vascular wilt are the oak wilt pathogen *Ceratocystis fagacearum* and *Ceratocystis fimbriata*, which causes vascular wilt on a wide range of hardwood trees.

Pine wilt caused by the nematode *B. xylophilus* is an extremely important disease of pines in Asia. This is an unusual disease because it occurs in the upper parts of trees and has many similarities to vascular wilts caused by fungi. The pathogen is vectored by longhorn beetles (Coleoptera: Cerambycidae) which, prior to the recognition of the cause of pine wilt in 1971, had been generally considered to be secondary wood-boring insects of minor importance. However, these insects and particularly species of *Monochamus* undergo maturation feeding on twigs of healthy *Pinus* spp. allowing the nematodes to enter the vascular tissues of the trees. The exact mechanism of tree death is not fully understood but is thought to include physical nematode feeding and the production of toxins by nematodes or bacteria associated with them.

Fungal vascular wilt pathogens that are typically soilborne include species of *Fusarium* and *Verticillium*. Both these genera of pathogens are also well known causal agents of serious diseases of agronomic crops. Thus, *Verticillium albo-atrum* is an important pathogen of potatoes but also causes a serious vascular wilt disease of hardwood trees such as maples and ash. Host specialized forms of *Fusarium oxysporum* also cause serious wilt diseases on a wide array of agronomic crops, such as panama wilt disease of bananas caused by *F. oxysporum* f. sp. *cubense*. There are fewer examples of this group of pathogens in forest trees, but they are relatively common on legumes such as species of Acacia.

Serious vascular wilt diseases are caused by various bacteria and phytoplasmas. A serious wilt disease of trees including for example *Eucalyptus* is caused by the bacterium *Ralstonia solanacearum*.

This pathogen occurs in various forms on a wide range of mainly agronomic crops and is generally recognized as being soilborne, entering wounds on roots. In contrast phytoplasmas such as the causal agent of the serious ash yellows disease are xylem limited bacteria and are typically vectored by leaf hoppers (Homoptera).

Root Diseases

Root diseases are most typically caused by fungi belonging to all the major groups, although perhaps the basidiomycetes are best known and most common. Root diseases are also caused by nematodes although there are few examples of serious nematode problems in native trees. Root diseases are often recognized by patterns of disease development arising from the gradual movement of the causal agents through the soil (*see* **Pathology**: Root and Butt Rot Diseases). Thus, for example, in the case of species of *Armillaria* and *Heterobasidion*, this movement is generally from a single point of infection resulting in discrete patches of dying trees, with the most recently killed trees at the periphery of the disease centers. Trees will die slowly or might appear to wilt and die rapidly, but they have generally been infected for a considerable time prior to the appearance of symptoms. Species of *Armillaria* are well known to produce huge infection centers caused by a single clone of the fungus, which has led to the discovery that these fungi represent the largest and the oldest living organisms.

Fungal root pathogens have various infection strategies. Some disperse through the production of large numbers of airborne spores. Typical examples are the species of *Armillaria* and *Heterobasidion annosum*. In the case of these pathogens, spores can infect the surfaces of stumps of freshly cut trees or wounds at the bases of these trees. The fungi then consume the stumps and roots of the infected trees to build up inoculum potential that enables them to move from tree to tree by root contacts or grafts. *Armillaria* species also produce bootlace-like rhizomorphs, which grow on the surface of roots and through the soil, facilitating infection of adjacent trees.

Waterborne and soilborne pathogens and particularly species of *Phytophthora* are amongst the most important root pathogens of trees (*see* **Pathology**: *Phytophthora* Root Rot of Forest Trees). These fungi produce motile zoospores which enable them to move through water. They also produce thick-walled sexual spores that facilitate their survival in the soil for extended periods. *Phytophthora cinnamomi* is by far the best-known tree pathogen in this category and its introduction into native woody ecosystems in Australia has resulted in severe disease epidemics.

An unusual and interesting root pathogen that requires heat to become active is the conifer pathogen *Rhizina undulata*. This pathogen is an ascomycete that disperses its spores actively and these appear to infest the soil, or possibly the fungus lives epiphytically associated with conifer roots. However, heat from fire and occasionally lightning is needed before *R. undulata* becomes active. The disease can result in substantial damage after forest fires and is also commonly associated with patches of dying trees, where camp-fires have been made; among forest workers in the UK it was often known as the coffee-break disease.

Insects can be responsible for the dispersal of tree root pathogens. The best examples are species of *Leptographium* that are asexual states of *Ophiostoma*. These fungi produce sticky spores in the galleries of bark beetles and weevils (Coleoptera: Curculionidae) and the fungi are thus transmitted to tree roots by these insects. The most serious pathogen in this category is the black stain root disease pathogen, *Leptographium wagneri*, which occurs in three forms and is restricted to conifers in western North America.

Canker Diseases

Canker diseases are most commonly caused by ascomycetes and occur on branches and stems of trees (*see* **Pathology**: Stem Canker Diseases). The most serious of these are stem cankers, which girdle the lower parts of stems, resulting in tree death. Canker pathogens tend to infect the cambium and trees can respond by producing callus to seal off the infected tissue. In the case of perennial cankers the pathogen is most active during one period and the tree responds during the remainder of the year. This results in target-like cankers with concentric rings of callus on the stems of trees. In contrast, annual cankers infect the cambium and in severe cases will often girdle the trees.

Although not strictly considered canker pathogens, many rust fungi cause perennial infections on the stems of trees. The rust fungi are unique obligate plant pathogens, having up to five stages in their life cycles, which can occur on two different hosts. Thus white blister rust caused by *Cronartium ribicola*, which has devastated white pine in the North America, gives rise to its most severe damage on the stems of white pines, but has *Rubus* species as alternate hosts. Likewise, serious damage is caused to the stems of various *Pinus* species by the fusiform rust pathogen *Cronartium quercinum* f. sp. *fusiforme*, while various species of oak serve as alternate hosts.

Most canker pathogens are dispersed by spores that are produced during moist weather and that are dispersed by wind. Certainly the best known and most devastating canker disease is caused by the chestnut blight pathogen which has virtually eliminated the American chestnut, *Castanea dentata*, from its native range. There are many other fungi that cause serious canker diseases and these include species of *Botryosphaeria*, the poplar canker pathogen *Hypoxylon mammatum*, and the pitch canker pathogen *Fusarium circinatum*, to name but a few. These pathogens all tend to infect natural or artificially caused wounds on trees, or they are endophytes in healthy trees that proliferate after the onset of stress.

Insects can be important associates of some canker pathogens. For example, the pitch canker pathogen is closely associated with twig and cone feeding insects. Pitch canker is one of the most serious diseases of pines and is responsible for a devastating disease of *Pinus radiata* in California. The pathogen occurs in countries such as Chile and South Africa but is restricted to nurseries. The absence of shoot and cone insects in these countries is thought to be the reason why the disease has not developed into a major problem on large trees.

An interesting recent example of an oomycete pathogen able to cause cankers on trees is *Phytophthora ramorum*. This pathogen is infecting many genera and species of trees in the western USA and is thought to have been introduced into that country from Europe where it occurs on leaves and shoots of *Rhododendron* spp. The sporangia of *P. ramorum* are dehiscent and dispersed by air, after which zoospores are produced in moisture and these directly infect the cambium of susceptible trees, to cause annual cankers.

Leaf and Shoot Diseases

As is true with all plants, trees have a very large number of leaf and shoot diseases (*see* **Pathology**: Leaf and Needle Diseases). These are most commonly caused by ascomycete pathogens but many are caused by rusts (Basidiomycetes: Uredinales) and in a small number of cases *Phytophthora* spp. These pathogens can infect shoots where severe dieback and damage can occur. They can also give rise to the death of large areas of leaf surface causing blight and severe defoliation. Although a single defoliation generally does not kill trees, repeated infections are common and can cause growth loss and even tree death. In other cases, leaf diseases cause discrete spots or localized symptoms on the leaves.

Ascomycete leaf and shoot pathogens have a number of different dispersal strategies. Some have exclusively airborne spores that tend to be actively discharged from fungal fruiting structures. Typical examples are for example in the sexual states of *Mycosphaerella* and the powdery mildews that cause leaf diseases on many trees. Many asexual states of ascomycete leaf and shoot pathogens produce spores that are discharged in association with rainfall. Typical examples amongst more serious tree pathogens are found in the needle blight pathogen *Dothistroma septospora* and the dogwood anthracnose pathogen, *Discula destructiva*.

The rust fungi cause leaf and shoot diseases as well as the cankers discussed above (*see* **Pathology**: Rust Diseases). Spores associated with most of these stages are powdery and windborne although moisture is generally required for the production of basidiospores and insects are known to be involved in fertilization of pycnia. Many rusts are important leaf and shoot pathogens of forest trees. These for example include needle rusts on conifers caused by *Coleosporium* spp., the aecial state of cedar apple rust on apples caused by *Gymnosporagium juniperi-virginianae* and eucalyptus rust caused by *Puccinia psidii*.

Insect Associated Diseases and Blue Stain

Many species of conifer infesting bark beetles are known to carry fungi that impart blue stain to the sapwood of infested trees (*see* **Pathology**: Insect Associated Tree Diseases). Most of these fungi are species of *Ophiostoma* and *Ceratocystis* and their asexual states. They are generally known to be nonpathogenic or only mildly pathogenic. However, their role in killing trees is poorly understood and deeply debated. Certainly some of these fungi such as *Ceratocystis polonica*, associated with the aggressive European spruce bark beetle *Ips typographus*, are highly pathogenic and appear to contribute substantially to tree death.

Irrespective of their pathogenic role associated with bark beetles, species of *Ophiostoma* and *Ceratocystis* that infest conifers impart substantial damage to timber products. After the insects have killed these trees, the sapwood typically becomes severely discolored with so-called blue stain. This discoloration is not strictly a stain in the sense that it is caused by a product of the fungi. It rather arises from the darkly pigmented hyphae of the fungi which colonize the tracheids and ray parenchyma. The fungi do not result in any weakening of the timber but the discoloration is aesthetically unattractive to wood markets and associated financial losses can be great.

Wood Decay

Decay and so-called heart rot in standing trees is most typically found in old-growth forest where trees are sufficiently old to develop columns of decay at their centers (*see* **Pathology**: Heart Rot and Wood Decay). Decay fungi enter wounds on the stems of trees or through broken branches and gradually consume elements of the heartwood. This decay is caused by basidiomycete fungi belonging to, for example, species of *Phellinus* and *Ganoderma*. Various important root pathogens such as species of *Armillaria*, *Heterobasidion annosum*, and *Phellinus weirii* also cause heart rot and decay after they have killed trees or roots.

There are various different types of decay and these arise from the different nutritional habits of the fungi that cause them. For example the white rot fungi consume approximately equal amounts of cellulose and lignin thus causing a relatively evenly spread softening of the wood, which is often stringy. Brown rot fungi utilize chiefly cellulose and the remaining wood is almost pure lignin that appears in a cubical pattern known as brown cubical rot. Another relatively common pattern of decay is white pocket rot where all the lignin is removed from small pockets that contain virtually pure cellulose.

Avoidance and Management of Tree Diseases

Management of diseases in native forests and woodlands is extremely difficult and in some cases virtually impossible. This is very different to disease management in plantations where many options exist for disease avoidance.

One of the most important components of tree disease management lies in excluding pathogens from new environments. As mentioned previously, some of the most devastating diseases have been caused by pathogens introduced into new environments. Exclusion of pathogens from new environments depends on quarantine regulations that ensure that they are not moved across borders. This objective can be very difficult to achieve, particularly where countries have large boundaries, especially with countries having less rigorous regulations. Island countries such as Australia and New Zealand have invested substantially in quarantine and they have achieved remarkable success. However, on the whole, plant quarantine commonly fails, and new and devastating diseases must be expected to continue to move between countries and continents as global trade and travel continue to grow.

Another strategy used to reduce the impact of disease is through eradication of pathogens after they have been introduced into new areas. This approach is complicated and depends on early recognition of the disease, a clear understanding of the biology of the causal agent, and intensive efforts to eliminate it. Various tree disease eradication programs have been launched and have failed. The best example was the program in the USA between 1930 and 1965 aimed at eradicating the alternate host of white pine blister rust. There are, however, more positive examples such as the virtual eradication of Dutch elm disease from New Zealand.

Chemical control or protection to reduce the impact of tree diseases is not commonly used in forestry. This is due to the fact that forests represent extensive, ecologically sensitive environments where most fungicides cannot be used responsibly. There are, however, some examples of very effective chemical control of tree pathogens. One of the best of these is the regular chemical control of *Dothistroma* needle blight in countries such as New Zealand, Australia, and Chile. Chemicals or biological products are used to protect conifer stumps from infection by the root rot pathogen *H. annosum*, and chemical control in nurseries is commonly applied.

An effective and commonly used strategy to manage tree diseases is through avoidance. Avoiding disease can be achieved through silvicultural methods aimed at reducing inoculum. For example, the efficient removal of dying elm trees that are infested with insects carrying the Dutch elm disease pathogen can be effective. Avoidance of wounds on trees at the time when they are likely to become infected is also an effective means of reducing diseases such as for example oak wilt. Natural forests can also be managed in such a way as to favor certain species that are not susceptible to the pathogens present, or management can include the removal of alternate hosts such as scrub oak, in the case of fusiform rust.

In the future, we might expect many new opportunities to reduce the impact of diseases. For example, DNA based techniques for disease diagnoses are becoming increasingly available and are likely to play an important role in quarantine. Biological control has not been particularly effective in tree disease management in the past, but new advances at the molecular level, for example in the use of fungal virus associated hypovirulence, are also likely to emerge in the future. Genetic modification of trees is also likely to advance to a point where trees previously eliminated from the landscape, such as in the case of the American chestnut, might be reintroduced. Furthermore, it is likely that new and nondamaging fungicides will be discovered in the future and that these will contribute to reduction in the impact of tree diseases.

Root and Butt Rot Diseases

M Garbelotto, University of California – Berkeley, Berkeley, CA, USA

Introduction

Diseases caused by root rots figure prominently amongst the most-studied pathologies of forest trees. Indeed, root and butt rots cause more economic damage to commercial forestry in the temperate world than any other known type of disease. While this notoriety underlines the negative impact of this type of disease on timber production, a much more dynamic and positive role can be assigned to root rots in natural ecosystems. Root rots are one of the driving forces ensuring spatial and temporal diversification of forests. While root rots as a whole encompass both generalistic and host-specific pathogens, aggressive primary microbes, and secondary opportunistic ones, their overall effect at the stand level is to accelerate, and sometimes cause, a patchiness in which some tree species are preferentially affected and weaker individuals culled. Because of their selectivity at the species and at the individual tree level, root diseases play a significant role in determining the structure and composition of a forest. Individual trees and/or clusters of individuals are taken out, and the gaps created allow for tree regeneration. Often, more resistant seral species will substitute the more susceptible pioneering species leading to forest succession. Ecotones between gaps and closed canopy offer rich and diverse habitats, home to a substantial amount of the local biodiversity. Finally, a further outcome of root rots is nutrient recycling: this is achieved by breaking down the chemically complex woody substrate in a synergistic activity with other wood decay fungi, bacteria, and wood-boring insects.

As stated above, concerns about root rots become serious when timber production is involved. Unfortunately, most habitat modifications, including but not limited to those related to logging, appear to increase the damage caused by root rots. In many cases, human activities allow for the establishment of or increase in root rots. Once disease is established, an irreversible process starts in which root rots will play a significant role in shaping the future of that forest. When root diseases affect ecosystems characterized by poor soils, limited host variability, or limiting climatic conditions, their impact may be significant even in the absence of further human activities.

Causal Agents of Root Rots: Establishment Strategies and Population Genetics

Root diseases can be caused by a wide range of organisms including oomycetes, ascomycetes, and basidiomycetes. Root and butt rots, instead, are exclusively caused by fungi belonging to the homobasidiomycetes. The three genera *Armillaria*, *Heterobasidion*, and *Phellinus* have broad worldwide distribution and probably are responsible for the majority of root diseases in temperate forests. Other less frequently encountered genera include *Inonotus* and *Phaeolus*.

All of the known root rotting organisms reproduce sexually. A fertile cell layer (called the hymenium) borne by the sexual fruit bodies of these fungi produces haploid meiospores. Hymenia can be porous or gilled (**Table 1**). Fruit bodies produced by root rot fungi can be an excellent diagnostic clue and include true mushrooms (*Armillaria*), bracket or shelflike conks (*Heterobasidion*), and relative inconspicuous resupinate fruit bodies entirely supported by the surface on which they are growing (*Phellinus weirii*) (**Table 1**). It should be noted that by the time the fruit bodies are produced, root rots are already in an

Table 1 A summary of characteristics of some important root rot diseases

Pathogen	*Disease*	*Hosts*	*Range*	*Decay*	*Fruit body*
Armillaria spp. complex	Oak root fungus; honey mushrooms	Very broad range, both angiosperms and conifers	Worldwide	White stringy	Fleshy gilled mushroom
Heterobasidion spp. complex	Annosus root disease	Primarily conifers, some angiosperms	Worldwide	White laminar	Perennial and annual porous brackets
Phellinus weirii spp. complex	Laminated root rot	Conifers	Western North America, Eastern Asia	White laminated decay, pitted	Resupinate porous
Inonotus tomentosus	Tomentosus root disease	Spruce, pines	Pacific Northwest, USA–Canada	White	
Phaeolus schweinitzii	Velvet top fungus	Conifers	Worldwide	Brown cubicle	Fleshy, velvety corrugated, porous, short or no stipe

advanced stage. Most root rot agents can be cultured, and in culture some produce asexual mitospores called conidia that may have diagnostic value.

In general, airborne basidiospores are the main means for primary infection by a root rot pathogen, and allow for the infestation of new areas. Vegetative or somatic spread of the fungal mycelium is the main means for secondary spread, allowing for the expansion of those individuals originally established through the primary infection process. This expansion may occur either by tree-to-tree contagion through root contacts and grafts, or by free growth of the pathogen in the soil through specialized structures such as mycelial cords or rhizomorphs. Root rotting basidiomycetes colonize a substrate and utilize it as they are growing. In this light, they can be considered territorial organisms, which physically occupy an area and do not easily allow other conspecific organisms to coexist in the same niche. While this phenomenon can be explained partially by the depletion of available nutrients by the pioneering individual, it has been shown that this exclusion of other individuals starts significantly earlier than nutrient depletion. Like most other wood-rotting basidiomycetes, species causing root rots have developed a multilocus system called vegetative (or somatic) incompatibility (VI). When two individuals belonging to the same species meet, a chemically mediated reaction results in the inhibition of growth of both individuals. The area between the two colonies is characterized by sparse or no fungal growth and represents one of the territorial borders of fungal clones or genets. Self-protection from viruses or pathogens present in other individuals is another function attributed to VI systems.

The VI system is active only in diploid ($2n$) and dikaryophytic ($n+n$) isolates. In dikaryons, the two parental nuclei pair up but do not undergo karyogamy. The lack of an active VI system in haploids allows mating to occur. Mating does not involve any specialized sexual structures but is attained by the simple fusion of vegetative haploid hyphae. The resulting $2n$ or $n+n$ thallus is long lived and leads to the production of fruit bodies and of meiospores. The haploid phase in nature is regarded as relatively short-lived and unfit, but some species, especially those relying heavily on primary infection (e.g., *Heterobasidion* spp.), are known to have long lived and virulent haploid phases.

Genetic studies on the clonal distribution of most root disease organisms have often shown complex patterns of colonization characterized by areas colonized by several individuals. In some cases both haploids and dikaryons coexist and there is evidence of genetic exchanges among individuals. VI barriers have thus to be interpreted not as absolute boundaries but as dynamic areas with potential interspecific interchanges.

Some root disease organisms, especially within the genera *Armillaria* and *Phellinus*, show a remarkable genetic homogeneity over large areas. In some cases, tens of acres have been shown to be colonized by a single individual, secondarily spreading among root systems of an entire forest for thousands of years. The case of a 33-acre (13.4 ha) genet of *Armillaria bulbosa* in northern Michigan has been reported as the largest living organism on earth. This case exemplifies a root disease organism for which secondary infection plays a very significant role and appears to be a much more frequent event than primary infection.

The relevance of primary vs. secondary infection is of paramount importance not only for understanding the biology and epidemiology of root diseases but also for management purposes. Pathogens like *Armillaria bulbosa* or *A. mellea* have the ability to spread secondarily over significant distances. When these organisms colonize woodlands extensively, there is often a carry-over of the pathogen into future generations; in these cases, new mortality may not necessarily be caused by new primary infection, but by the remnant of infections established at the site in previous rotations. The clear-cutting of infested stands may not resolve the problem, as most root disease organisms will survive for decades in larger woody debris and in stumps. A study of *Armillaria* infections in the south of France showed that the disease spread radially from a source point in all directions, causing a classic root disease center. Natural regeneration of the stand would always occur in the middle of the infection center, after the root disease had expanded and the pathogen in the oldest infection area was no longer viable. Interestingly, as the nucleus of regeneration expanded, its outer margins would eventually overlap with the outer margins of the disease center, where the pathogen was still viable. These regeneration patches would then become infected in the areas of overlap and start dying back inwards towards the center of the infection center.

Plantations of forest trees or woody crops in areas previously infested by a root disease like *A. mellea* may result in regeneration failures. In these cases, it may be important to identify and isolate sources of secondary infection, while ensuring trees are vigorous and less prone to become infected. When dealing with root diseases characterized by abundant primary infection events such as *Heterobasidion* spp., forest management should focus on minimizing those activities likely to create good primary infection courts, e.g., wounds on roots, stems and branches, and stumps. In general, heavy use of the land and logging will exacerbate these types of root diseases, with losses becoming apparent only after several years.

Symptoms Caused by Root Diseases

The lag between infection and the visible development of symptoms is due to the obvious fact that most symptoms caused by root diseases are in the roots. It has been shown that up to 50% of the root system needs to be affected before any symptoms of tomentosus root disease may be visible above ground. Colonization of the root system may thus go undetected for long periods of time. Although roots of all sizes can be infected by root pathogens, the most reliable underground symptom is the decay of woody roots. Root diseases are equipped with many enzymatic systems and can cause a brown (lignin not being utilized by the pathogen) or a white (lignin utilized by the pathogen) rot. Root rots can also be further characterized by being cubicle, pitted, laminar, and so forth. **Table 1** summarizes the types of rots caused by some important root diseases. Roots can be decayed in two ways: either by starting from the cambium (root girdling) and then proceeding inwards (sapwood rot) (**Figure 1**), or by decaying the central portion of the root (heart rot). The first pattern will result in the rapid death of infected roots and of the root collar, and in a relatively rapid death of the host by girdling. The second type may kill the smaller woody roots by physically breaking them down, but the larger ones may be hollowed and remain physiologically functional for long periods of time. Infection will proceed into the tree sapwood (or in some cases the heartwood), resulting in a physiological loss of vigor due to the loss of functional outer sapwood. Sapwood infection might make trees more vulnerable to other pests, diseases, and unfavorable climatic conditions. This type of decay, when advanced and extensive, may result in the significant weakening of the roots and lower bole of infected trees. Infected trees will be mechanically compromised and more likely to crash due to the effects of wind, rainstorms, or snowfall.

These two major patterns of root rotting are often determined not only by the pathogen species, but also by the host being infected. It is not uncommon

Figure 1 A section of the cut stump of a white fir (*Abies concolor*) in a California site infested by the root pathogen *Heterobasidion annosum*. A white laminated decay caused the rot pockets visible in the sapwood. Trees affected by sapwood rot will have reduced vigor and may decline rapidly at the onset of further problems.

to have the same pathogen species colonizing roots in two different ways when infecting two different hosts. Patterns of butt decay will also depend both on species of the pathogen and of the plant host. Not all root infections proceed into the tree butt. When surveying for incidence of root diseases, results have been different depending on whether surveys were based on root sampling or basal wood coring of tree buttresses. At any rate, root diseases figure as one of the most significant causes of cull in timber production, and the problem intensifies with each new rotation.

The time lag between root infection and the onset of symptoms above ground may vary depending on climate, host and pathogen species, and tree age. Smaller trees with smaller root systems may die rapidly after infection, even within the same season. In contrast adult trees may survive for decades after infection. When infection levels start affecting tree physiology and vigor, visible symptoms can be seen in the crown. Infected individuals will display slower growth. Tree crowns will appear thin as a result of both the slower growth and the shorter retention time of leaves. For instance, pines infected by a root disease may only keep needles produced in the current year while 2- and 3-year-old needles may be prematurely dropped. A single cluster of 1-year-old needles at the end of a barren branch gives these branches the so-called 'lion's tail' appearance. Root infection will also result in a shift in the color of the foliage, which generally appears less vibrant than the foliage of healthy individuals.

All of the above symptoms indicate trees with significantly altered physiology. The obvious question is whether such symptoms may always be considered as the effect and not the cause of infection by a root disease. The issue of causality is an important one and it has not been fully investigated. There are several studies indicating a strong correlation between physiological stress and infection by root diseases. These studies have shown that infected trees grow slower, that trees exposed to air pollution are more likely to be found infected, and that short-term draughts increase the frequency of trees with root diseases. Finally, trees affected by root diseases will be more attractive to bark and ambrosia beetles, and may provide an initial substrate for the growth of beetle populations that may then overflow and affect healthy trees. While there is enough evidence to suggest that these symptoms are the effect of infection by root diseases, there is still the possibility that these pre-existing symptoms may facilitate infection by root pathogens. Further research is needed to verify the role played by weakening agents in facilitating infection of trees by root rots.

An interesting perspective, when correlating root diseases and tree stress, may be to differentiate between primary aggressive pathogens and secondary less virulent ones. While primary pathogens can cause significant disease and alter the tree physiology with or without pre-existing tree stress, secondary ones require a pre-existing or concomitant stress factor (including other pathogens) in order for disease to develop. In the Sierra Nevada of California, for instance, rhizomorphs of the nonaggressive *A. gallica* can be found on the surface of the roots of large numbers of true firs (*Abies* spp.). Although the rhizomorphs are growing ectotrophically on the roots, there is no or little associated decay. *Armillaria* decay, though, may start soon after the same roots are infected by the more aggressive pathogen *Heterobasidion annosum*.

Those rhizomorphs could almost be interpreted as exploratory outposts ready to capitalize on the availability of weakened trees. This exploratory function of a secondary pathogen, although apparently extremely costly, allows for the rapid utilization of a substrate that may otherwise be fully colonized by the aggressive primary pathogen or other competitors. The above example highlights another important feature of root pathogens capable of secondary (vegetative) spread: i.e., their ability to maintain functional networks covering a sizeable area and several plants. Most of the network may be maintained at comparable levels until resources become available in one spot. At that point, most of the resources of the network are dynamically allocated to increase the utilization of that substrate. The apparent new attack on a host (e.g., a weakened tree), may be the result of energy reallocation through an already established network, rather than being the result of the advancement of an infection front.

At later stages, symptoms of root disease include progressive dieback of the crown, starting from the top downwards, and the presence of signs of decay. Fungal fruit bodies are produced either on the colonized woody substrates (normally at the root collar or on the roots) or on the duff layer thanks to the presence of masses of finer roots. Rhizomorphs are specialized structures produced by many *Armillaria* species; they consist of a strand of hyphae encased by a highly hydrophobic melanin layer. Rhizomorphs, commonly referred to as 'shoestrings' because of their appearance, can grow freely in the soil and allow the pathogen to move from tree to tree without the need to follow root contacts. The consistency, thickness, and cross-sectional structure of rhizomorphs can be a useful diagnostic tool to differentiate among *Armillaria* species. Rhizomorphs are commonly found on the roots and root collars of host trees, but they can also be found on several meters of the main bole, growing under the bark. Another sign of decay associated with root diseases is the presence of mycelial mats. *Armillaria* mycelial mats appear as fans radiating under the bark from the root collar. Wood in an advanced state of decay will present cavities often colonized by the white mycelium of root pathogens like *Heterobasidion* spp. or *Phellinus weirii*. The mycelium of the latter species is characterized by the presence of hair like structures called setae. Advanced decay also results in obvious punks and defects in the wood, often associated with resinosis, sap bleeding, or wetwood.

Root disease centers can be differentiated from clusters of trees killed by pest outbreaks or abiotic factors because tree mortality is not synchronous but occurs over a period of time. In the middle of the root disease center, there are those trees initially killed by the disease; some of them may have already been windthrown. More recent mortality may be present in a ring encircling the older mortality. Recently killed trees will still bear most of the dead foliage, while relatively older mortality will be characterized by trees made barren by winter storms. Symptomatic live trees may represent the visible edge of the root disease center (**Figure 2**). Studies on control options aimed at halting the secondary spread of the root pathogen *Heterobasidion annosum* in ponderosa pine (*Pinus ponderosa*) stands have highlighted the fact that the pathogen had already infected several tiers of apparently asymptomatic trees outward and beyond the apparently symptomatic ones. Root disease centers may thus be larger than judged by the presence of visible symptoms. It has been noted that enlargement of root disease centers does not proceed indefinitely but eventually stops. The factors regulating the spread of root disease centers are only marginally known.

Figure 2 A typical root disease center caused by *Heterobasidion annosum* in the mixed conifer forest of the Sierra Nevada, California. While true firs appear symptomatic or dead, pines (distinguishable by the longer needles) are not affected. This species of the pathogen in fact is specialized on true firs, Douglas-fir, and sequoias, and is very different from the species found on pines. Stumps and trees dead for several years are visible in the center, the location where the pathogen had originally established itself. Secondary growth leads to an expansion of the mortality center. Symptomatic trees and trees recently killed by the pathogen (note the brown–orange foliage still borne by the branches) mark the expanding edge of the pathogen.

The Ecology of Root Diseases

While root pathogens vary in their ability to freely grow in the soil (**Table 1**), their biology is intimately linked to soil properties. In general, loose, well-drained soils, poor in organic matter, are extremely conducive to the development of root diseases. The ecological and trophic requirements of these pathogens are rather species-specific, and root pathogens have evolved to minimize spatial overlap amongst individuals from the same species or from species having identical requirements. When requirements differ, spatial overlap may occur, as each species may be utilizing a different niche. In general, primary infection of root pathogens is successful only during the very initial stages of decay. In the case of conifer stumps infected by *Heterobasidion annosum*, infection rates drop dramatically each day after logging and become fairly minimal after 5 or 6 days. *Heterobasidion* spp. are not good competitors and need to arrive on substrates that are relatively available. Thus other wood-inhabiting fungi have the ability to exclude this pathogen from a substrate otherwise available. This basic observation has resulted in a biological control approach prescribing the application of strong competitors on the wood surface at the time of logging. Because with time there is a sharp decrease in infection success by spores of this pathogen, competitors only need to be active for a few days in order to be effective.

Precipitation requirements may differ among root pathogens but in general mild temperatures and good precipitation favor sporulation. Dry weather, or temperatures under 10°C or above 25°C, are in general unfavorable to sporulation and infection alike. Excessive rain may also be unfavorable to root pathogens relying mostly on airborne inoculum (e.g., *Heterobasidion*). In the case of pathogens relying more heavily on secondary spread (e.g., *Armillaria*), heavy rains can at times cause a temporary anoxia in the root systems and trigger a more aggressive root colonization by the pathogen. In areas with cold and dry winters, sporulation by *Heterobasidion* spp. is extremely low. Sporulation by the same species in areas with mild winters continues throughout the year; winter sporulation is relatively abundant in areas where precipitation, even if in the form of snow, occurs mostly in the winter season.

Although fruit bodies of most root pathogens produce unimaginably large numbers of basidiospores, the role of such spores is not always clear. This is particularly true for root pathogens relying heavily on secondary spread. While basidiospores can travel a long distance, sometimes on the order of hundreds of kilometers, spore densities undergo a huge dilution after the first few meters. The likelihood of primary infection is thus directly correlated with distance from a source point. While the migration of even a few spores may be significant for areas still not colonized by a root pathogen, it is unlikely the few spores from a distant source would have a huge impact on the large number of locally produced spores.

The presence of marked host specificity among morphologically indistinguishable populations of the same pathogen is prominent in root diseases. In fact the discovery of host specificity within the broad host range of pathogens *Armillaria* and *Heterobasidion* was a milestone towards the better understanding of the concept of biological species for the fungi. This host specificity was backed up by genetic studies indicating that populations specializing on different groups of hosts were genetically isolated from one another. The term intersterility group (ISG) was coined in the late 1970s to describe these host-specialized and reproductively isolated root pathogen populations. In the case of *Heterobasidion annosum*, a series of crosses between the two North American ISGs revealed for the first time the genetic system regulating intersterility and consequently speciation among these host specialized groups. Nowadays, thanks to the advancement of our genetic techniques, most of these biological species have been elevated to the rank of species (**Tables 2–4**).

Host specificity has several relevant consequences:

1. In a mixed forest not all trees species will be equally susceptible.
2. Disease severity in a mixed forest should be less than in a forest comprising a single susceptible species.
3. Susceptible species may be replaced by more resistant ones (succession).

It should be noted that host specificity might be relaxed when infection occurs on stumps rather than on live trees. This phenomenon has been reported for *Heterobasidion* species both in Europe and North America. In the case of this pathosystem, stumps may have a triple effect: (1) they greatly enhance primary infection, (2) allow for the establishment of a pathogen species once rare, and (3) allow for two or more species to grow in the same habitat. This close proximity, rarely present in nature, where different species are segregated on their specific plant hosts, has resulted in interspecific hybridization and gene introgression with unpredictable outcomes for California forests. Furthermore, as stated above, once stumps are infected, they can be the source of inoculum for several decades. Fruit bodies may in fact proliferate on stumps, and at the same time the infection of the stumps' root system represents a source of secondary infection.

Table 2 Details on some common taxa within the *Armillaria* species complex

Pathogen	*Main hosts*	*Range*	*Disease*	*Primary pathogenicity*[a]
Armillaria ostoyae	Conifers	Worldwide, circumboreal	Cambium and sapwood rot	+ + +
Armillaria borealis	Conifers	Northern Europe, Asia	Butt rot	+
Armillaria calvescens	Hardwoods	North America	Butt rot	+
Armillaria cepistipes	Hardwoods	Europe, North America, Japan	Butt rot	+ +
Armillaria mellea	Hardwoods, conifers	Worldwide, circumboreal	Cambium and sapwood rot	+ + +
Armillaria gallica	Hardwoods	Worldwide, circumboreal	Heartrot and sapwood rot	+ +
Armillaria sinapina	Hardwoods, conifers	North America	Heartrot and sapwood rot	+
Armillaria luteobubalina	Hardwoods	Australia	Heartrot and sapwood rot	+ +

[a] Refers to ability of killing hosts: + + +, more aggressive (primary pathogen); + +, less aggressive; +, secondary pathogen.

Table 3 Details on taxa within the *Heterobasidion annosum* species complex

Pathogen	*Main hosts*	*Range*	*Disease*	*Primary pathogenicity*[a]
H. annosum	Pines, spruce	Europe, Asia	Root and root collar girdling	+ + +
H. parviporum	Spruce	Europe, Asia	Heartrot	+
H. abietinum	True fir	Central and southern Europe	Sapwood rot and heartrot	+ +
H. annosum P ISG	Pines, incense cedar, juniper	North America	Root and root collar girdling	+ + +
H. annosum S ISG	True firs, sequoia, Douglas-firs	Western North America	Sapwood rot and heartrot	+ +

[a] Refers to ability of killing hosts: + + +, more aggressive (primary pathogen); + +, less aggressive; +, secondary pathogen.

Table 4 Details on taxa within the *Phellinus weirii* species complex

Pathogen	*Main hosts*	*Range*	*Disease*	*Primary pathogenicity*[a]
Phellinus weirii	Western redcedar	Western North America	Sapwood rot and heartrot	+ +
Phellinus henrichii, North American biological species	Douglas-fir, mountain hemlock, and other conifers	Western North America	Root girdling and sapwood rot	+ + +
Phellinus henrichii, Asian biological species	Conifers	Japan, Siberia	Root girdling and sapwood rot	+ + +

[a] Refers to ability of killing hosts: + + + more aggressive (primary pathogen), + +, less aggressive.

Root Rot Pathogens Shape our Forests

Forest management and the resulting forest structure and composition have a significant impact on root disease epidemiology, and conversely root disease will affect forest structure and composition. Disease severity tends to be higher in forests frequently logged and thinned, in forests with higher tree density, and in older forests. Logging and thinning provide either an abundance of primary infection courts (e.g., for *Heterobasidion annosum*) or may facilitate the secondary root colonization of the remaining stumps by *Armillaria* spp. Denser stands will facilitate secondary spread directly by making root contacts more abundant, and indirectly because of the overall reduced vigor of trees growing in overcrowded stands. Older stands are subject to greater amounts of root diseases; this is due to several factors including the greater availability of a substrate (i.e., roots) in larger trees, the tendency of older trees to be more prone to decay processes, and the loss of structural integrity allowing for some secondary root rots to colonize trees previously unavailable. Finally, larger trees will favor extensive secondary spread because of the presence of larger and far-reaching root systems. Furthermore it has been shown that some root rots grow faster in larger roots. This relationship appears to be true especially if the pathogen is not capable of growing ectotrophically on the root surface (*Heterobasidion*, *Phaeolus*): if ectotrophic growth is possible (*Armillaria*, *Phellinus*), the pathogen may not be limited by the presence of thin roots or the absence of root grafts.

Root diseases will in turn affect forest structure and composition. Root diseases create gaps where regeneration, often by different, light-loving, and more resistant plant species, will take place. Trees on the edge of the gaps will be released and their growth rates increased. In general, root diseases will create ecotones with increased biodiversity. It is clear that trees infected by root diseases become more attractive to bark and ambrosia beetles. Beetle attacks will generally significantly accelerate tree mortality. Diseased trees will also allow for the local growth of beetle populations. When beetle populations surpass certain thresholds, attacks may include neighboring healthy trees and expand tree mortality beyond that predictable solely by the effects of the root disease. Broad generalizations should be avoided when looking at the complex interactions between two natural disturbance agents such as root diseases and insects. In the case of *Inonotus tomentosus*, for instance, diseased trees were shown to be more attractive to beetles only where endemic beetle populations were present.

Droughts, pollution, and wind have been shown to interact with root diseases in increasing tree mortality. Root diseases will also affect nutrient cycling at the landscape level. In the case of ecosystems in harsh environment these effects may be long term. It has been determined that the openings in mountain hemlock (*Tsuga mertensiana*) stands caused by the pathogen *Phellinus weirii* in Oregon result in negative levels of carbon production for about 100 years. Increased nitrogen mineralization processes follow the edge of the expanding root disease center, with important consequences for growth rates of the regeneration and resistance of the remaining standing trees. In this case, therefore, the effects of root diseases may be long lasting.

In some instances, root disease centers are characterized by a complexity in the pathogen population that does not fit the picture of individual infections spreading radially in all directions as shown for *Armillaria* spp., *Inonotus tomentosus*, and *Phellinus weirii*. An alternative hypothesis has been formulated suggesting that initial infection processes may trigger a chain effect in neighboring trees (for instance by allowing more oxygen into roots of neighboring trees grafted to decayed roots) where resident infections may be latently waiting to be activated. Genetic data from true fir infection centers caused by *H. annosum* in California partially support this hypothesis.

Management Options for Root Diseases

Root diseases are virtually impossible to eradicate once they are established, and their introduction may have a long-lasting impact on forest ecosystems. These diseases may also shape the future of forests: once introduced and established they may make a return to the original type of forest an unlikely outcome. For instance, logging and fire suppression have allowed for the establishment of large mortality centers caused by *Armillaria* and *Heterobasidion* spp. in the Yosemite Valley in California. These pathogens will now in turn limit the possibility of regeneration of the forest, and are likely to lead the landscape towards a mosaic of open meadows interspersed by clusters of trees.

When forests are threatened by root pathogens, approaches can be taken to limit their establishment and spread. These interventions are often complex and long term and may be worth executing only if dealing with fragile ecosystems or when the disease has resulted in hazardous trees. Once the biology of the causal organism is understood, precautions can be taken to minimize levels of primary infection. For instance, in the case of *H. annosum* in pine, precautions include treating stumps (important primary infection courts) with chemicals such as borate or urea or, alternatively, applying the biological control fungus *Peniophora gigantea* at the time of cutting. In the case of *H. annosum* in true fir, thinning wounds may represent the most important source of primary infection courts, and thus a strategy aimed at limiting thinning entries or wounding of standing trees may be helpful. Operations should preferably be done when environmental conditions are unfavorable to the pathogen; this strategy has been adopted with some success by logging *Heterobasidion*-infested pine plantations in the southern USA during the hot summer months.

Lowering stand density may regulate secondary spread of the pathogen. Early precommercial thinning, when trees may be too small to be favorable infection courts, or the use of prescribed fires may help achieve this goal. When high-value sites are in question (e.g., campsites, public areas, etc.) a physical disruption of the vegetative growth of the fungus can be attempted. In southern California, trenching the soil and removing two tiers of apparently asymptomatic trees beyond the visible outer margin of an infection center successfully halted the spread of *H. annosum* in pine. In the case of pathogens capable of growing freely in the soil via rhizomorphs, this attempt may be futile, as portions of root systems left behind may actually be ideal colonization substrates for *Armillaria* spp.

If the removal of an individual tree is in question, pathogen identification is essential. For instance, the stump of a felled tree will provide an ideal substrate for *Armillaria* and become a source of inoculum if other trees are in the same vicinity. On the other hand complete removal of the tree, including the root system, may beneficially lower the amount of inoculum.

If a forest is affected by a pathogen with restricted or defined host range, it may be possible to increase the percentage of trees more resistant to the pathogen. Because resistance is often only partial, it may be a good idea to avoid complete removal of the susceptible species, as the resulting selection pressure on the pathogen may result in the infection of plants normally considered nonhosts.

When dealing with trees at the urban–wildland interface, avoid any horticultural treatment or practice that may result in physiological stress. Often even single events, e.g., the overwatering of a tree in the summer, may result in the colonization of that tree by a root pathogen that originally was growing ectotrophically on the roots. In some cases, when trees are affected by root disease but appear to decline very slowly, the application of insecticides on the bark before the tree is attacked may significantly prolong its life. The effects of such treatments are short-lived and valid only for conifers with a known beetle infestation. These treatments require the use of chemicals with a relatively broad spectrum of action and should be used sparingly and only in high-value landscape situations.

Phytophthora Root Rot of Forest Trees

G E St J Hardy, Murdoch University, Murdoch, Western Australia

Introduction

As a genus *Phytophthora* can be considered as the most devastating group of plant pathogens on earth. Members of the genus cause huge economic losses in agricultural crops annually and are extremely destructive in a range of forest ecosystems worldwide. Their direct affect on plant losses is really quite well documented. The genus name is aptly derived from the Greek that means *phyto* (plant) and *phthora* (destroyer). There is still much debate over the taxonomy of *Phytophthora* and there are over 64 species, but this constantly changes with new species being described and others amalgamated as molecular diagnostics tools are used to characterize the genus. Some species such as *P. cinnamomi* have a wide host range whilst others have one to only a few hosts, consequently as a genus it is extremely plastic in terms of the range of plant species it impacts on. This article will provide a general but not a comprehensive overview of the major *Phytophthora* diseases of forest trees and cover impacts, threats, and methods of control.

Life History

The genus belongs to the class Oomycetes in the Kingdom Chromista and is more closely related phylogenetically to the heterokont algae than the true fungi or Mycetae. Oomycetes are diploid, have a coenocytic thallus or mycelium, and they reproduce asexually to produce chlamydospores or by the production of sporangia. Chlamydospores are formed terminally at tips of hyphae or are intercalary. They can be thin- or thick-walled and function as survival spores. Sporangia or more correctly zoosporangia are produced under warm and moist conditions from specialized hyphae or sporangiophores. The sporangia can germinate directly to produce a germ tube or indirectly to produce uninucleate, biflagellate zoospores within the sporangium. The zoospores emerge from the sporangium into a temporary vesicle that rapidly breaks, allowing the zoospores to swim away. The zoospores are propelled by two flagella; one is a long whiplash and the other a shorter tinsel. The zoospores can remain motile for hours and are attracted chemotactically to substrates where they encyst. The cysts germinate to produce a germ tube and if appropriately located will invade living organs of susceptible plant species to cause disease.

The sexual structures of *Phytophthora* consist of an oogonium (egg-containing female component) and an antheridium (male component). Reduction division (meiosis) of the chromosomes from the diploid to haploid in nuclei occurs in the coenocytic antheridium and oogonium (**Figure 1**). Sexual reproduction occurs when a fertilization tube from the antheridium deposits its nucleus inside the oogonium, fusion between the two nuclei occurs, and an oospore forms within the oogonium. Oospores like chlamydospores are survival spores and under suitable environmental conditions will germinate to produce single to multiple germ tubes at the tips of which sporangia can

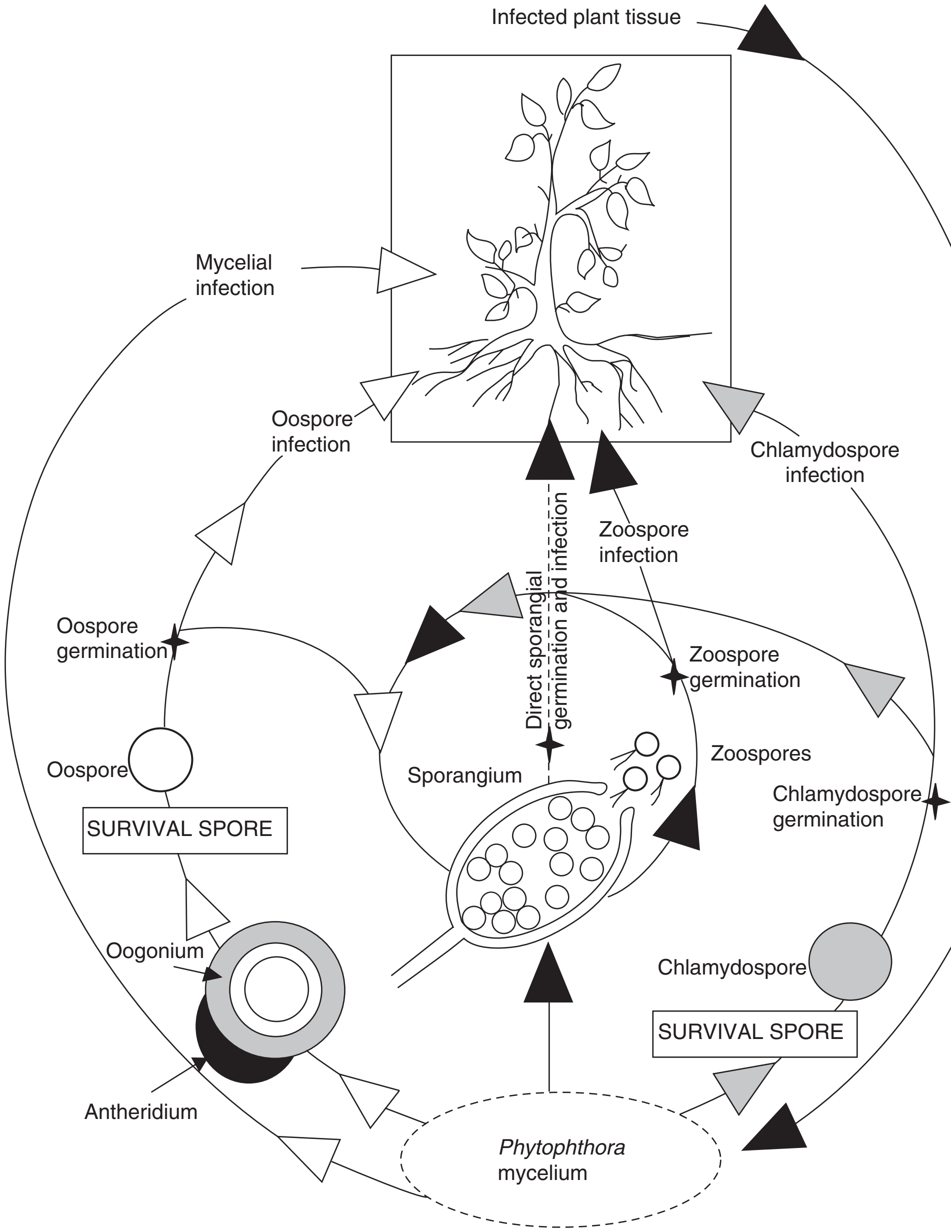

Figure 1 *Phytophthora* life cycle and infection strategies.

form. However, in some self-fertile (homothallic) species, oospores can be important sources of dissemination, germinating rapidly to produce sporangia under optimum conditions.

Phytophthora species are either homothallic or self-sterile (heterothallic). In the heterothallic species two compatible mating types must make contact before oospores will form at the point of contact between the two. In heterothallic species, the crossing of compatible (A1 and A2) mating types is likely to be the source of new races or biotypes, whilst in homothallic species, oospores function as survival propagules in plant debris.

The above characteristics of *Phytophthora* make it unique among pathogenic fungi since members within this genus are able to initiate and cause disease on nearly all parts of the host plants. In forest trees this includes the roots and collars (e.g., *P. cinnamomi*) and foliage (e.g., *P. ramorum*).

Spread

It is highly likely that many phytophthoras have been spread between countries and continents since the European settlement of the Americas, Australasia, Africa, and other countries. This would have occurred in the soil of containerized horticultural and ornamental trees being transported between countries. For example, *P. cinnamomi* was likely to have been introduced on planting stock into Australia on one of the first sailing ships from Europe. More recently, as trade barriers break down within the European Union, less stringent quarantine regulations will certainly provide avenues for the transfer of different *Phytophthora* species between regions. This introduces *Phytophthora* species to new hosts that previously have had no contact with a particular *Phytophthora* species and/or alternatively allows sexual reproduction to occur between compatible species allowing for new hybrids to develop. The latter is a likely scenario for the alder phytophthoras (see below).

Once in a region, phytophthoras can be spread through the movement of soil on vehicles, heavy earth-moving equipment, on the feet of hikers, feral or wild animals, surface water flow, and infested nursery stock. Consequently, once phytophthora are present, autonomous spread and spread through the movement of vehicles, people, and animals are extremely difficult to control.

Symptoms

In susceptible trees, many types of symptoms are observed and these depend on the *Phytophthora* species and the host species being colonized. In many trees, primary invasion is through the small absorbing roots and causes brownish to black firm roots with little progression into the larger lateral roots. In this case decline and death tends to be gradual and often associated with other predisposing biotic or abiotic factors. In other hosts, *Phytophthora* invades the lateral roots and colonizes the phloem girdling the roots and frequently moving up into the collars of the tree, where cankers are produced. Cankers can cause cracking of the stem or trunk, bleeding or exudation of kino or red sap, often with entire girdling of the trunk, leading to a restriction of transpiration, followed by tree death.

In broadleaved trees, invasion results in a gradual deterioration of the crown, with chlorosis, reduction in leaf size, absence or reduced new growth, wilting of leaves, and dieback of small branches usually being the first symptoms. These are followed by the development of epicormic shoots on large branches, which over time will die back resulting in a gradual decline leading to the eventual death of the host, although in highly susceptible hosts death can be extremely rapid.

In conifers, wilting does not usually occur and in 'littleleaf' disease of pine, for example, the first symptoms are yellowing of the foliage and needles that are smaller than usual; thereafter shoot growth decreases. In many tree species, decline can be slow and trees do not die until many years after infection.

Predisposing Factors

As with all plant diseases the key components of the *Phytophthora* disease – host, pathogen, environment, and time – are all necessary for a disease to occur. In the absence of the pathogen or a susceptible host disease will not occur. *Phytophthora* species generally require moist and warm conditions in order to cause disease; if these conditions are not present or present for too short a time, again disease will not occur. Consequently, it is critical to understand these factors when considering the biology, ecology, and pathology of a *Phytophthora* pathogen and the diseases it causes. For example, oak decline in Europe and adjacent parts of Asia has been associated with a variety of *Phytophthora* species (**Table 1**).

However, oak decline is also recognized to be a multifactorial disease syndrome with predisposing factors (e.g., industrial pollution, climatic extremes, and inappropriate site), inciting factors (e.g., drought, frost, waterlogging, insect attack, soil nutrient characteristics), and contributing factors (e.g., secondary pathogens) all contributing to decline in certain circumstances. Therefore, predisposition can and does play a role in disease syndromes associated with *Phytophthora* species. A predisposing factor such as drought will frequently speed up death of infected plants.

Phytophthora cinnamomi in Australasia

Over 31 *Phytophthora* species have been associated with plant deaths in Australia. The majority of these are horticultural, agricultural, or nursery pathogens with only *P. cinnamomi* causing major losses to forest trees. The loss of floristic and structural diversity, and consequential effects on faunal diversity are now considered a major problem of ecosystem breakdown and economic loss. As a result, *P. cinnamomi* has been listed as a 'key threatening process' to Australia's biodiversity in the Commonwealth's Environment Protection and Biodiversity Conservation Act 1999. *Phytophthora cinnamomi* is one of 11 key threatening processes and the only microorganism listed.

The major impact and threat is to open forests, woodlands, and heathlands of southern Australia. Its impact has been likened to that of the last ice age by botanists. For example, in the southwest of Western Australia alone it affects over 2000 of the approximately 7000 native plant species, of which 3000 are

[a]This list of *Phytophthora* species and hosts is not intended to be comprehensive but rather indicative of the number of each involved in tree decline and death.
[b]*Phytophthora* species isolated from soils in association with forest trees; pathogenicity still to be ascertained through further testing.

endemic; a number of these are important woodland or forest species.

On infested sites, resistant species that replace susceptible plant species tend to be wind-pollinated and do not produce nectar or nutrient-rich pollen and, therefore, do not attract or provide food sources for birds or smaller animals. Regeneration of such sites with susceptible species may never occur if seed reserves are lost; consequently many birds and animals may be lost from infested sites.

Phytophthora cinnamomi in the Americas

Phytophthora cinnamomi has been introduced into most forested regions of the western hemisphere and elsewhere in the world, where it has considerable impact in a range of forest species. It caused significant and catastrophic deaths of American chestnut and related *Castanea* species in forests and woodlands in the USA and removed much of the chestnut from the southern Appalachian foothills. Deaths were first reported in the early 1820s and it was not until 1932 that *P. cinnamomi* was associated with dying chestnut. Together with *Cryphonectria parasitica*, *P. cinnamomi* has essentially removed American chestnut from this region. *Phytophthora cinnamomi* is also the cause of 'littleleaf' disease in shortleaf pine (*Pinus echinata*), where it has caused decline across much of the tree's range in the southern USA. Unlike its association with *Castanea* and the many plant species in Australia where it attacks the main root system and stems of trees, *P. cinnamomi* is a fine feeder root disease in shortleaf pine. It plays a central role in 'littleleaf' disease as it causes severe fine root mortality, predisposing trees to other biotic and abiotic influences that contribute to the disease syndrome.

Phytophthora cinnamomi also causes the decline and death of oaks in Mexico. Although widespread in forests in the Pacific Northwest, *P. cinnamomi* does not impact severely if at all on many susceptible tree species since it is too cold in the wet winters and too dry in the hot summers for it to cause disease. This indicates the importance of the interactions of disease factors for disease to occur in the presence of the pathogen.

Phytophthora cinnamomi and other *Phytophthora* spp. in Europe

Phytophthora cinnamomi has been associated with oak decline throughout Europe and the Mediterranean region, and of all the *Phytophthora* species associated with oak, it is the most devastating. Oaks affected include *Q. cerris*, *Q. frainetto*, *Quercus ilex*, *Q. petraea*, *Q. pubescens*, *Q. pyrenaica*, *Q. robur*, *Q. rotundifolia*, *Q. rubra*, and *Q. suber* (**Table 1**). In Europe, the oak decline phenomenon is a complex disease with predisposing, inciting and contributing factors also contributing to the decline syndrome. *Phytophthora cambivora*, *P. citricola*, and *P. quercina* have also been associated with fine feeder root disease of oaks in Germany and are probably involved in oak decline, although their precise roles are still to be determined.

A total of 13 *Phytophthora* species has been recorded in Europe, with *P. cambivora*, *P. citricola*, and *P. quercina* being widespread. Frequently, *P. cinnamomi* and *P. cryptogea* are restricted to warmer climatic regions of Europe, *P. europaea*, *P. gonapodyides*, and *P. uliginosa* to wet sites, *P. pseudosyringae* sp. nov. to acid sites. There are infrequent isolations of *P. cactorum*, *P. megasperam*, *P. psychrophila*, and *P. syringae*. *Phytophthora* species are certainly associated with oak decline. However, more research is required to understand fully their interactions with abiotic and other biotic factors.

Phytophthora lateralis

The ecologically and economically important forest cedar, Port-Orford-cedar (*Chamaecyparis lawsoniana*) endemic to southwest Oregon and northwest California is severely affected by the introduced *P. lateralis*. It rapidly colonizes trees through the fine roots until it reaches the main stem. The pathogen also infects and kills the Pacific yew (*Taxus brevifolia*), but only when it grows in close association with Port-Orford-cedar. *Phytophthora lateralis* was rapidly spread throughout the native range of Port-Orford-cedar along the Oregon coast with road building and logging activities during the 1950s.

The endemic range of *P. lateralis* is still unknown. However, its introduction into Oregon and California before the 1920s, when deaths were first observed, illustrates how unregulated international plant movements in the horticultural trade has resulted in devastating forest tree epidemics. Deaths of Port-Orford-cedar along infested streams are especially high; however, today the impact appears to be less dramatic, as most of the vulnerable cedar stands are already infected.

Most disease management is directed around road management, such as wet season closures, and washing down of vehicles before moving between infested and noninfested areas. These sanitation activities reduce the likelihood of spread by reducing inoculum loads along roads. In addition, the most vulnerable trees growing along roads are removed. Recently, heritable resistance in Port-Orford-cedar has been shown to exist and breeding is a viable strategy to provide resistant planting stock into forest areas where the pathogen is present.

Phytophthora ramorum

Phytophthora ramorum was first described in 2001 from Germany and the Netherlands associated with blight disease in *Pieris* spp., *Rhododendron* spp., and *Viburnum* spp., although the disease caused by this pathogen had been observed since 1993. It is yet to be isolated from oaks in Europe, but pathogenicity experiments under controlled quarantine conditions indicate that a number of forest tree species (**Table 1**) including *Fagus* and *Quercus* species are susceptible to *P. ramorum*. Therefore, the risk to forest species in Europe is great.

In the USA, 'sudden oak death,' a rapid mortality of oaks (mainly tan oak and live oaks) in wildlands and the urban–wildland interface, has been observed since 1994 in the coastal fog belts of southern Oregon and northern California and is also caused by *P. ramorum*. The disease is currently in epidemic proportions in coastal California, covering an area that runs approximately 600 km south to north from central California to southern Oregon. It has a wide host range including a range of tree species (**Table 1**) and shrubs. In the oak family, all the susceptible species belong to the red oaks (section *Lobatae*), whilst so far no white oaks (section *Quercus*) or golden cup oaks (section *Protobalanus*) are found to be susceptible.

In Europe, only the A1 sexual compatibility type has been found which contrasts to the presence of only the A2 sexual compatibility type in North America. The internal transcribed spacer sequences of the European and American isolates are identical. In mating tests, the isolates rarely, if ever, mate together. Consequently, it is unclear whether *P. ramorum* has a normally functioning A1 × A2 outcrossing system. *Phytophthora ramorum* is exclusively aerial in its biology, unlike other *Phytophthora* species that cause disease in forest trees which are predominantly soilborne pathogens. Although recovered from soil and litter, *P. ramorum* has not been observed to cause symptoms below the soil line. It has been recovered from up to 20 m above the ground from stems with no basal cankers. However, it is still not understood how the pathogen has spread so widely, although it is recovered from rainwater indicating its possible dissemination by rain splash and wind-driven rain.

In northern America, the current geographic range of the disease includes a wide range of forest types within the Mediterranean climatic region of California receiving predominantly winter rainfall and with mean annual rainfall ranging from 85 to 200 cm. It is known to have a wide host range which includes members of the *Caprifoliaceae*, *Ericaceae*, *Fagaceae*, and *Lauraceae* and it is likely that other susceptible taxa will be found.

Of concern is the observation from pathogenicity tests that a number of Australian species from a range of families are susceptible to *P. ramorum*; this includes members of *Eucalyptus* spp. (Myrtaceae) a keystone plant genus of many plant communities. Therefore, if introduced into Australia, it is likely to be a major ecological threat to southern Australian forest or woodland ecosystems with a similar climate to California. The risk is real since *P. ramorum* has very recently been isolated from an ornamental *Rhododendron* species on the island of Mallorca (Spain), another Mediterranean environment. Consequently, it is critical that stringent quarantine measures are in place to ensure *P. ramorum* does not enter Australia or other countries where it is likely to be a problem.

Alder Phytophthora

In 1993, a lethal disease of alder (*Alnus* spp.) was observed in horticultural shelterbelts and along rivers in Britain. It was caused by a new *Phytophthora* species that superficially resembled *P. cambivora*, a common pathogen of European hardwood trees. The disease is now found through much of Europe, including Austria, Belgium, France, Germany, Hungary, and the Netherlands. Trees of all age classes are affected and symptoms include small and yellow leaves, tarry spots and exudations, top dieback, and death. The alder phytophthora is hard to isolate as it is considered a primary parasite and is soon replaced by other more opportunistic but secondary pathogens. Therefore, a range of insect pests and other pathogens are frequently isolated from alders but these are probably a result of the alder phytophthora predisposing the trees to secondary invasion.

The alder phytophthora comprises a range of species hybrids, with a common 'standard' alder phytophthora type found throughout much of Europe. The parents of the alder phytophthoras are probable hybrids between two developmentally different phytophthoras: *P. cambivora*, a fast-growing, sexually outcrossing species, and a phytophthora close to *P. fragariae*, a slow-growing, inbreeding and nutritionally fastidious species.

The standard alder phytophthora is extremely difficult to isolate from soil around diseased alder trees; thus its oospores are unlikely to contribute to survival or spread in the field. Local spread along river systems is probably via zoospores and through dispersal of infected alder debris containing healthy mycelium. International spread may have occurred through the distribution and planting of infested nursery stock. The alder phytophthora represents a serious threat to both natural and managed stands of alder and to the stability of riparian ecosystems in Europe and possibly elsewhere if introduced into other countries.

Currently, there are no clearly defined control strategies in place, although early coppicing of diseased trees is being considered. Trials are being established to evaluate whether differences in disease resistance are present within *Alnus* species.

Other *Phytophthora* Diseases

Many *Phytophthora* species have been isolated from the soils under rainforest, temperate forest, and Mediterranean forest plant species and have not been associated with plant deaths. For example, these include *P. katsurae*, *P. megasperma* var. *sojae*, and *P. palmivora* from rainforest in Papua New Guinea; *P. cactorum* in Australia; *P. europaea*, *P. psychrophila*, *P. citricola*, and *P. uliginosa* from under oaks in Europe; and *P. gonapodyides* in Australia, Europe, and North and South America.

Phytophthora gonapodyides does cause significant damage to fine roots of *Castanea* and *Quercus* in Europe; and with further research is likely to be associated with tree declines in Australia and North and South America. However, it is likely that these could become pathogenic as a result of climate change or through the breakdown of quarantine practices. If, for example, new species are introduced into a region it is possible that hybridization between these and existing species could occur resulting in destructive pathogens. This was the case observed for the alder pathogen in Europe.

Impact on Ecosystem Health and Function

Although it is reasonably well understood how different *Phytophthora* species impact directly on plant species, we have very little understanding on how they impact indirectly on ecosystem health and function. For example, we do not fully appreciate how the loss of the litter layer, changed soil-water status, loss of cover to shade-loving plant species, the loss of vertebrate and invertebrate pollinators, and the potential loss of the fruiting bodies of ectomycorrhizal fungi influence the function and health of ecosystems. These indirect effects are likely to be very profound. For example, in Australia, *P. cinnamomi* has been shown to impact adversely on fauna through the loss of habitat and food sources such as pollen, nectar, and possibly fruiting bodies of epigeous and hypogeous macrofungi, many of which are ectomycorrhizal. A number of small marsupial species rely almost totally on fungal fruiting bodies in their diet, so a decline in a fungal host species can result in loss of animals from an impacted environment. In turn, a loss of animals that turn over soil whilst digging for fungi can affect the incorporation of litter into the soil and result in the increased incidence of nonwetting soils. Reduced soil water uptake can result in increased erosion through increased surface water runoff and drought stress.

These are just a few examples of how *Phytophthora* species can impact on ecosystem function and health, and only very recently have researchers started to take a more holistic approach to examine the wider implications of plant diseases caused by *Phytophthora* diseases on communities in general.

Control

Effective hygiene and quarantine measures must always remain the primary methods of control and containment of all forest pathogens. These must include the stringent control of movement of plant material between regions, countries, and continents. The majority of *Phytophthora* diseases in forests today appear to be the result of new introductions into a region. Therefore, it is critical to stop the spread of the pathogen(s) into noninfested areas. Disease management aims to prevent and restrict spread and intensification of the pathogen and to protect and conserve conservation and economic values and includes:

- rating hazard or identifying levels of risk
- assessing risk or analysis of risk at the landscape level
- hygiene procedures
- manipulating conditions to disfavor the pathogen and to enhance host resistance
- education of the public and land managers and users
- appropriate use of research to address questions as they arise.

Chemical Control

Recently, in Australia, phosphonate compounds applied as foliar applications from aircraft, backpacks, or by trunk injection have been extremely effective in reducing the impact and spread of *P. cinnamomi* in forests and natural ecosystems. Control by one trunk injection have been extended beyond 6 years in some forest species and by 2–3 years with aerial applications. Consequently, applications along disease fronts or to plant communities containing rare or threatened plant species can be a viable and effective way of maintaining plant communities.

Phosphonate (also referred to as phosphite), the anionic form of phosphonic acid $(HPO_3)^{-2}$, controls many plant diseases caused by a range of *Phytophthora* spp., even at concentrations *in planta* that only partially inhibit pathogen growth *in vitro*.

Phosphonate is a systemic fungicide that is translocated in both the xylem and the phloem. In the phloem, phosphonate is trapped and therefore translocated through the plant in association with photoassimilates in a source–sink relationship. Phosphonate treatment induces a strong and rapid defense response in the challenged plant. These defense responses stop pathogen spread in a large number of hosts. Phosphonate exhibits a complex mode of action, acting directly on the pathogen and indirectly in stimulating host defense responses to ultimately inhibit pathogen growth. Recent work in the USA has also shown the chemical to be effective on *P. ramorum*.

It is critical to add an adjuvant when applying phosphonate as a foliar application, otherwise efficacy and persistence of the chemical are severely limited. These increase spray coverage by droplet spreading, promoting spray retention, and reducing spray drift, evaporation and wash-off. Care must be taken to ensure adjuvants are not phytotoxic in their own right.

It is important that plants are treated when they are actively growing and not drought-stressed otherwise uptake and distribution of phosphonate is substantially reduced. Rates of application vary significantly between plant species and communities. In Australia, foliar applications to runoff vary between 0.5% and 2.0% (5–$20\,g\,l^{-1}$), whilst aerial applications are normally in the range 12–$36\,kg\,ha^{-1}$ applied as ultra-low-volume sprays. Trunk injections vary between 5% and 20% (50–$200\,g\,l^{-1}$) depending on the species to be injected. Phosphonate can cause severe phytotoxicity and plant deaths if inappropriate concentrations are applied; consequently it is important to conduct preliminary trials before applying the chemical to large areas. It is important to note that although the chemical contains the spread of the pathogen *in planta* it does not always kill it. Therefore, the pathogen can still reproduce and disseminate its infective propagules under optimum environmental conditions. Reduced flowering, pollen viability, and seed viability have been observed in some species and more research is required to determine the long-term impacts of these. To date no adverse affects have been observed on mycorrhizal fungi. However, there is some evidence that repeated applications of phosphonate in horticultural situations does select for phosphonate-tolerant isolates of *P. cinnamomi*, and these isolates also appear to be more virulent. In natural ecosystems, where the chemical is applied infrequently it is unlikely that selection for tolerant *Phytophthora* isolates will occur. The main concern is the movement of supposedly 'pathogen-free' container plant stock from nurseries into areas where the pathogen can escape into forested regions. If these contain tolerant *Phytophthora* isolates problems may arise in the future. Irrespective, of these possible drawbacks, phosphonate provides us with a very viable control option for plant species or individual trees of importance whilst alternative control strategies are developed.

Conclusion

Phytophthora as a genus is extremely plastic in terms of genetic and phenotypic variability, pathogenicity, host range, and long-term survival strategies. As exotic pathogens they are devastating in forest and other plant ecosystems as has been observed in Australia, Oregon, Europe, and elsewhere. It is apparent that there are numerous *Phytophthora* species, with many still to be described in forests worldwide. The biology, ecology, pathology, and genetics of the majority of *Phytophthora* species are still poorly understood. However, it is clear that in addition to the presence of a pathogen and a susceptible host, conducive environmental conditions are critical for a *Phytophthora* disease outbreak to be triggered. Often only small shifts in environmental conditions whether biological, chemical, or physical are required to trigger a *Phytophthora* disease event. Therefore, with increasing global movement of humans and their associated plant produce, and climate change through global warming, new outbreaks of devastating *Phytophthora* diseases are likely to occur.

Vascular Wilt Diseases

K Jacobs and M J Wingfield, University of Pretoria, Pretoria, South Africa
J N Gibbs, Aberyail, Llangynidr, Wales, UK

Introduction

The vascular wilts include some of the most destructive of all tree diseases, in terms of both the scale of the damage and the speed of attack. Vascular wilt diseases mainly occur in angiosperms and only one example in a gymnosperm has been documented. True vascular wilts are caused by fungi, although there are some similar diseases caused by bacteria. Pine wilt disease caused by the pine wood nematode *Bursaphalenchus xylophilus* is covered elsewhere (*see* **Pathology**: Pine Wilt and the Pine Wood Nematode).

The Characteristics of Vascular Wilt Diseases

The fungi that cause vascular wilt diseases are initially restricted to the xylem elements. They can often achieve rapid dissemination within these elements through the passive movement of spores in the transpiration stream. Xylem anatomy can influence this process, with ring-porous genera, such as oaks and elms, that have large, long earlywood vessels which are particularly vulnerable to invasion. Vascular wilt pathogens often grow out from the xylem into the surrounding tissues after the tree has died. This enables them to establish contact with the outside world and, in particular, with insects that can act as vectors for transport to new hosts. Typically, vascular wilt pathogens do not have the capacity to survive long in the tissues of a dead host.

Generally, all vascular wilt diseases display similar symptoms. Leaves and young shoots on one or more branches suddenly wilt and die. If such a branch is cut, a marked discoloration can often be observed in the xylem of the current year. In a severe attack, symptoms can rapidly develop to kill the whole tree. Much still remains to be learnt about the process of pathogenesis. Vascular wilt fungi have the capacity to produce conidia in water-filled xylem vessels without causing cavitation (i.e., the breaking of the column of water). This can lead to rapid dissemination of the fungus throughout the tree in the transpiration stream. However, at some stage cavitation and an interruption to the water flow will occur. Gums, gels, and toxins may also be produced. In some cases the tree responds by producing balloon-like tyloses within the vessels by extrusion from adjacent parenchyma cells.

Ascomycetous fungi (and related mitosporic fungi) are responsible for most true vascular wilt diseases. Important examples are Dutch elm disease (*Ophiostoma ulmi* and *O. novo-ulmi*), oak wilt (*Ceratocystis fagacearum*), black stain root disease of conifers (*Leptographium wageneri*), and verticillium wilt (principally *Verticillium dahliae*). These diseases are discussed separately below.

Fungal Wilt Diseases

Dutch Elm Disease

Dutch elm disease has caused devastation to elms in Europe and North America. It is caused by two different, although closely related, species of fungi: *O. ulmi* and *O. novo-ulmi*. *Ophiostoma ulmi* was responsible for the first epidemic, which began in the

Netherlands (hence the name) in the late 1910s and quickly spread through much of Europe. In the late 1920s it was introduced to North America, where it proved to be particularly damaging on *Ulmus americana*. The second epidemic, caused by *O. novo-ulmi,* and proving to be very destructive in Europe, began in the late 1960s. It is now known to have developed from two centers, one in Eastern Europe and the other in the mid-west of North America. Two subspecies of *O. novo-ulmi* are associated with these two centers. Hundreds of millions of elms have been killed and huge sums spent in attempts at control and in the removal of dead trees. Most elm species are susceptible to the disease, with the American elm being especially vulnerable to both species of the fungus (**Figure 1**). Where there is some resistance, as in the Siberian elm, it is often found in trees that are lacking in aesthetic and silvicultural qualities.

The first symptoms of Dutch elm disease on a previously healthy tree typically take the form of the wilting or yellowing of the leaves on a vigorously growing branch in midsummer. Such a branch will show pronounced streaking in the vessels of the outermost xylem ring. The speed of subsequent symptom development down the branch and into the rest of the tree will depend, *inter alia*, on the species of host and pathogen involved. In some cases symptoms may remain relatively restricted in the first season, only to flare up throughout the crown early in the second season. Rapid general symptom development occurs if a tree becomes infected as a result of the transmission of the pathogen via grafted roots from an adjacent tree.

Various bark beetles act as vectors of the pathogen. The most important of these are *Hylurgopinus rufipes* and *Scolytus multistriatus* in North America and *S. scolytus* in Europe. (*see* **Entomology**: Bark Beetles). From the infection viewpoint, the key event is the establishment of the fungus within water-filled xylem vessels to which it has gained access by the feeding activities of the beetles. Early stages of colonization may be quite slow. However, once in the large, long, springwood vessels, spores of the fungus can be disseminated very rapidly under the influence of transpiration. They can also be drawn from a diseased tree to a neighboring healthy one if the trees have developed on a common root system or have grafted together (**Figure 2**).

Deleterious viruses may be present within the mycelium of *O. ulmi* and *O. novo-ulmi* and can lead to a reduction in pathogenicity. These viruses, known

Figure 1 English elm (*Ulmus procera*) killed by Dutch elm disease during the early 1970s. Photograph courtesy of J. Gibbs.

Figure 2 A hedgerow of English elm which has originated as sucker growth. Dutch elm disease is spreading rapidly through the common root system that links the trees. Photograph courtesy of J. Gibbs.

as d-factors, can spread from one unit of mycelium to another, provided that the latter is vegetatively compatible (i.e., belong to the same vc-group). Within *O. novo-ulmi,* one vc-group predominates, making it vulnerable to infection. However, hybridization between *O. novo-ulmi* and *O. ulmi,* once the former has moved into a new area, can lead to an exchange of vc-genes and hence to the formation of new vc-groups.

Management of Dutch elm disease requires effective removal and destruction of diseased or dead trees to reduce breeding material for the bark beetles. Disruption of root grafts between infected and healthy trees can restrict movement of the pathogen. In the case of trees of high value, fungicidal injections can be used. Breeding programs have resulted in the release of a number of resistant trees.

Oak Wilt

Oak wilt, caused by *C. fagacearum,* is a wilt disease known only in North America, where it mainly affects oaks (*Quercus* spp.) belonging to the red oak group. Currently the disease occurs in 21 states of the USA and has been recorded on 20 species of oak. *Ceratocystis fagacearum* is considered to be potentially as destructive as the fungi causing Dutch elm disease, but while they have effective vectors for dispersal, the oak wilt fungus currently lacks such vectors.

In red oaks such as *Q. rubra* and the northern pin oak (*Q. ellipsoidalis*), disease symptoms spread rapidly throughout the crown and trees can die within a few weeks. In contrast, white oaks such as *Q. alba* and bur oak (*Q. macrocarpa*) are substantially less susceptible. The disease progresses slowly with only a few branches being affected each year. In some cases trees may recover. In the live oaks of Texas (*Q. fusiformis* and *Q. virginiana*) the leaves become chlorotic or bronze, often with a yellow or brown color along the veins. Trees may defoliate and die quickly but commonly survive for several years (**Figure 3**).

Through experiments conducted in the USA, it has recently been discovered that the European white oaks *Q. robur* and *Q. petraea* are highly susceptible to *C. fagacearum*. This discovery, combined with the recognition that the European oak bark beetle, *S. intricatus*, has the characteristics to make it an effective vector for this fungus, has reinforced

Figure 3 (a) A red oak (*Quercus ellipsoidalis*) killed by oak wilt. A healthy tree can be seen in the background. (Courtesy of JN Gibbs; in Forestry Commission Collection.) (b) A white oak showing symptoms of oak wilt on one branch while adjacent branches remain healthy. Courtesy of JN Gibbs; now in Forestry Commission Collection.

concerns that the fungus could be extremely destructive were it to cross the Atlantic. Strict quarantine regulations are in force.

Ceratocystis fagacearum moves rapidly through the xylem, as spores are drawn along in the transpiration stream. This process is aided by the fact that the fungus commonly enters a tree via root grafts with a neighboring tree that is already diseased. After tree death, *C. fagacearum* grows out of the xylem and forms mats of mycelium just below the bark. The bark splits open as a result of pressure exercised by a special structure, the pressure cushion, and volatiles produced by the fungus act as attractants for insects such as sap-feeding beetles (Coleoptera: Nitidulidae). The insects become contaminated with conidia and ascospores from the fungus mats and, if they move to fresh xylem wounds on healthy trees, are capable of transmitting the pathogen. Trees are most vulnerable in late spring and early summer shortly after the new earlywood (springwood) vessels have become functional. There are several weak points in this association between insect and fungus. For infection to take place, wounds on susceptible trees have to be less than 3 days old. Moreover, relatively few of the insects visiting the wounds are carrying spores of the fungus.

Oak wilt is best managed by preventing infection. This is achieved through removing diseased stems on which sporulating mats might form (or by treating them to stop mat production) and by taking steps to minimize the creation of wounds on valued trees in late spring/early summer. Root grafts can be disrupted to prevent tree-to-tree spread. As with Dutch elm disease, high-value trees can be injected with fungicides, although this is very costly and is restricted to very specific situations.

Black Stain Root Disease of Conifers

Black stain root disease is caused by *L. wageneri*. The disease is restricted to the western USA and parts of western Canada where it has caused significant losses, particularly to Douglas-fir (*Pseudotsuga menziesii*) and ponderosa pine (*Pinus ponderosa*). It is recognized to be of high quarantine significance as it is seen to pose a serious threat to both conifer plantations and indigenous forests elsewhere in the northern hemisphere.

External symptoms of the disease may develop gradually over several years. These include reduced height growth, reduced needle size, and premature needle fall. In the xylem of the roots and lower stems, a black stain can be found, typically in bands that follow the annual rings. Resinosis may be observed and the presence of the disease predisposes the tree to attack by bark beetles and other pathogens.

As in the case of other wilt pathogens, *L. wageneri* colonizes only the xylem elements of the host. Members of the Pinaceae do not have long vessels but only short tracheids, and hence rapid passive transport of spores is not a feature of this disease.

Rather, the fungus grows from tracheid to tracheid via the bordered pits. The dark mycelium of the fungus, together with a discoloration of the tracheids themselves, is principally responsible for the visible stain. In pines, the stained wood may be impregnated with resin and many tracheids may become occluded with tyloses.

Leptographium wageneri represents a species-complex including three different host specific variants, *L. wageneri* var. *wageneri* (occurring on pinyon pine), *L. wageneri* var. *pseudotsugae* (occurring on Douglas-fir), and *L. wageneri* var. *ponderosum* (occurring on jeffrey, lodgepole, and Ponderosa pines). Although all three varieties of *L. wageneri* can infect tree species other than those from which they were isolated, this rarely occurs in nature.

Black stain root disease spreads over relatively small distances through root grafts. Also, the fungus can grow for short distances (up to *c*. 15 cm) through the soil and infect healthy rootlets. For dissemination over longer distances, *L. wageneri* requires insect vectors, in particular bark beetles (Coleoptera: Scolytidae). It has been associated with two weevils *Pissodes fasciatus, Steremnius carinatus*, and the root-feeding bark beetles, *Hylastes nigrinus* and *H. macer*. These last species are thought to be the primary vectors on Douglas-fir and ponderosa pine respectively. These insects colonize declining roots of diseased trees and introduce the pathogen to the roots of healthy trees if attracted to them for maturation feeding or by the presence of preexisting wounds. Infection centers enlarge at the rate of about 1 m $year^{-1}$ but in Douglas-fir stands they tend to slow down markedly when the trees reach 30–35 years of age.

The incidence of black stain root disease is increased by environmental factors. The disease is prevalent near roads or railroad tracks, where logging has occurred or trees have been thinned. Management treatments for disease-prone areas should be those that cause least site disturbance and tree injury. In affected stands, resistant species should be favored.

Verticillium Wilt

Verticillium wilt caused by *Verticillium albo-atrum* and *V. dahliae* is widespread in both temperate and tropical regions of the world. In the northern hemisphere, many woody plants are affected, all in the class of Dicotyledons. Gymnosperms and woody monocotyledons are not susceptible. The two fungi differ in a number of characters and, where proper attribution to species has been made, almost all the cases of damage to woody plants involved *V. dahliae*. Verticillium wilt is principally a problem in nurseries and ornamental plantings, such as those in gardens, parks, and streets, and it rarely occurs in forests and natural stands. It affects several important shade tree genera, including maple (*Acer*), lime (*Tilia*), and ash (*Fraxinus*), as well as some orchard trees such as cherry and apricot (*Prunus* spp.).

Symptoms of this disease can vary depending on the host and the environmental conditions. Most species display wilting and browning of the foliage first, while others may exhibit rapid chlorosis and necrosis of the foliage. In some cases, symptoms develop rapidly to tree death, while in others they are chronic and include slow growth, sparse and distorted foliage, stunted twigs, and dieback. In some species, examination reveals marked xylem staining that varies in color with the host, e.g., in maples it is typically green (**Figure 4**). In others, such as ash, no discoloration can be seen. Most fatalities occur in nursery stock and small trees. In mature trees, chronic infection is more usual, with symptoms

Figure 4 Staining caused by *Verticillium dahliae* in the xylem of a small stem of the Indian rain tree (*Koelreuteria paniculata*). Photograph courtesy of J. Gibbs.

affecting just part of the crown, and recovery the following year being quite common.

Verticillium dahliae differs from the vascular wilt fungi described above in having considerable capacity to survive in the absence of its host. This survival is in the form of dark microsclerotia, which can persist in the soil for up to 10 years. Most information on the infection process comes from studies of herbaceous hosts. Hyphae from germinating microsclerotia invade via root tips and root wounds. In plants not immune to vascular infection, the fungus grows into the xylem where conidia are produced and disseminated into the stem. In the past, fungal toxins affecting leaf function were thought to be key to the development of symptoms but current views emphasize the importance of vascular disruption. Effective host resistance mechanisms are thought to depend on processes such as the rapid production of gels in the vessels to trap and immobilize the conidia, followed by the production of toxic secondary metabolites.

There is little evidence for host specialization in *V. dahliae* and some of the most dramatic disease outbreaks have occurred when tree nurseries have been established on old fields of susceptible species like potato or cotton. Such sites should not be used unless there is the option of carrying out soil fumigation. Once the disease is present in a tree, there may be some scope for promoting natural recovery by improving the growing conditions, although heavy irrigation and nitrogen fertilization should be avoided.

Other Fungal Vascular Wilt Diseases

Strains of *Fusarium oxysporum* cause important vascular wilt diseases on herbaceous and woody plants, particularly in warm temperate and tropical regions. A tree example is provided by *F. oxysporum* f. sp. *pernicosum* that has become a limiting factor in the use of mimosa (*Albizzia procera*) as an ornamental in parts of the USA. The fungus is soilborne, germinating from chlamydospores in the presence of host plants to penetrate both wounded and unwounded rootlets and then to colonize the xylem. Another race of the same fungus is known from *A. procera* in Puerto Rico. *Fusarium oxysporum* has also been implicated in the death of *Acacia koa* in Hawaii. *Ceratocystis albofundus* is the causal agent of Ceratocystis wilt on black wattle in South Africa and other parts of Africa. In the Seychelles, takamaka disease, caused by *Leptographium calophylli*, is a serious problem on takamaka (*Calophyllum inophyllum* var. *takamaka*), a broad-leaved evergreen tree that plays an important role in littoral habitats around the Indian Ocean. The bark beetle *Cryphalus trypanus* has been shown to act as a vector.

Bacterial Wilts

There are a number of wilt diseases of trees caused by bacteria in which the causal organism is restricted to the tissues of the xylem during pathogenesis, if not to the xylem elements. Most notable are bacterial wilt of willow and bacterial wilt of *Eucalyptus*.

Watermark Disease of Willow

This disease was first recorded in eastern England during the 1920s on *Salix alba* var. *caerulea* grown for the manufacture of cricket bats. In the 1930s it was recorded in the Netherlands but it is not known from any other European country. In 1993 it was found affecting several species of willow (*S. bakko*, *S. sachalensis*, and *S. kinuyanagi*) in natural forests in a mountainous part of Hokkaido, Japan. The symptoms involve the wilting of young leaves and shoots in early summer. The foliage turns a reddish-brown and the dead leaves are typically retained on the tree. Cross-sections of the stems of affected shoots show a marked brownish 'watermarking' of the xylem. In large branches and trunks this normally follows the position of one or more annual rings. On exposure to air, the discolored tissues darken and a brownish-black liquid may be exuded (**Figure 5**).

The causal bacterium is a Gram-negative nonsporing rod with peritrichous flagella. It falls within the *Erwinia amylovora* group and has been named *E. salicis*. Microscopic examination of the stained tissues of a diseased tree reveals masses of bacteria in some of the vessels, often in association with tyloses. Ray parenchyma cells show plasmolysis and become necrotic, and bacteria can also be seen in these.

Large numbers of bacteria can ooze from affected branches and it used to be thought that infection resulted from the dissemination of these bacteria by wind and rain to injured tissues on healthy trees. However, serological studies in the UK have shown that the bacterium can be detected in the wood of many healthy trees, and also in the coppice stools that provide cuttings for willow propagation. Isolates from adjacent diseased trees often fall into different groups on the basis of electrotyping and this supports the idea that the bacterium is disseminated within the cutting material in a latent or endophytic state, only developing to cause disease under the influence of some as yet unknown environmental factors.

In the UK a sanitation felling program for symptomatic willows is conducted in commercial

Figure 5 Cricket-bat willow (*Salix alba*) felled because of watermark disease. Staining due to the disease can be seen in the xylem of both trunk and stump. Photograph courtesy of J. Gibbs.

cricket-bat willow plantations. Although there was an initial fall in disease incidence following the introduction of this program in the 1930s, there has been little subsequent evidence for a further reduction in disease. In the Netherlands, serious losses in the 1960s can be attributed to the widespread amenity planting of a number of very susceptible clones of *S. alba*.

Bacterial Wilt of *Eucalyptus*

The bacterium *Ralstonia solanacearum* has been reported to cause bacterial wilt in commercial *Eucalyptus* plantations. This disease was first described in Brazil and later in China, Taiwan, Australia, Venezuela, and South Africa. *Ralstonia solanacearum* is divided in different biovars based on their nutritional requirements and in different races based on their host ranges. Biovars 1 and 3 are able to infect *Eucalyptus* and race 1 has been recorded from all the areas where the disease occurs on *Eucalyptus*.

Symptoms of bacterial wilt on *Eucalyptus* include wilting, leaf drop, reduced growth, discoloration of the vascular system, and death of stems. Infected trees may die within 6 months of showing the first signs of infection. Bacterial exudation can also be seen from the cut surfaces of the stems. Fortunately, only some *Eucalyptus* species are susceptible to this disease and it can be managed by planting resistant species or hybrid close.

Pine Wilt and the Pine Wood Nematode

K Suzuki, The University of Tokyo, Tokyo, Japan

Introduction

Pine wilt is caused by the pine wood nematode *Bursaphelenchus xylophilus* (**Figure 1**). This pine wilt disease, which is endemic to North America, has already spread epidemically to East Asia, and recently to Portugal in Europe (**Figure 2**). *Monochamus* spp. beetles (pine sawyer beetles) are the only insects that disperse the pine wood nematode. The incidence of the disease is closely related to environmental conditions such as high temperature with little rainfall. Pine wilt disease is becoming a serious threat to pine forests in the northern hemisphere.

Figure 1 The pine wood nematode, *Bursaphelenchus xylophilus*. The left image shows the head of a nematode. The right image shows the larvae in a cultural media.

History

Pine wilt was initially recognized as an unusual wilt of pines in 1905 in the port city of Nagasaki in southern Japan, which was the only port open to foreign culture in the nineteenth century. Pine wilt spread thereafter from many port cities in southern Japan. This suggests that the disease is artificially distributed by the shipment of infested logs. The loss of timber by pine wilt showed an abnormal increase in the late 1940s soon after World War II and then pine wilt became a matter of public concern. Thereafter, the damage was called 'matsukuimushi,' which is a general term covering more than 70 species of pine bark beetles and pine wood borers thought to be concerned with pine wilt in those days.

As a causal agent of pine wilt, the pine wood nematode was recovered from a dead Japanese black pine, *Pinus thunbergii*, in 1969. The pine wood nematode is associated with cerambycid beetles, the Japanese pine sawyer, which is a matsukuimushi (**Figure 3**). The pine species susceptible to the disease are Japanese red pine, *P. densiflora*, and the Ryukyu pine, *P. luchuensis*, in addition to Japanese black pine.

In 1979, the pine wood nematode was discovered in Missouri, USA. Most pine species in the USA are moderately resistant to the disease. The pine wood nematode is naturally found in diseased *Abies* spp., *Cedrus* spp., *Larix* spp., *Picea* spp., and *Pseudotsuga* spp. in the USA and Canada. It is hypothesized that

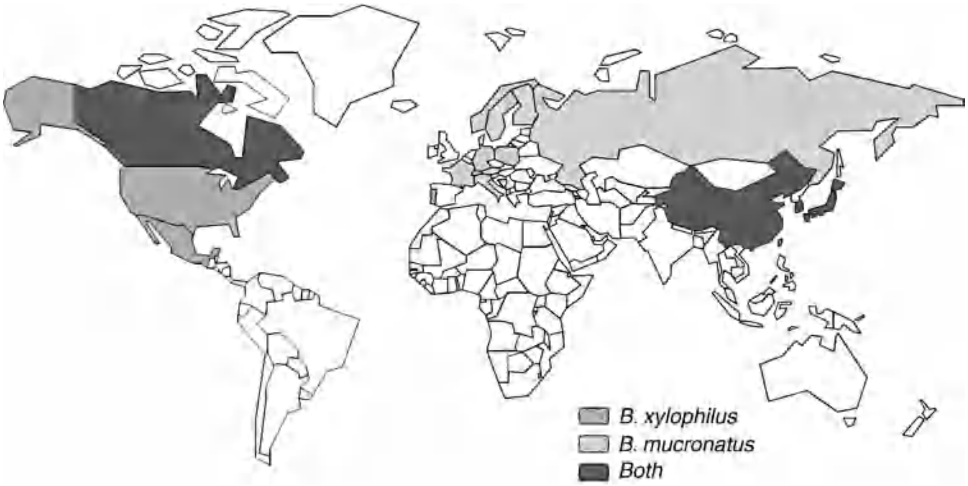

Figure 2 The distribution of *Bursaphelenchus xylophilus* and *B. mucronatus* in the northern hemisphere.

Figure 3 The Japanese pine sawyer, *Monachamus alternatus*.

the pine wood nematode was introduced in pine logs to Japan possibly from the USA early in the twentieth century.

Pine wilt disease had spread to Nanjing, China, by 1982 on Japanese black pine and southern red pine, *P. massoniana*, to Taipei, Taiwan, by 1985 on Japanese red pine and *P. luchuensis*, and to Pusan, Korea, by 1988 on Japanese black pine and Japanese red pine. Recently, pine wilt disease was found at Setubal, Portugal, in 1999 on maritime pine, *P. pinaster*.

The Pathogen, the Pine Wood Nematode

The pine wood nematode was first named as *B. lignicolus* in Japan in 1972, but was morphologically similar to the timber nematode, *B. xylophilus,* in the USA. The genus *Bursaphelenchus* belongs to the family Aphelenchoididae, and *B. xylophilus* was initially described as *Aphelenchoides xylophilus* from the wood of long-leaf pine, *P. palustris,* in 1934. Thereafter, *A. xylophilus* was transferred to the genus *Bursaphelenchus* in 1970. Based on genetic crossing between *B. lignicolus* and *B. xylophilus*, it was elucidated that they are the same species. Therefore, the name of *B. xylophilus* is valid based on the priority of nomenclature for a causal agent of pine wilt disease.

All species of the genus *Bursaphelenchus* have a relation with bark beetles and wood borers. As the pine wood nematode is mycophagous, it can propagate easily on cultures of *Botrytis cinerea* and other fungi. The pine wood nematode is also cultured on callus tissues of Japanese red and Japanese black pines grown on artificial media. This indicates that the pine wood nematode is able to feed on parenchymatous cells of living pine wood.

The pine wood nematode has four larval stages (L_1, L_2, L_3, L_4) and two different forms in its life cycle, that is, a propagative form (L_3, L_4) and a dispersal form (L_{III}, L_{IV}). The former develops under favorable conditions and the latter under unfavorable conditions. As to the propagative stage, females of the pine wood nematode lay an average of 80 eggs during a 30-day oviposition period. The pine wood nematode completes its life cycle in 3 days at 30°C, 4 days at 25°C, 6 days at 20°C, and 12 days at 15°C. No reproduction occurs at a temperature higher than 33°C and the limit of low temperature is 9.5°C for growth on *B. cinerea*. The dispersal stage is adapted to surviving unfavorable conditions, such as low temperature and lack of food. The larva of this stage, which is called the dispersal third-stage larva (L_{III}), is different in its morphological and biological features from the propagative third-stage larva (L_3). Larvae molt to become the dispersal fourth-stage larvae (L_{IV}) in wood under natural conditions. They have specific features such as a dome-shaped head, lack of stylet, degenerate esophagus, and subcylindrical tail. The fourth-stage larvae (L_{IV}, dauerlarvae) are adapted to being carried by the insect vector and are easily transmitted to healthy pines. When dispersal third-stage larvae (L_{III}) are placed under favorable conditions, such as on fungal culture at 25°C, they molt soon after to the propagative fourth-stage larvae (L_4) and multiply rapidly.

Meanwhile, a closely related pine wood nematode, *Bursaphelenchus mucronatus,* is found in declining pines, and is distributed over a geographically wider area than *B. xylophilus* (**Figure 2**). The hosts of *B. mucronatus* are *Pinus* spp. in Austria, Canada, China, Finland, France, Italy, Japan, Korea, Norway, Russia, and Sweden. In addition to *Pinus* spp., *Abies* spp., *Cedrus* spp., *Larix* spp., and *Pseudotsuga* spp., are its host species. *Bursaphelenchus mucronatus* has a similar life cycle to *B. xylophilus*; however, its pathogenicity is very weak. Based on hybridization and phylogeny of the pine wood nematode, the Japanese and the American strains of the pine wood nematode, *B. xylophilus*, are supposed to be derived from common stock of *B. mucronatus* originating in western Europe.

The Vector, the Pine Sawyer

Most species of *Bursaphelenchus* are associated with cerambycid beetles. *Monochamus* spp. called pine sawyer beetles are the only means for dispersal of the pine wood nematode in Asia and USA. *Monachamus alternatus*, the Japanese pine sawyer, is the major vector for *B. xylophilus* throughout Japan, and is widely distributed in Southeast Asia, including China, Korea, Laos, Taiwan, and Vietnam.

Japanese pine sawyer grows and develops each stage linearly in relation to effective temperature. The threshold temperature to commence development of overwintering larvae is 12.5°C. Japanese pine sawyer beetles often complete a single generation in 2 years in a cool climate in northern Japan. In this case, the larvae overwinter as immature larvae and become fourth-instar larvae in pupal chambers after feeding again in the following spring.

Before the emergence of the Japanese pine sawyer in the wood, the dispersal fourth-stage larvae (L_{IV}) of the pine wood nematode enter a body of the adult beetle through the abdominal spiracles and are held in the tracheae. The number of nematodes varies greatly in the body of the beetle. The maximum number of nematodes was recorded as 289 000 per beetle. The adult beetle emerges from May to July. Larvae (L_{IV}) have been observed on the body surface of beetles, mostly on the abdomen, with the largest numbers at the tail tip. The number of nematodes in a beetle's body decreases gradually with time after emergence. The Japanese pine sawyer has been shown to fly a maximum distance of 2.4 km by mark-recapture tests; however, most adult beetles are found around 100–200 m from the release point. Emerging adults of the beetle feed on the bark of pine twigs for maturation and the larvae (L_{IV}) of the pine wood nematode invade the living pine tree from the scars of maturation feeding.

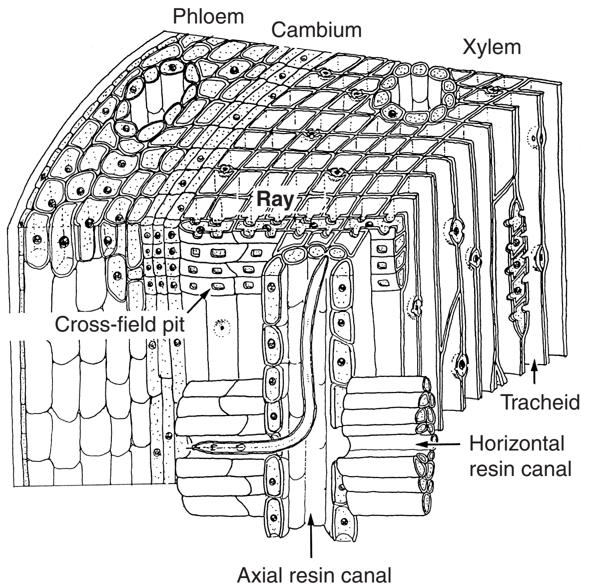

Figure 4 Main anatomical features involved in the movement of the pine wood nematode, *Bursaphelenchus xylophilus*, in Japanese black pine, *Pinus thunbergii*.

Symptoms and Development of Disease

Pine wood nematodes are introduced into the shoots of pine trees during maturation feeding of Japanese pine sawyer beetles. They move initially through cortical resin canals and then migrate rapidly into the whole trunk through xylem resin canals at a maximum speed of 40–50 cm day^{-1} (**Figure 4**). A slight reduction in the flow of oleoresin exudate is observed as a unique symptom at an early stage of the disease. This symptom is due to the destruction of epithelial cells around resin canals by the invasion of the nematode. The nematodes then eventually move from resin canals to adjacent rays, from rays to tracheids through cross-fields, and from tracheids to tracheids through pits. At the same time, enhanced ethylene production is observed 2–3 days after an invasion of pine wood nematodes. The ethylene increase is partially caused by an excretion of a considerable amount of cellulase by the pine wood nematode. The nematode density is very low at an early stage of disease development, often as low as a few nematodes per 100 g fresh weight of wood, even following highly concentrated inoculations.

As a general rule, disease developments following an invasion by the pine wood nematode are divided into two stages: an early stage and an advanced stage (**Figure 5**). In the early stage, cytological changes in the xylem parenchymatous cells occur, and these are soon followed by cavitation and embolism formation in tracheids, which cause dysfunction of conduction in the vascular system of the pine tree. Such internal symptomatology is induced not only in compatible but also in incompatible combinations of pine trees and nematode isolates. However, growth of the nematode population is not assured in pine trees under conditions unfavorable to the nematode, even if a high concentration of nematodes is inoculated. Therefore, this stage is considered to be latent, that is, denaturation of parenchymatous cells by a nematode invasion results in cavitation and embolism of some tracheids.

At the onset of the advanced stage, visible symptoms appear as a severe reduction of the oleoresin exudation rate and a chlorosis of 2–3-year-old needles, accompanied by a decrease in transpiration. This phenomenon is a unique characteristic of pine wilt disease, accompanied by a further increase in ethylene production. Furthermore, death of cambial cells and cavitation of tracheids occur within a large part of the outer xylem, and result in water deficiency, which induces a decrease in both transpiration and photosynthesis. At the same time, other pathophysiological phenomena are observed, for example, electrolyte leakage from pine tissues and production of abnormal metabolites such as benzoic acid. From the onset of

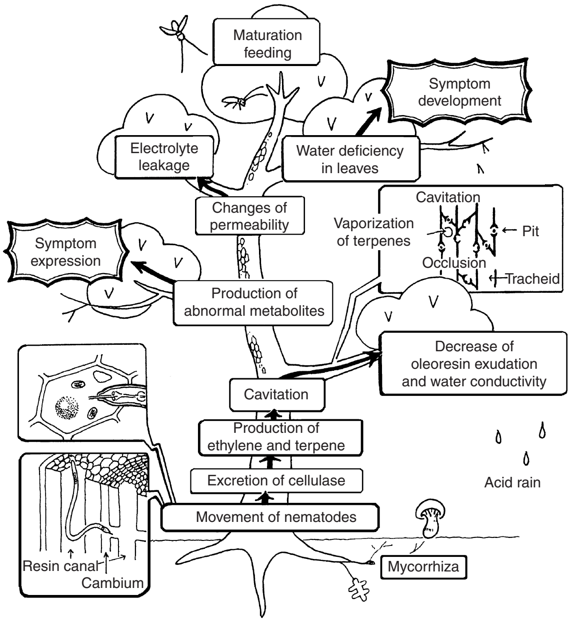

Figure 5 Schematic representation of the wilt mechanisms in the development of pine wilt disease.

water stress, caused by the cavitation of tracheids, the nematode population begins to increase rapidly.

In terms of disease development, the water status of pine trees plays a very important role in the pine tree–pine wood nematode relationship. Experimental results suggest that a lot of pine seedlings do not wilt solely by virtue of numbers of nematodes existing under conditions unfavorable to them, such as a well-watered environment. Empirically, pine wilt disease seems to occur more frequently and to be more destructive in high temperatures with little rainfall. Therefore, these two factors, physiological water status and nematode population density, are considered to be the decisive factors in the development of pine wilt disease.

Disease Control

Before the discovery of pine wood nematode as a causal agent of pine wilt disease, nobody knew an actual pathogen of the disease. However, felling, debarking, and burning of damaged pines immediately proved effective against the disease. Following the discovery of the pine wood nematode as a pathogen of pine wilt disease, the Japanese pine sawyer beetle, *M. alternatus*, was determined as a vector of pine wood nematode. Accordingly, control measures were directed to the Japanese pine sawyer by insecticide spraying.

A large-scale 5-year control project for pine wilt disease was initiated in 1977 by a special law in force in Japan. The project involved aerial spraying to prevent maturation feeding of the Japanese pine sawyer. In spite of these efforts, severe damage was not completely controlled and the disease spread widely from the south to the north of Japan. The reasons for incomplete control are thought to be the limitations of aerial spraying, relying too heavily on the special law in force, and failure to recognize the severity of the disease. In 1997, the special law in force came to an end after three revisions and having been enforced for 20 years since 1977, because considerable damage was continuing and it is still a great threat to the community and the landscape in Japan. Thus, the measures included in the special law in force were incorporated in the common law on forest pest control in 1997.

Control measures against the disease are aimed at breaking the pine tree–pine sawyer beetle–pine wood nematode disease triangle. Present control measures consist for the most part in aerial spraying of insecticides that are effective against the pine sawyer (to break the pine tree–pine sawyer relations), trunk injection of chemicals active against the pine wood nematode (to break the pine tree–pine wood nematode relations), and spraying of insecticides on timber damaged by infestation (to kill the Japanese pine sawyer).

Meanwhile, present control measures are classified under three categories: (1) direct control measures of felling and extermination; (2) preventive control measures of aerial/ground spraying and trunk injection; and (3) biological control measures of pathological microorganisms (*Beauveria bassiana*), predaceous insects (*Dastarcus longulus*), and predatory birds such as woodpeckers (*Dendrocopos major*).

Future Prospects for Pine Wilt Disease

It is generally believed that the pine wood nematode was introduced into Japan from North America a century ago. Subsequently it was introduced into eastern Asian countries and Portugal. European countries show great interest in avoiding the introduction of the pine wood nematode into Europe by timber imports. At present they impose an embargo on all raw softwood materials from North America.

The incidence of pine wilt disease is closely related to environmental conditions such as high temperature with little rainfall as mentioned before. Environmental changes such as increasingly warm and unusual weather conditions which are expected in the near future will most certainly affect the susceptilbility of pine trees. Changes in forest ecosystems resulting from the deposition of acidifying substances may significantly influence pine wilt disease. Pine wilt disease could become the most serious threat in pine forests in European countries, because Scots pine (*P. sylvestris*) and maritime pine (*P. pinaster*) are very susceptible to it.

Leaf and Needle Diseases

J K Stone and M L Putnam, Oregon State University, Corvallis, OR, USA

Overview of Foliage Diseases

Foliage diseases of forest trees can be caused by a variety of biotic agents: fungi, bacteria, algae, phytoplasmas, and viruses, as well as abiotic agents such as air pollutants, chemical deposition (e.g., salt injury, acid precipitation), thermal injury, and nutritional deficiencies, both individually and in combinations. Recognition of the primary cause of diseased plants is often a difficult puzzle for the diagnostician, who must consider interactions between host plant, pathogens, environmental conditions, and management history to determine accurately the underlying cause of a foliar disorder. Often, unhealthy-looking foliage may actually indicate a root or stem disease problem.

Foliage diseases affect trees in nurseries and greenhouses, forest plantations, and urban and natural forests worldwide. Foliage pathogens, like their hosts, can occur either as natural components of a forest ecosystem or as exotics introduced through human activity. Exotic pathogens on endemic hosts, and endemic pathogens on exotic hosts, are often more destructive because host plants have no coevolved resistance to the pathogens. Diseases affecting trees in managed situations, such as nurseries and plantations, tend to be more uniformly distributed than in natural forests. Uniform host populations (with respect to species, clone, and age), i.e., monocultures, are more prone to damaging epidemics than plantations and forests managed for genetic diversity.

The inventory of pathogens that pose a threat to forest health is constantly expanding. The lists of forest foliage pests given below are a necessarily selective attempt to enumerate the most common and important foliage pathogens and their current known distributions, recognizing that forest pathogens and pests are constantly changing. New pest organisms are continually being discovered and described. Probably fewer than 20% of the pathogens that pose a threat to forest health have been recognized. Very little information is available on foliage diseases of several important forest trees such as dipterocarps, *Metrosideros*, and *Nothofagus*. Biological evolution continues to shape the interactions between plants and pathogens, as evidenced by development of pesticide resistance and the emergence of aggressive strains and races in pathogen species. Interspecific hybridization and resultant changes in host range have been documented for *Melampsora* and *Phytophthora* pathogens affecting forest trees. Despite international phytosanitary regulation, international trade involving plant and forest products continues to provide an avenue for introduction of insects and pathogens to new hosts and environments. The changing state of scientific knowledge also affects our understanding of pathogen distribution and importance. As increasingly powerful methods of population genetic analysis are applied to the study of forest pathogens, a more detailed picture of the dynamics in pathogen populations and species is revealed.

Diseases Caused by Fungi (Including Oomycetes)

Fungi are eukaryotic, heterotrophic microbes in the kingdom Fungi that occur either as single-celled (yeast) or filamentous forms. The filamentous fungi have evolved a variety of structural adaptations to penetrate directly and colonize plant tissues and cells to establish parasitic relationships. Fungal pathogens can also invade host tissue through wounds caused by breakage, insect feeding and freezing injury. Symptoms caused by fungal foliar pathogens can vary in severity from severe defoliation to inconspicuous leaf spots. Many have prolonged (1 year or more) incubation periods during which infected foliage remains symptomless. Symptoms of fungal foliage diseases include leaf spots, leaf blotch, scorch, anthracnose, needle blights, and needle casts. Typically, the presence of a fungal pathogen is indicated by minute fruiting structures characteristic of the pathogen species or taxonomic group.

Fungal foliage diseases rarely cause death of mature trees, although they can be responsible for serious economic losses due to decreased growth yield. Chronic fungal foliage diseases can weaken or stress trees so that affected hosts are outcompeted by other species, or are predisposed to attack by secondary agents such as bark beetles or opportunistic root diseases. Control of fungal diseases in forest plantations by protectant fungicides is feasible for certain pathogens and hosts. Successful control depends on timing of applications to coincide with optimum periods of pathogen sporulation and host susceptibility. Specific recommendations for control depend on approved materials, pathogen, tree crop, and local conditions, and are available from local pest management agencies. Judicious selection of planting stock and careful sanitation, where practicable, are often effective means of controlling fungal foliage diseases. The greatest diversity of fungal foliar pathogens of woody hosts are ascomycetes (phylum Ascomycota) and basidiomycetous rusts (Uredinales) (*see* **Pathology**: Rust Diseases).

Oomycetes

Because of their filamentous habit, parasitic oomycetes (kingdom Stramenopila) traditionally have been considered together with fungal pathogens, although they are more closely related to chrysophyte algae. Relatively few oomycetes are associated with foliage diseases of trees; those that cause tree diseases mainly attack roots. However, recent discoveries of foliage-inhabiting *Phytophthora* species, several as yet unnamed, suggest that foliar *Phytophthora* of woody hosts may be much more widespread than previously thought. *Phytophthora ramorum*, the causal agent of sudden oak death in the western USA, also infects foliage of species of *Acer*, *Lithocarpus*, *Quercus*, *Umbellularia*, and several other unrelated hosts, such as *Pseudotsuga*, and causes symptoms ranging from leaf spots and marginal necrosis to shoot blight and dieback. Other *Phytophthora* foliage pathogens include *P. palmivora*, which causes bud rot of coconut palm (*Cocos nucifera*) and other hosts throughout the tropics and subtropics. Littleleaf disease, caused by a suite of factors including the oomycete pathogen *P. cinnamomi*, affects short-leaf pine (*Pinus echinata*) in the southern Appalachians of eastern North America. Although *Phytophthora cinnamomi* infects rootlets, the primary symptoms are initially chlorotic, stunted foliage, and a progressively thinning crown.

Diseases of Conifers

Needle casts Foliage diseases of coniferous trees are usually categorized either as needle cast diseases, where affected needles are prematurely abscised, or needle blights, where needles are abruptly killed and typically remain attached. Needle cast pathogens generally have longer periods of development than those causing needle blights. Typical needle cast pathogens infect newly emerging foliage and complete their development to produce infective ascospores the following spring. An exception is the larch needle cast pathogen *Meria laricis*, which infects needles and sporulates in the same growing season. Needle blights typically attack and kill foliage and sporulate in a period of a few weeks. Important needle cast diseases are *Lophodermella*, *Cyclaneusma* and *Elytroderma* needle casts of pine, *Rhabdocline* and Swiss needle casts of Douglas-fir (*Pseudotsuga menziesii*), *Lirula* needle cast of spruce (*Picea* spp.), and *Meria* needle cast of larch (*Larix* spp.).

Pinus radiata is planted widely in forest plantations and hence *Cyclaneusma* needle cast is probably one of the most significant needle cast diseases worldwide. *Cyclaneusma minus* causes severe damage to *P. patula*, *P. ponderosa* and *P. radiata*, and *C. niveum* affects *P. nigra* and *P. pinaster* plantations in Europe, North America, South America, New Zealand, and southern Africa. *Elytroderma* needle cast of pines is unique in that the pathogen invades shoot tissue, causing hypertrophy and deformation, often killing branches. Although most damaging to young trees, *Elytroderma* needle cast can cause severe growth losses in medium-aged and mature stands, and can predispose mature trees to attack by insects and root diseases. *Elytroderma deformans* is a serious pathogen of *P. ponderosa* in western North America, and *E. torres-juanii* affects *P. brutia* in Greece, *P. halapensis* and *P. uncinata* in Spain, and *P. pinea* in Portugal.

Swiss needle cast of Douglas-fir, caused by *Phaeocryptopus gaeumannii*, is ubiquitous wherever Douglas-fir is grown worldwide, but generally is more destructive on trees grown outside their native range of western North America, and is more damaging on the interior (var. *glauca*) variety of Douglas-fir. The pathogen was first noticed on diseased Douglas-fir in plantations in Switzerland but later shown to be widespread throughout the natural range of Douglas-fir in western North America, where it is presumed native. Serious outbreaks of Swiss needle cast have occurred in Europe, New Zealand, and coastal Oregon; however in most of western North America the disease has negligible effects. *Rhabdocline* needle cast, caused by *R. pseudotsugae* and *R. weirii*, can cause severe defoliation of Douglas-fir, particularly on the interior form (*Pseudotsuga menziesii* var. *glauca*) in the Rocky Mountain region of western North America and in other regions where it has been planted as an exotic. The related asexual fungus *Meria laricis* is the cause of larch needle cast in western North America, northern Europe, and Siberia.

Lophodermella needle casts caused by *L. concolor* and *L. montivaga* affect *Pinus attenuata*, *P. contorta*, and *P. banksiana* in North America. In severe years entire hillsides of affected stands can aquire a reddish color due to the effect of these pathogens. Repeated years of severe defoliation can weaken trees, leading to mortality through attack by bark beetles and root pathogens. Tar spot needle cast is the most common needle cast of soft pines, mainly *P. strobus*, in northeastern North America. It is readily identified by the shiny black raised ascomata on the undersides of necrotic needles. *Ploioderma lethale* is the most damaging needle cast of hard pines (mainly *Pinus clausa*, *P. echinata*, and *P. elliottii*) in the southeastern USA.

The small (2–3 mm) but conspicuous gray to black, raised, elliptical fruiting bodies of several species of *Lophodermium* are very common on fallen needles of many species of pines, but most are considered harmless. One species however, *L. seditiosum*, is considered a serious pathogen causing *Lophodermium* needle cast. *Lophodermium* needle cast affects several species of pines, especially *P. sylvestris* in Europe and *P. resinosa* in North America. Attack by *L. seditiosum* kills young needles, and in nurseries and on young trees defoliation by this pathogen can be fatal.

Needle blights Important needle blights of conifers include *Dothistroma*, *Diplodia*, and brown spot needle blights of pine. *Dothistroma* blight, caused by *Mycosphaerella pini* (anamorph *D. septospora*), affects several important pine species, including *P. contorta*, *P. nigra*, *P. ponderosa*, and *P. radiata*, and has been especially damaging in *P. radiata* plantations in South America, southern Africa, and New Zealand. The disease has also recently caused severe losses in lodgepole pine (*P. contorta*) in northwestern British Columbia. Often a reddish band appears between the killed tips of needles and the green base and this is diagnostic for *M. pini*. *Sphaeropsis sapinea* (= *Diplodia pinea*) causes a needle blight and shoot dieback of many species of pine worldwide, notably *P. nigra*, *P. pinea*, *P. sylvestris* in Europe; *P. patula*, *P. pinaster*, *P. radiata* in southern Africa, where it has mainly been associated with hail damage; *P. nigra*, *P. palustris*, *P. ponderosa,* and several other pine species in New Zealand; *P. greggii*, *P. elliotii*, and *P. patula*, in Brazil; *P. canariensis*, *P. radiata*, and *P. sylvestris* in Argentina; several pine species in North America including *P. nigra*, *P. ponderosa*, *P. resinosa*, and *P. strobus*; *P. canariensis*, *P. elliotii*, *P. pinaster*, and *P. roxburghii*, in Australia; and *P. luchuensis* in Taiwan. Other hosts affected by *S. sapinea* include *Abies*, *Cedrus*, *Chamaecyparis*, *Juniperus* and *Pseudotsuga*. In addition to the needle blight and shoot dieback, *S. sapinea* also causes stem cankers and root disease in several pine species.

Other significant foliage blights include *Gleosporidina cryptomeriae* and *Cercospora sequioiae* which cause twig blight of *Cryptomeria japonica* in plantations in Japan and Brazil. Brown needle disease of pines, caused by *Cercoseptoria pini-densiflorae*, affects several species of pines including *P. pinaster* and *P. radiata* and can be particularly destructive to nursery stock. Young plantations and seedlings in nurseries are most severely affected. *Hypodermella laricis* causes a severe needle blight of larch and is distributed throughout the northern hemisphere. Tip blight and shoot dieback caused by *Kabatina juniperi* affect several Cupressaceae in North America and Europe.

Bud blights of conifers are caused by several pathogens. *Gemmamyces piceae* kills buds and causes abnormally twisted shoots of *Abies alba*, *Picea abies*, and *P. pungens* in Europe. In North America, severe bud and shoot blights of *P. englemanii*, *P. glauca*, *P. sitchensis* and *Pseudotsuga menziesii*, are caused by *Dichomera gemmicola* and buds of *Abies lasiocarpa*, and *P. glauca* by *Camarosporium strobilinum*. *Sirococcus conigenus* also causes shoot dieback of several conifer species, including *Picea sitchensis*, *Pinus resinosa*, *Pseudotsuga menziesii,* and *Tsuga heterophylla*, and can be particularly damaging to seedlings in nurseries. Shoot dieback of several conifer species, especially Douglas-fir, caused by *Botrytis cinerea* is most commonly associated with succulent young shoots damaged by late spring frost.

Felt blights and snow molds are diseases of alpine and boreal conifer foliage that is covered by snow for extended periods, typically affecting young trees and the lower branches of mature trees. The pathogens in the genera *Herpotrichia* and *Neopeckia* rapidly colonize snow-covered foliage in a distinctive wooly felt that binds needles together, initially gray and becoming brown as the foliage is exposed. The masses of brown felt mycelia are persistent and can survive summer desiccation, resuming growth when snow cover returns to cause a perennial blight. *Neopeckia coulteri* affects pines; *Herpotrichia juniperi* and *H. parasitica* affect various Pinaceae and Cupressaceae in North America and Europe, respectively. Snow molds (snow blights) similarly attack snow-covered foliage, but mycelia of these pathogens are evanescent, not persisting as felt mats after snowmelt. Several genetic variants of *Phacidium infestans* are recognized; var. *infestans* occurs on species of *Abies*, *Juniperus*, *Picea* and *Pinus*, throughout boreal Eurasia, mainly attacking *Pinus sylvestris*; a southern race mainly affects *P. cembra* in the Alps. Several different snow blight fungi attack conifers in North America. *Phacidium abietis* and *Sarcotrochila balsameae* are snow blight pathogens affecting *Abies* in western North America, *Hemiphacidium planum* attacks pines in the southern Rocky Mountains, and *S. piniperda* spruce, mainly in northeastern North America. Symptoms of snow blight are a progressive discoloration, eventually becoming gray-brown, with the dead needles remaining attached until the following year.

Diseases of Broadleaved Hosts

There is a bewildering diversity of foliage parasites of broadleaved woody hosts worldwide, the majority of which are ascomycetes or asexual states. Many occur as inconspicuous leaf spots and cause negligible injury to their hosts. Other than rusts, there are very few basidiomycetous foliar pathogens. One exception is *Chondrostereum purpureum*, which is primarily a sapwood rot, but basidiospores from nearby sporocarps are able to infect leaves of several broadleaved trees, causing a typical 'silver leaf' symptom due to the formation of air spaces between epidermal and palisade tissues. Silver leaf disease can be damaging to fruit orchards, but also occurs on maple, birch, willow, and *Eucalyptus* species.

Powdery mildew diseases are caused by fungi in the Erysiphaceae, which are specialized, host-specific ectoparasites of foliage of many plants, including broadleaved woody hosts. The mycelia of powdery mildews grow over the leaf surface, often appearing cottony, with intermittent penetration of epidermal cells by haustoria, specialized feeding structures by which nutrients are translocated from the host leaf to the superficial mycelia. The name derives from the masses of asexual spores (conidia) which can give the appearance of dusty patches on leaves. Important powdery mildews of forest trees include *Uncinula* species on maples and *Microsphaera* and *Sphaerotheca* species on oaks. In Europe, *M. alphitoides* causes death of leaves and shoot deformation of *Quercus petraea* and *Q. robur*, and also occurs on several species of oak in North America. Species in the *M. penicillata* complex affect a number of broadleaved host genera including *Acer*, *Betula*, *Carya*, *Castanaea*, *Cornus*, *Corylus*, *Fagus*, *Fraxinus*, and *Platanus*. Although powdery mildew is seldom seriously damaging to mature trees, nursery stock may need to be protected by fungicides.

Taphrina species are yeastlike ascomycetes that form a thin, superficial layer penetrating just the epidermis of leaves of several broadleaved hosts. Like the powdery mildews, *Taphrina* species are specialized, host-specific parasites. *Taphrina* symptoms are typically patchy swelling and gall-like deformations of leaves (leaf blisters), sometimes coalescing and causing 'leaf curl.' *Taphrina* gall of alder (*Alnus* spp.) also causes a hypertrophy in shoots and can be a persistent problem in nurseries, requiring control by fungicides. Other hosts commonly affected by *Taphrina* are *Quercus*, *Populus*, *Prunus*, and *Salix*.

Anthracnose diseases are characterized by sunken, often confluent, necrotic lesions on foliage, and are caused by several genera of ascomycetes, particularly those with acervular asexual states. In general, anthracnose pathogens infect foliage in spring, and more severe symptoms are associated with rain in late spring and early summer. Several anthracnose pathogens initially infect leaves and spread to shoots by hyphal growth, causing dieback. *Glomerella cingulata*, together with its anamorph *Colletotrichum gloeosporioides*, is one of the most widely distributed foliar parasites in temperate and tropical forests worldwide, and one of the most common fungi associated with anthracnose symptoms on numerous broadleaved woody hosts in nurseries, plantations, and forests. Some of the hosts affected by *G. anthracnose* include poplar, cashew, mango, citrus, papaya, *Robinia*, *Hevea*, and many others. *Glomerella anthracnose* has been reported as a particular problem in establishing plantations of *Gmelina arborea* in Malaysia.

Other fungus species associated with anthracnose symptoms include *Apiognomonia errabunda*, *A. tiliae*, *A. veneta*, and *A. quercina*, the causes of beech, lime (*Tilia*), plane (*Platanus*), and oak anthracnoses, respectively, in Europe and North America. *Kabatiella apocrypta* is common on several maple species in North America, causing interveinal necrosis and scorchlike blight of leaves and shoots. In Europe, *K. apocrypta* is associated with necrotic lesions around feeding sites of psyllid larvae on oak leaves. In North America, *A. errabunda* causes a damaging anthracnose of ash that can cause severe defoliation and shoot dieback when spring rain favors heavy infection. Oak anthracnose can also be particularly damaging in years when conditions are conducive to infection. Rain-dispersed spores produced on killed twigs infect emerging leaves and quickly generate more fruiting bodies, multiplying the amount of inoculum during rainy periods. Several oak species are susceptible, but white oak in the northeastern USA and California live oak are the most severely affected by shoot dieback and foliage blight from this disease. *Discula destructiva*, the cause of dogwood anthracnose in the USA, apparently was introduced almost simultaneously in the 1970s from an unknown source to both the eastern and northwestern USA, where it has spread rapidly, attacking the native species *Cornus florida* and *C. nuttallii*.

Tar spots of maple and willows are conspicuous, black, disk-like, 1–2 cm diameter spots, caused by *Rhytisma* spp. The tar spots are fungal stromata that complete their maturation during the winter and spring after leaves are abcised. Ascospores are released in the spring, coinciding with the emergence of new foliage.

A number of serious foliage diseases of broadleaved forest trees are associated with species classified in *Mycosphaerella*, or in the several genera of asexual states connected to it. *Septoria, Cercospora, Coniothyrium, Dothistroma, Lecanosticta, Ramularia*, and several other form-genera are used for different asexual forms of *Mycosphaerella*. A large number of *Mycosphaerella* species are associated with leaf spots of *Eucalyptus*. A recent monograph lists 55 *Mycosphaerella* species that cause leaf diseases of *Eucalyptus* worldwide, many of which are host-limited and cause injury only to certain species or hybrid clones. For example, *Mycosphaerella* leaf blotch disease has been shown to cause growth reduction in *E. nitens*, and also has been particularly damaging to *E. globulus* in South Africa and Australia. *Ramularia* shoot blight, caused by the fungus *Ramularia* (= *Quambalaria*) *pitereka*, causes a severe leaf and shoot blight of several of the *Eucalyptus* subgenus *Corymbia* species in eastern Australia.

Since *Eucalyptus* species are some of the most widely planted forest crops in Asia, Australia, South Africa, and South America, their pathogens are economically important. The emergence of specialized foliage pathogens on certain species and clones in plantations has forced changes in selection of *Eucalyptus* species in several regions where the diseases occur. The susceptibility of *E. globulus* to the leaf spot pathogen *M. nubilosa*, considered one of the most important leaf pathogens in South Africa, caused the planting of this species to be abandoned in parts of South Africa. *Phaeoseptoria eucalytpti* causes severe defoliation of lower branches and is particularly damaging to certain clones of *E. grandis*. It can also cause severe damage to seedlings in nurseries and hedges used for clonal propagation. *Eucalyptus* leaf and shoot blight caused by *Cryptosporiopsis eucalypti* is particularly damaging to *E. camaldulensis* in nurseries and plantations in Southeast Asia. An undescribed species of *Gleosporidina* has recently been reported associated with leaf lesions and shoot dieback of *E. nitens* and *E. globulus* in Tasmania, but apparently is infrequent.

Wattle (*Acacia* spp.), particularly black wattle (*Acacia mearnsii*), also has been planted in many parts of the world outside its native range in Australia, including India, Sri Lanka, and South Africa, and has led to the appearance of new pathogens of this host. Foliage pathogens of wattle include *Calonectria indusiata*, which caused complete defoliation of trees in parts of India and Sri Lanka. *Glomerella acaciae* is the cause of *Acacia anthracnose* in Japan.

Several important foliage diseases affect species of poplars (*Populus* spp.) and their hybrids grown for fiber. *Melampsora* rusts are probably the most significant foliage pathogens of poplars. Leaf and shoot blight caused by *Venturia macularis* on *P. tremuloides* and *V. populina* on *P. trichocarpa* can be particularly damaging in years with favorable mild wet weather in spring. Certain hybrid clones are resistant. Symptoms include discolored, blighted foliage and a characteristic blackened shoot dieback. *Septoria populicola* causes a severe leaf spot and defoliation of *P. deltoides* and susceptible hybrids in western North America. In eastern North America, *S. musiva* also causes severe leaf spots as well as cankers. The related *Venturia saliciperda* causes a similar dieback of willow, often in association with *Glomerella miyabeana*. *Linospora* leaf blight caused by *L. tetrasperma* affects *P. balsamifera* and *P. deltoides* as well as several hybrids, occurring across northern North America from eastern Canada to the Pacific Northwest. *Linospora* blight tends to be local in occurrence, but damage can be heavy in years when wet spring weather favors infection. Species of *Marsonnina* cause leaf spots and blights of several broadleaved woody hosts. The species *M. brunnea*, *M. castagnei*, and *M. populi* are particularly important as forest pests of *Populus* plantations worldwide, causing defoliation and dieback of several poplar species and hybrids. Subspecies and pathovars of *M. brunnea* differing in pathogenicity to different hosts are recognized.

Diseases Caused by Bacteria

Bacteria are single-celled microscopic prokaryotes of the kingdom Eubacteria. Unable to penetrate plants on their own, bacteria require natural openings such as lenticels, stomata, hydathodes, and leaf scars; or wounds due to events such as pruning, breakage, herbivory, or insects. Local dispersal of bacteria from an infected tree occurs via water splash, wind, insects, and rubbing together of infected and healthy foliage. Long-distance dispersal is primarily through transport of infected material such as seed, stools, and cuttings.

Although bacterial pathogens are widespread, information on bacterial diseases of forest trees is limited. In general, bacterial diseases of trees in mixed-forest systems (not trees isolated in landscapes, in fringes around cities, or in forest nurseries) are minor, often because they occur in low incidence or in more severe but sporadic outbreaks, during which they can cause heavy losses locally. The most serious losses occur in monoculture of same-age plantings, especially when derived from a single clone, or when the trees are exotic to the area.

Symptoms caused by bacteria on foliage range from small round leaf spots from which the tissue drops out, leaving a hole (shothole leaf spots); angular, water-soaked leaf spots; whole leaf blight; leaf scorch; and chlorosis or reddening of leaves, often associated with lesions or marginal necrosis. Bacteria can also cause blighting of small twigs or whole branches; cankers of twigs, branches and main stems; galls of branches, stems, or roots; vascular plugging leading to wilting; and death. Leaf spots and blights, occasionally leading to blighting and dieback of small twigs, are often caused by bacteria of the genera *Pseudomonas*, *Xanthomonas*, and *Erwinia*. Such blights are often limited to the current year's growth, and, in the case of *Pseudomonas syringae*, disease often follows cold injury. For this reason, leaf spots, leaf blight, and twig dieback are of minor significance, since complete defoliation is rare. Some bacteria can cause dieback of older branches, or, by infecting the trunk and causing large cankers, have a greater impact. This includes bacteria such as *Erwinia amylovora* (cause of fire blight), *Xanthomonas campestris* pv. *populi*, and some species of *Pseudomonas* on particularly susceptible hosts. Vascular diseases are caused by the xylem-inhabiting *Xylella fastidiosa* and *Ralstonia solanacearum* (= *Pseudomonas solanacearum*) and, by their systemic nature, can cause either rapid death or chronic stress via impedance of water movement throughout the canopy, rendering the tree more susceptible to additional stresses.

Specific bacterial pathogens of forest trees include *P. syringae* and its pathovars which affect a wide range of broadleaved hosts worldwide, including *Acer, Fraxinus, Populus, Quercus*, and *Salix*. *Ralstonia solanacearum* also affects a variety of hosts, primarily with tropical and southern distributions (China, South America, Australia, southern Africa) including *Acacia*, *Casuarina*, and *Eucalyptus*. Xanthomonads occur on both tropical and temperate woody hosts. *Xanthomonas populi* is widely distributed throughout Europe and causes a serious disease of *Populus* species and hybrids, resulting in blighted buds and shoots and the formation of persistent cankers. *Xylella fastidiosa*, a xylem-limited bacterium which causes Pierce's disease of cultivated grapes, causes leaf scorch and may contribute to a general decline in *Acer*, *Aesculus*, *Fraxinus*, *Platanus*, *Quercus*, and *Ulmus* in North America. Bacterial wilt of bamboo caused by *Erwinia sinocalami* has been reported from Fujian and Taiwan.

In situations where bacterial diseases require control, copper sprays and the antibiotics streptomycin and tetracycline have been used with varying success on cultivated trees with fire blight, but use in situations other than nurseries is extremely rare. Tetracycline is not as effective as streptomycin, and bacterial populations can become resistant to both streptomycin and copper. The loss of efficacy of these chemicals makes it imperative that sanitation measures be carried out, and sanitation is often the only option in situations where the trees are outside a nursery setting. This includes cutting and destroying affected limbs (with nonvascular diseases) or entire trees, establishing quarantines, clonally propagating from disease-free material, and preventing the reintroduction of the pathogen.

Diseases Caused by Phytoplasmas

Phytoplasma is the name given to microscopic, plant pathogenic, cell wall-less prokaryotes of the class Mollicutes that were formerly known as mycoplasma-like organisms or MLOs. Phytoplasmas are obligate parasites and have not been grown in axenic culture. Because of this, they have not been fully characterized and their pathogenic nature has not classically been confirmed, although it is assumed. Until the plant-inhabiting pleomorphic mollicutes can be cultivated and characterized apart from their hosts, they are provisionally classified as *Candidatus* Phytoplasma, with species delineated by genome size and phylogeny as inferred by the nucleic acid sequence of the 16S ribosomal RNA. Phytoplasmas cause 'yellows' diseases (named for the response of infected foliage) and other disorders in over 300 species of plants. Systemic and limited within the plant to the phloem cells, phytoplasmas are vectored by over 100 species of phloem-feeding insects, primarily leaf hoppers, plant hoppers, sharpshooters, and psyllids of the families Cicadellidae, Fulgoroidae, and Psylloidae. Parasitic plants of the genera *Cuscuta* and *Cassytha* may also transmit phytoplasmas.

Symptoms with which phytoplasmas have been associated may include several of the following: leaf stunting (little leaf); pinkish, or more commonly, yellow discoloration of the foliage (yellows); greening of flower petals; precocious or suppressed flowering; precocious shoot growth, proliferation of shoots or branches (witches' brooming); loss of apical dominance of the shoots, leading to deliquescent branching; phloem necrosis; branch dieback; progressive loss of vitality; suppressed root development; wilting; and eventual plant death. Phytoplasmas have also been detected in plants with no apparent symptoms, possibly indicating the existence of tolerance in the asymptomatic plants. Alternatively, it may be that plants with phytoplasmal diseases die due to multiple causes, with the phytoplasma being one of several contributory factors. Virus particles are often found in plants coinfected with phytoplasmas, as are other pathogens and pests.

Phytoplasma-affected plants may not be cured, although symptom remission does occur with treatment by tetracycline antibiotics. For this reason, effective disease management must consist of prevention, such as establishment of quarantines to prevent introduction into a new area, removal and destruction of infected trees, clonal propagation from only healthy trees, vector control, and breeding for genetic resistance.

Phytoplasma diseases are relatively rare in comparison with fungal diseases. Although important in agricultural production, the impact of phytoplasmal diseases in most forest ecologies is rather limited, probably due to the diversity of species present in most forests and the feeding preferences of the vectors. Phytoplasmal diseases will do most damage in situations where monoculture, especially of clonally propagated material, is predominant and where vectors flourish. Some phytoplasma diseases have been extremely important to the local economy, even while they are severely limited in geographic distribution (e.g., sandal spike, which only occurs in southern India). This is in contrast to diseases such as lethal yellowing of coconut, which has spread rapidly throughout the Caribbean, and a related disease of palms found in equatorial Africa, both caused by group IV phytoplasmas. It is difficult to assess the true distribution (and hence impact) of phytoplasmas on forest ecosystems, since many early reports of phytoplasma diseases are based on symptoms which are not exclusive to phytoplasmas. Commonly reported and substantiated (via light or electron microscopy, or molecular analyses) phytoplasma-caused diseases in forest trees include, from the tropics, witches' broom of *Paulownia* spp. in China (16S ribosomal RNA group I) and spike disease of *Santalum album* from India (group I). There are few reports of phytoplasma diseases in Europe, but alder yellows on *Alnus glutinosa* (group V) can cause problems. In North America elm yellows of *Ulmus* spp. (group V) occurs in the USA, whereas witches' broom of *Salix* spp. (group VI) and ash yellows of *Fraxinus* spp. (group VII) are widely distributed in the USA and southern Canada.

Diseases Caused by Viruses

Viruses are submicroscopic agents of disease composed of nucleic acids, either single or double strands of DNA or RNA, encased in a protein coat or capsid. Viruses are transmitted mechanically, by contact of infected plant material with healthy tissues (e.g., root grafts); by insect, fungal, or nematode vectors; by pollen; and via seed. Grafting of diseased material on to healthy trees is a primary means of spreading viruses in cultivated trees, but is less common in forest trees.

The mixed-species composition of most forests is a limiting factor to the impact of viruses in forest ecosystems. Viruses are often implicated in forest declines, in which a majority of trees exhibit poor vigor leading to reduced growth, decline, and eventual death. Although viruses may be detected in trees showing slow growth, poor color, branch dieback, and other nonspecific symptoms of poor performance, trees with these symptoms in the same area may not have any detectable levels of virus. The inconsistent association of virus particles in symptomatic trees has confounded the understanding of forest declines, and the role of viruses in these situations remains in many cases undetermined.

Sources of viruses in forest ecosystems include insect and nematode vectors, infected seed or pollen, forest soils, surface waters, and even fog, as with tomato mosaic tobamovirus in New York state. Many of the viruses documented in forest situations are nepoviruses, tobamoviruses, potexviruses, and ilarviruses. Cherry leaf roll nepovirus has been reported from several forest trees, including species of *Betula*, *Cornus*, *Fagus*, *Fraxinus*, *Juglans*, *Prunus*, and *Ulmus* in Europe and North America. Elm mottle ilarvirus affects *Ulmus* spp. in Europe. Tobacco necrosis necrovirus affects both conifer (*Larix*, *Picea*) and broadleaved (*Betula*, *Fagus*, *Populus*, *Quercus*) species. Bamboo mosaic potexvirus has been found in several species of *Bambusa* and *Dendrocalamus* from Taiwan and Brazil.

Trees infected with viruses may be asymptomatic or show one or more of the following: variations in leaf color, including light-green/dark-green mottling, striking rings or jagged lines of yellow or shades of red; leaf speckling; leaf spots; foliar distortion; shot hole; stunted leaves; reduced shoot or root growth; or branch dieback. Symptoms are best documented for domesticated trees which may also grow wild, such as apple mosaic virus on *Malus* or *Prunus* necrotic ringspot virus on *Prunus* spp. Virus infections are systemic, and there is no cure for infected trees.

Diseases Caused by Viroids

Viroids are the smallest known plant pathogens. Consisting of a single circular strand of ribonucleic acids a few hundred basepairs in length and without benefit of even a capsid, it is unknown exactly how these organisms are capable of infecting plant cells and causing disease. However, viroids can cause extensive damage in some hosts. There are fewer than 30 known diseases of viroid etiology, primarily of fruit trees, potatoes, and a few ornamentals. Their natural mode of transmission is largely unknown, but it is suspected that human activities play some part. In at least one temperate forest, trees showing symptoms of decline were assayed for the presence of viroids. None were found and so far there are no known viroid diseases of temperate forest trees. In contrast, in the Philippines, a viroid disease known as cadang-cadang of coconuts (*Cocos nucifera*) has been devastating. The disease has been spreading since it was first recorded in 1931; there is no known vector, no known means of control, and no known resistant coconuts. It is estimated that 30 million coconut palms died, as of 1980, from cadang-cadang. It is caused by a viroid of the potato spindle tuber viroid group, based on the sequence of their central conserved region, and exists as four distinct molecular forms which occur over the course of infection. A related viroid, causing tinangaja disease, has permanently destroyed the commercial coconut industry on Guam. Both diseases can be difficult to diagnose due to the long period over which the disease develops (7–16 years) and the similarity of symptoms to those produced by water stress, poor nutrition, typhoon damage, physiological sterility, and insect feeding damage. Foliar symptoms, which may take as long as 2 years after infection to develop, begin as nonnecrotic water-soaked spots which eventually enlarge with time. Spots may grow together to give an appearance of general chlorosis. With increased time, leaflets become brittle, the crown size is reduced, and death follows. Other palms found to be naturally infected with cadang-cadang include oil palm (*Elaeis guineensis*) and buri palm (*Corypha elata*). Artificial inoculations have resulted in disease of other members of the Arecaceae, but inoculations failed in 44 species from 12 other families. Viroidlike molecules have been detected in oil and coconut palms in other parts of the southwest Pacific, but cadang-cadang disease has not been identified in these areas.

Diseases Caused by Nutrient Deficiencies

Foliar abnormalities may be caused by factors other than pathogens. Insects, mites, and other arthropods may cause distortion, speckling, or the destruction of leaf or shoot tissues. However the arthropods are often present or at least leave evidence of their presence in the form of frass, eggs, or skins cast during molting. Abiotic factors of foliar problems, such as nutrient deficiencies and injury from air pollutants, are not as easily diagnosed or recognized. Symptoms of nutrient deficiencies appear when plants are grown in soils low in organic matter, in soils with extremely high or low pH, in heavily leached soils, or when growing in soils derived from native rock which is nutrient-poor. Nutrient deficiency symptoms are rarely diagnostic in themselves. Often one nutrient is essential in the metabolism of another, so that a deficiency in one will produce a concomitant deficiency in the other. Deficiency symptoms may be similar for more than one element and can resemble those caused by waterlogged soils, salt spray, drying winds, drought, compacted soils, or pathogens. Broadleaved plants will show symptoms differently than conifers, and even within a given species of plant symptoms may vary depending on time of year and plant maturity. If deficiencies are suspected, a leaf tissue and soil analysis can help target the insufficient element.

Diseases Caused by Air Pollution

Anthropogenic air pollution may also produce abnormalities in leaf color, size, and vigor, and has been implicated in forest decline, especially in northern temperate forests. Pollution may arise from point sources, e.g., power generation plants or industrial smelters, or from nonpoint sources such as automobiles. Injury may be due to long-term exposure of low levels of pollutants (chronic exposure) or from short- or long-term exposure to high levels of pollutants (acute exposure). Injury is most likely to occur when downwind from factory smokestack plumes, at edges of cities, or in areas of air inversions.

Diagnosis is difficult as pollutants are rarely present singly and symptoms often mimic those caused by other abiotic or biotic factors. Degree of injury will vary by species, physiological age of the tissues, and proximity to the source. Generally, chronic exposure results in yellowing, stippling, dwarfing, reduced vigor, and premature senescence. Acute exposure often results in well-defined areas of dead tissues, dwarfing, or plant death.

Rust Diseases

G Newcombe, University of Idaho, Moscow, ID, USA

Rust Fungi are All Parasites

Symbionts of forest trees may be parasites, mutualists, commensalists, amensalists, competitors, or neutralists. Rust fungi are unquestionably all parasites in that their interactions with plants are of benefit to their own fitness but detrimental to their hosts. There may be some, as-yet-unknown benefits to some hosts of rust infection, but detriments are obvious. Forest trees do not seem to constitute a special class of plant hosts for rust fungi, although herbaceous and woody perennials alike do afford opportunities for long-lasting infection unlike annuals.

Rust Fungi in Relation to Other Fungi

Systematists tend to accept between 5000 and 7000 species of rust fungi belonging to somewhere between 100 and 125 genera in from 10 to 15 families. Rust fungi constitute the order Uredinales, and they represent most of the species diversity in the class Urediniomycetes.

Some rust genera appear to be monophyletic, or natural groups of species descended from a common ancestor. *Chrysomyxa*, *Coleosporium*, *Cronartium*, *Gymnosporangium*, *Melampsora*, *Phragmidium*, and *Tranzschelia* appear to be in this category. However, some of the other genera that affect forest trees and woody plants and that are listed in **Table 1**, are not monophyletic: *Puccinia*, *Pucciniastrum*, *Thekopsora*,

Table 1 Distribution of rust fungi on selected genera of plants that are primarily of the northern hemisphere and 'woody'. 'Nonhost genera' are only genera that include species native to the US, for which the detailed databases of the US National Fungus Collections were consulted, and for which there were no rust records. Use of these databases also explains the North American bias that is evident in columns 3 and 4. The fifth column lists rust genera that are not necessarily Norh American in distribution.

and *Uromyces*. Such artificial groups of species cloud interpretation of host–parasite trends at the generic level, but these are presented regardless in **Table 1** so as to reflect current knowledge.

In spite of considerable research, even today rust fungi are far from fully known at the species level, and there are at least two reasons to believe that considerable species diversity in this group remains to be elucidated: (1) plants of many parts of the world, especially in the tropics, host rust fungi that have been little studied; and (2) even in North America, Europe, Japan, Australia, and New Zealand where rust fungi have received the most attention, single, poorly delimited taxa may actually represent large complexes of cryptic or sibling species. The latter may not be distinguishable morphologically but they may still be species that are reproductively isolated from their 'look-alike' congeners.

The host specialization of rust fungi is clearly a major factor in speciation, and thus evolution of such cryptic complexes. Specialization provides a special form of sympatric isolation for parasite populations; gene flow will stop in the absence of a common host. Divergence at many levels may then follow.

Rust fungi parasitizing the forest trees and woody plants of the tropics are only beginning to receive study that could add substantially to species diversity in the order. Perhaps even more importantly, discoveries of ecologically unusual rust fungi in the tropics could deepen understanding of the entire group.

Importance of Rust Fungi in Causing Diseases of Forest Trees

All reviews of the interactions of rust fungi with plants emphasize negative consequences for the plant hosts. Negative effects vary from mortality of seedling, sapling, and even mature trees to reduced growth in all age classes. Rust diseases of trees include foliar and needle rusts, cone rusts, limb rusts, stem rusts, and broom rusts. Cankers, galls, premature defoliation, and broken limbs and tops can all be the work of rust fungi.

Symptoms Caused by Rust Fungi

Signs (cells and tissues of the parasite itself) typically accompany symptoms of infection by rust fungi.

Timing is an issue in that symptoms such as chlorosis, or yellowing of normally green leaves or needles, may frequently precede signs. In stems, swellings or galls (symptoms) may be evident long before signs, and this is also true of abnormally dense clusters of stems or twigs that are called 'witches' brooms', or just 'brooms.' In some cases, genetic resistance of the host prevents signs from ever appearing (i.e., the host prevents the parasite from reproducing). When the host is susceptible, rust fungi parasitize its living cells, and their pustules may then frequently be surrounded by what appears to be healthy and normal host tissue.

In **Figure 1**, dark spermogonia are surrounded by orange, swollen tissue in which a *Gymnosporangium* rust has proliferated. However, the host tissue contiguous with the rust is typically green, even as it supplies the parasite with the products of photosynthesis. Once spermatia (**Figure 2**) from spermogonia of opposite mating type are transferred by insects to effect fertilization, aecia develop on the lower leaf surface (**Figure 1**). Once again, host tissue immediately surrounding the aecia typically appears green or 'healthy.'

When signs do appear in the form of sporulating structures or pustules (e.g., spermogonia, aecia, and subsequent uredinia, and telia), rusts are not easily mistaken for other fungi. This is especially true when spores from the pustules can be examined microscopically, either in the light microscope or scanning electron microscope, as in **Figure 2**.

Figure 1 Intimate association of spermogonia and aecia in the 'aecial host' of a heteroecious rust. Dark spermogonia embedded in orange rust tissue on the upper, adaxial surface of a leaf of the host, and following fertilization, aecial 'horns' emerging on the lower surface. A sp. of *Gymnosporangium* on *Amelanchier alnifolia* in mid-summer in the northern Rocky Mountains. Aeciospores released from the 'horns' must infect. *Juniperus*, the 'telial host' to complete the life cycle. Magnification × 10.

Life Cycle of Rust Fungi

Rust fungi are macrocyclic when their life cycle includes five spore states that are often designated by Roman numerals: spermatia (0), aeciospores (I), urediniospores (II), teliospores (III), and basidiospores (IV). A representative of each of the five is shown in **Figure 2**. However, it is important to note that the spore states are not recognized through morphology or appearance alone; the spore states are related to the nuclear cycle, as will be briefly explained.

Basidiospores, and the spermatia that follow them in the 'typical' sequence of spore states, are both genetically haploid and structurally small and simple with thin, smooth walls (**Figure 2**). They differ in that basidiospores are the haploid products of meiosis in addition to being unicellular and relatively ephemeral. Basidiospores must also infect and parasitize a host, whereas spermatia serve only in mating. In rust fungi, mating initiates a dikaryotic phase that encompasses the aecial (I), uredinial (II), and telial (III) states. It is only in the teliospore that the two nuclei of the dikaryon fuse to undergo meiosis to produce basidiospores once again.

Given the role of spermatia in mating, spermogonia and aecia are typically close together (**Figure 1**). Urediniospores and teliospores are sometimes closely associated also; they can even be produced in the same pustule. However, more often uredinia are produced in repeating cycles of infection until finally some host and/or environmental cue provokes the rust fungus to produce telia. Some rust fungi overwinter in a dormant telial state but others form teliospores that immediately produce infectious basidiospores. For example, non-dormant teliospores of the white pine blister rust fungus, *Cronartium ribicola*, produce basidiospores in fall that infect white pines. Those rusts that produce dormant teliospores require some ambient conditioning before they will produce basidia and haploid basidiospores.

Some rust fungi are heteroecious in that the so-called 'aecial host' supports the 0 and I phases of the life cycle, but an unrelated plant is the telial host for the II, III, and IV states. Whereas heteroecious rust fungi have alternate hosts, autoecious rusts lack

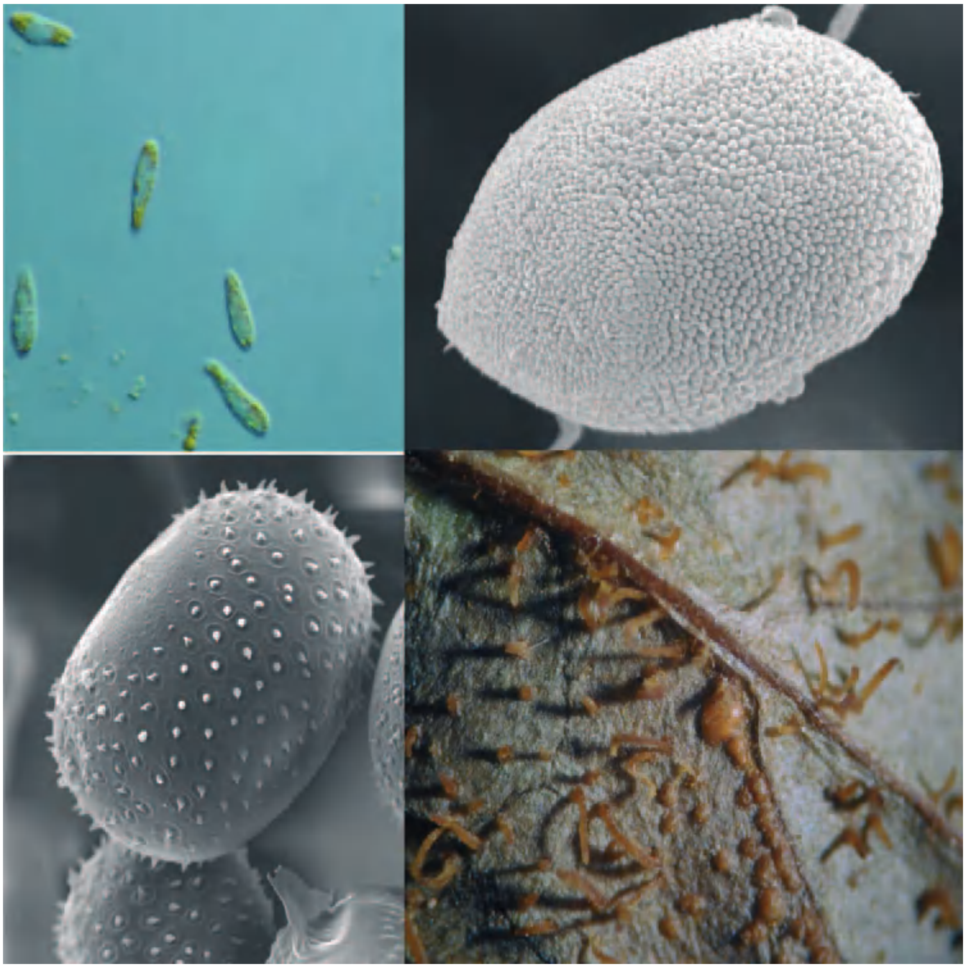

Figure 2 LM and SEM micrographs representative of different spore states, and of the association of uredinia and telia. The LM photo in the upper left is of spermatia from a spermogonium of **Figure 1**. In general, when spermatia of one mating type are transferred by an insect to a spermogonium of the opposite mating type, the aecia develop (× 1000). To the right of the spermatia is a 'warty' aeciospore, produced within an aecium (× 2500). Below the spermatia is a spiny urediniospore; these spores develop within uredinia and may repeatedly infect the same host (× 2000). However, not all aeciospores of rust fungi are warty and not all urediniospores are spiny. The LM micrograph at the lower right shows closely associated uredinia (round pustule in the middle) and telia (hairs or horns) or *Cronartium ribicola* on *Ribes* (× 10). The hairs are chains of teliospores that produce basidia and through meiosis, haploid basidiospores that infect white pines. Note the superficial but misleading, macroscopic similarity of aecial 'horns' and telial 'hairs'.

them. Life cycles from which some spore states are absent are commonly classified as demicyclic (no uredinia) or microcyclic (neither uredinia nor aecia). However, many other variations of life cycle are known. Finally, the life cycles of many rust fungi are still poorly studied.

Host Specialization

If current estimates were correct and there are from 250 000 to 300 000 species of plants, and 7000 species of rust fungi, one might calculate that the average rust fungus thus possesses a host range of roughly 35 to 43 host species. However, well-studied rust fungi are known to be specialists with much narrower host ranges. The discrepancy results from the following factors: (1) not all plant species are parasitized by rust fungi, and (2) not all species of rust fungi are known.

The first factor is demonstrated in **Table 1**. The 120 genera of woody plants in **Table 1** represent genera, primarily of the northern hemisphere, for which the research literature and the databases of the US National Fungus Collections could be used to summarize some major trends. Although rust fungi do parasitize a wide variety of angiosperms, gymnosperms, and even 'primitive,' vascular plants such as *Selaginella*, there are surprisingly genera of woody plants in which resistance to rust fungi has evidently become fixed in evolutionary time (i.e., nonhost genera). It is important to note also that within many genera that do host rust fungi (e.g., *Cornus*, dogwoods), there are many species that appear to be nonhosts. Interestingly, in *Cornus* it is the tree and shrub species that appear to be nonhosts, whereas the circumboreal, herbaceous species are hosts. The one exception is the giant dogwood, *Cornus controversa*, which in Japan hosts a rust fungus in the genus *Aplopsora*.

Another trend that is apparent in **Table 1** and is intriguing, has to do with the number of genera in which North American species are nonhosts for rusts in contrast to at least some of their Eurasian congeners: maple (*Acer*), hazel-nut (*Corylus*), bittersweet (*Celastrus*), *Euonymus*, persimmons (*Diospyros*), redbud (*Cercis*), chinquapin (*Castanopsis*), beech (*Fagus*), witch hazel (*Hamamelis*), mulberry (*Morus*), fringe-tree (*Chionanthus*), devilwood (*Osmanthus*), bladdernut (*Staphylea*), basswood or linden (*Tilia*), and hackberry (*Celtis*).

Among the 33 nonhost genera that are scattered across families that include woody plants of the northern hemisphere, there may be species that host rust fungi that have not been observed. However, most of these genera are quite well studied, and it would seem unlikely that rust infection has been missed. This seems especially true of the 10 nonhost genera that are endemic to North America (including Mexico): *Kalmia*, *Oxydendrum*, *Robinia*, *Umbellularia*, *Cercocarpus*, *Purshia*, *Sequoia*, *Sequoiadendron*, *Taxodium*, and *Planera*. The proportion of nonhost to host genera also seems significant: it is 33 to 87. In any case, there is evidently only a subset of the plant kingdom that hosts rust fungi. This fact transcends the artificial dichotomy between woody and herbaceous plants in that there are also many nonhosts among the latter although such plants are not the focus of this article. It is also true that many rust species or taxa are unknown or improperly delimited. In the latter case, complexes of cryptic or sibling species, among which morphological variation is subtle and continuous, present a considerable challenge to species delimitation.

Ideally, the host ranges of rust fungi would be experimentally determined so as to avoid the conflation of host ranges of cryptic species. To date however, few host ranges have been so determined. In any case, on the one hand there are fewer host species and on the other hand there are more rust species, than may be generally belived.

Rust Fungi Are Specialists in Relation to Plant Tissues and Age

Typically, woody plants are more susceptible to rust fungi when they are young. On a seasonal basis, young tissues are typically also more susceptible than older tissues. However, there may be exceptions to these generalizations about host ontogeny in relation to resistance. In the case of box rust (i.e., *Puccinia buxi* on *Buxus sempervirens* in the UK) there is at least circumstantial evidence that older individuals are more susceptible.

Rust fungi are not known to infect the roots of forest trees, but they may infect all portions of the aboveground shoot system. Similarly, there do not appear to be any clear examples of vertical transmission of seedborne rust, although introductions of rust fungi to new regions may cause the question to be raised.

Genes for Resistance to Rust Fungi

Most of what is known about genetic resistance to parasites of forest trees has been learned by studying rust fungi. Various researchers have identified major genes for resistance to the fungi causing white pine blister rust, poplar rust, western gall rust, and fusiform rust. If other rust fungi parasitizing forest trees received similar attention, it is likely that major genes for resistance would characterize those interactions as well.

Major genes that have been cloned can be proven to function in resistance in transgenic assays. Although major genes for rust resistance from forest trees have not been cloned, they would presumably be like such genes in crop plants in passing such a test. In contrast, partial resistance, that has also been described as quantitative or horizontal, is thought to be under polygenic control in that many genes of minor effect are thought to act in concert (*see* **Tree Breeding, Practices**: Breeding for Disease and Insect Resistance).

Interactions of Rust Fungi with Other Fungi

Less is known about the effects of other fungi on rust infection. *Sphaerellopsis filum* parasitizes rust fungi, and can thus be described as a hyperparasite or mycoparasite. However, *S. filum* is not found on all rust fungi, nor is it always found in all parts of the geographic range of any particular rust fungus. Many other fungi are associated with rust pustules; these may be hyperparasites or opportunists that consume host cells parasitized or killed by the primary parasite, or rust fungus. Some fungal symbionts of forest trees could conceivably stimulate host resistance to rust fungi. However, in general, other fungi have not been developed as tools to control rust diseases of forest trees.

Control of Rust Fungi of Forest Trees

Forest pathology has been greatly influenced by attempts to control rust diseases. Avoidance of areas of high inoculum is generally recommended for new plantings of all forest trees. In the famous case of the introduced *Cronartium ribicola*, or white pine blister rust, extensive and expensive efforts were made to eradicate the alternate host (i.e., species of Ribes), albeit without much success. Pruning, avoidance of areas in which the environment favors infection by *C. ribicola*, nursery applications of fungicide, and programs to breed for resistance are all components of the arsenal deployed against white pine blister rust.

Breeding for resistance to the native, fusiform rust of loblolly and slash pines in the southern United States has also been combined successfully with silvicultural techniques of intensive management. Breeding for resistance to poplar rust is an ongoing battle both in Europe and North America, but again this subject is presented in more detail in this volume and elsewhere.

Stem Canker Diseases

T R Gordon, B J Aegerter and C J Friel, University of California, Davis, CA, USA

Introduction

Canker diseases are caused by a diverse array of pathogenic fungi, and are grouped together based on similarities in the symptoms they produce on their host plants. Our treatment will be restricted to diseases caused by fungi in the group known as Ascomycetes. This includes most of the biotic pathogenic agents responsible for cankers, but does exclude at least one noteworthy group: the obligate parasites known as rust fungi, some of which cause diseases referred to as cankers (*see* **Pathology**: Rust Diseases). Even with this limitation, canker diseases represent a heterogeneous grouping, which is unified more by the nature and location of the damage on the tree than the appearance of the diseased tissue.

Pathology

A canker would typically be defined as a more or less sunken area on a stem or branch where pathogen growth has killed the underlying cambium, and which is often bordered by host-produced callus tissue. Thus, it is the combination of no growth where host tissue is killed and a somewhat elevated border of callus produced in response to infection that defines a depressed area known as a canker. However, many so-called canker diseases do not have symptoms at all similar to the forgoing description, and among the pathogens that produce typical cankers, some will do so only on certain plant parts, such as large-diameter branches, because younger branches die too quickly after infection for a canker to develop.

To account for variation in the appearance of cankers induced by different pathogens, three subgroupings have been recognized: perennial, annual, and diffuse cankers. Perennial cankers would most closely match the description given above. As the name implies, perennial cankers persist for many years. Their appearance may change over time, reflecting the dynamic nature of the interaction between host and pathogen. For example, the sunken appearance becomes increasingly apparent as surrounding healthy tissue expands while growth has ceased in the cankered area. Concentric rings may develop around the canker due to annual production of callus tissue in response to infection (these have been termed 'target cankers'). In some cases the callus may expand into the interior of the canker and even cover it completely. The appearance of the canker may help to identify the causal agent, and many publications and internet resources provide photographs that are useful for diagnostic purposes.

Annual cankers are those that do not persist past a single year, so there is insufficient time for differential growth of infected and healthy tissue, and/or production of callus to produce the distinctive appearance of a perennial canker. Annual cankers are often associated with an effective host response that contains the infection, and the affected area may be overgrown with callus, which effectively 'heals' the wound. On the other hand, those in the third category, diffuse cankers, expand rapidly and outpace radial growth of the tree. The inability of the host to contain the pathogen effectively often results in girdling of the affected branch or stem. This type of canker would commonly be found in young tissue on a highly susceptible host.

In summary, canker diseases are those that affect branches and stems of various age and size classes, where growth of the pathogen leads to death of the colonized tissue, which, combined with structural alterations to the bordering healthy tissue, may or may not lead to a sunken appearance. Where cankers occur on young branches near the growing tip, the end result will likely be girdling of the affected branch and the disease might well be placed in the category of 'shoot blight' or 'tip dieback.' The same pathogen growing on larger diameter branches may produce a more discernible canker; *Diplodia pinea*, described below, is one example of a pathogen that produces both types of symptoms.

Economic Impact of Cankers

Where damage is restricted to tip dieback, the principal economic impact will be reduced growth due to loss of photosynthetic tissue and redirection of resources to defense and away from growth. This effect will be greatly magnified when cankers form on larger branches, increasing the proportion of crown affected. Cankers on the main stem can affect the entire tree by compromising transport of water to the canopy and photosynthate to the roots. Cankers on the main stem can also lead to differential rates of radial expansion, enhancing the risk of structural failure and providing points of entry for other wound-infecting pathogens, such as wood-decay organisms. Wood quality is affected as well. A higher proportion of non-woody cells reduces the strength of the wood, whereas discoloration and resin accumulation (two commonly co-occurring symptoms) impair the appearance of the wood and reduce its permeability to preservatives.

In general terms, one might ask how canker diseases developed into problems for forest trees, and if there are common features that can explain these syndromes and thereby suggest ways in which their impacts can be minimized. A first step toward answering such questions is to consider the diversity of pathogens that are associated with canker diseases and the nature of their relationships with host trees. Not surprisingly this exercise quickly exposes our lack of knowledge of pathogen biology and the host–pathogen interactions that give rise to disease syndromes. In particular, we are largely ignorant of how contemporary associations came to be; i.e., what was the relationship between host and pathogen prior to human intervention and how has the latter altered the situation? Although the information available on these subjects is incomplete, some well-studied examples provide a basis for speculation on hypothetical pathways to pathogenicity that may account for much of the present inventory of canker diseases.

Ecology of Canker-Causing Pathogens

We can begin by considering the ecological role of canker-causing pathogens in a native forest. Trees are primary producers in forested ecosystems and as such represent a source of fixed carbon to be exploited by other organisms, including fungi. In principle, fungi could access the nutrients available in standing trees through overt pathogenesis, leading to death of the host and assimilation of its constituent parts. No doubt fungi have pursued this strategy at various times, but it has not led to associations of long duration, for obvious reasons. Host trees susceptible to such an onslaught would be eliminated from the forest and leave relatively few propagules to seed later generations. Populations would thus be extirpated or, through natural selection, enriched with individuals more resistant to the aggressive pathogen. In the latter case, presumably either the pathogen would be eliminated for lack of a suitable host or a more stable relationship would ensue. Such a relationship could involve limited colonization of living trees, whereby the pathogen obtains nutrients without severely impacting the host.

Weakly parasitic associations could develop as described above, or more directly through selection from strictly saprobic fungi for strains that are sufficiently invasive to gain limited access to host tissue prior to its demise. Regardless of how it came about, fungi employing this strategy can persist, albeit with limited growth in most cases, at the expense of their host, and may further benefit from their proximity to the underlying tissue, which can support more extensive growth when the tree, or a part of it, is no longer living. Such a relationship is obviously beneficial to the fungus, with a more variable and less predictable impact on the host. The literature on forest pathology clearly shows that many fungi exploit trees in this way and they are regarded as benign colonizers of nonliving tissue or minor pathogens of little consequence.

Relationships between organisms are inherently dynamic as they are subject to alteration due to physiological or genetic changes in either participant, and to changes in the ambient environment. These factors provide a framework within which pathways to pathogenesis can be recognized. In the context of a native forest, trees growing on sites to which they are well adapted could be expected to tolerate the presence of weakly parasitic fungi in their bark and to a lesser degree in more internal tissues. In fact, healthy trees commonly support the growth of many fungi within their living tissues and may never suffer ill effects from them (such fungi are often referred to as endophytes). On the other hand, trees growing under less suitable circumstances may be unable to devote the resources necessary to limit growth of parasitic fungi, and one or more of them may thus be allowed to grow aggressively and cause visible damage to the tree. Such parasites are generally referred to as opportunistic pathogens, and it seems likely they serve as one means by which the geographic range of a tree species is enforced. It follows from the nature of this relationship that its pathogenic manifestation is seldom observed, but its historical role in shaping biogeographical patterns in the forest may be profound.

Incidence and Severity of Canker Diseases

Evidence for an effect of growing conditions on the incidence and severity of canker diseases may be found in observations of numerous host–pathogen combinations. For example, in a US Forest Service publication on diseases affecting native conifers on the Pacific Coast, 12 of the 14 canker diseases included are described as being more severe on trees growing on poor sites and/or subjected to drought stress; the absence of this qualification in two cases may be due only to incomplete information on the diseases. A particularly dramatic example of site effects on disease severity is provided by cypress canker, caused by *Seiridium cardinale*. This disease is unknown in native stands of Monterey cypress, which are found on the California coast where temperatures are moderate and fog is frequent, but is common and often fatal to planted Monterey cypress in warm, dry environments farther inland. Thus, for a forestry enterprise and for landscape plantings, proper site selection is an important component of managing canker diseases.

Physical location will not be the only determinant of the growing environment to which trees are subjected. For example, stand density can impose limits on access to light and soil moisture, which may lead to stress that, in turn, may promote the activity of otherwise minor pathogens. This density-dependent effect of plant pathogens provides one mechanism for natural thinning, which will tend to promote stocking levels that are more sustainable. Just as dense stands can render light-deprived trees more prone to damage from canker diseases, shade-suppressed lower branches on otherwise vigorously growing trees are often preferred sites for development of these pathogens. As a result, weakly parasitic fungi participate in the early stages of nutrient cycling by initiating the breakdown of plant parts no longer making a positive contribution to the carbon economy of a growing tree.

Many factors that influence tree health and vigor can render the impact of canker diseases more severe. One commonly cited predisposing factor is water stress brought about by an abundance of neighboring trees and/or insufficient precipitation. *Diplodia pinea*, for example, is known to be more damaging on trees subjected to drought. Additional predisposing factors reported to be important for some canker diseases include: extremes of weather such as frost and hail, and infection by other pathogens such as dwarf mistletoe. Any of these factors could lead to elevated incidence of a disease in a native forest. Obviously exotic plantations invite the possibilities of more severe and persistent problems.

The foregoing discussion implies that vigorous, healthy trees growing under conditions to which they are well-adapted should not sustain serious damage from canker causing pathogens. This generalization is reasonably well supported, but is predicated on a critical assumption: that the depredations of pathogenic fungi have been moderated through a long history of association between host and parasite. Thus, weakly parasitic saprobes in-waiting are a part of the environment to which native trees are adapted. Such adaptations will not necessarily be applicable to foreign microbes, which can expose inherent genetic susceptibilities of native trees, with catastrophic consequences.

Long-distance movement of parasitic fungi offers an alternate path to pathogenesis for tree-associated fungi. Here too the pathogen may have originated as a weak parasite, but in this case it has been moved to a new host to which it is preadapted for virulence. Whereas in its native environment the fungus was a benign associate of its host tree, it has the potential for more aggressive growth on a related host species that has not previously been exposed to the parasite, and lacks the ability to contain its growth. It should be added here that it is probably the exception when introduced fungi become successful pathogens; the failures are likely to be far more numerous but they are difficult to document.

In the sections that follow, we will provide a detailed account of three canker diseases, all of which have become problematic due to movement of the pathogen to new areas. For the first of these diseases, chestnut blight, the historical impacts have been particularly dramatic, whereas the second, pitch canker, is a more recent development that continues to unfold. For the third disease, *Diplodia* canker, pathogen introductions have been important, but movement of the host to suboptimal growing sites can also be a critical determinant of disease severity. The three diseases differ in the extent of the damage they have caused and the manner in which the host–parasite relationships have stabilized. Although this is but a small sampling of the many canker diseases known to affect forest trees, it will serve to illustrate key features found among pathogens causing this type of disease.

Chestnut Blight

The causal agent of chestnut blight, *Cryphonectria parasitica*, infects species of chestnut (*Castanea*) as well as several species of oak (*Quercus*) and chinquapin (*Chrysolepis*). The fungus is a weak pathogen on some live oak species in the southeastern USA. It is more damaging to European and eastern US white oaks and other *Quercus* species, causing twig and branch dieback and perennial cankers on larger trunks leading to mortality in some cases. In species of *Chrysolepsis* from the eastern USA, similar symptoms accompany more extensive mortality, whereas *Chrysolepsis* species in California are unaffected by *Cryphonectria parasitica*. All species of *Castanea* are susceptible to some extent. On Asian species (*C. crenata* and *C. mollissima*), the pathogen is predominantly an opportunist, living as a saprobe and infecting pruning wounds and weather-induced injuries, causing deformations and some canker damage, but rarely death.

The manifestation of chestnut blight on American and European chestnut species (*C. dentata* and *C. sativa* respectively) is infamously more serious than on those described above. The fungus was introduced to the USA in 1904 and rapidly spread through the entire native range of American chestnut in the eastern third of the country. Presumably, the disease was introduced on infected young trees or seed from Chinese chestnut planted as an ornamental in New York. The chestnut blight pathogen isolated from those trees was also known from Asia where it had little effect on native trees; but by the mid-1950s *Cryphonectria parasitica* had devastated native stands of American chestnuts, reducing the trees to dense collections of vegetative shoots emerging from the bases of otherwise dead trees, and ruining the vast economy supported by products harvested and manufactured from this once-dominant tree species. Similarly, introduction to Europe is thought to have occurred in the 1920s when Japanese chestnut trees, resistant to a disease which had plagued the local chestnut industry, were planted among the extant European chestnut in Italy, Spain, and France. *Cryphonectria parasitica* was first reported in Italy in 1938 and quickly spread throughout European stands causing severe and sometimes total crop losses over a 25-year period.

Development of the Disease

Chestnut blight is initiated when spores are introduced into wounds on stems primarily by the actions of insects and birds. The fungus grows to gain access to the inner bark and cambium layers and eventually, sunken cankers form on the bark. The cankers are characterized by long cracks and the orange–brown color of stromata (a mixture of fungal and plant tissue) that hold spore-containing pycnidia (**Figure 1**). Orange strands of asexually produced spores ooze from pycnidia during moist weather and are again spread by insects and birds and by rainsplash. Brown mycelial mats form under the bark, and eventually callus tissue forms at the margin of the elongated canker and the bark sloughs off. Successive callus formation and sloughing sometimes leave a bull's-eye appearance to the cankers. As the disease progresses, perithecia form in the stromata and produce ascospores (i.e., sexual spores) that are forcibly discharged and dispersed by the wind. Both

pycnidia and perithecia can be present within the stromata at the same time. The fungus continues to grow until it ultimately girdles the stem, restricting the flow of water thus killing the affected part distal to the infection.

On American and European chestnuts, the early stage of disease reveals yellow and brown leaves that remain on the branch for the first year of infection. Bare branches appear as a result of earlier infections. The disease affects twigs, branches, and trunks but not the roots, which continue to live and send up numerous vegetative shoots. These shoots are eventually subjected to infection by the pathogen, canker development, and dieback. New shoots soon form and the cycle continues; the roots never produce a mature tree.

Genetic Resistance

There is no control for chestnut blight on *Castanea dentata* in the USA. Breeding programs are plagued by a high frequency of disease escapes in resistance trials. Furthermore, many Asian varieties and Asian hybrids that are resistant or show tolerance to the pathogen are grown as ornamentals and for nut production, but also provide potential reservoirs of inoculum that threaten extant American chestnut trees that were previously protected by isolation from the native stands. Outbreaks in small, isolated plantings located in California, Oregon, and southwestern Canada have been kept in check only through sanitation and early intervention to eradicate affected trees. Also, small plantings of *C. dentata* in Wisconsin, 200 miles west of the westernmost boundary of the native range, have remained intact until the relatively recent appearance of *Cryphonectria parasitica*. Intensive research efforts are focused on controlling the disease there.

Biological Control

Biological control efforts hold considerable promise for management of chestnut blight in Europe. These measures follow from observations of natural recovery of European chestnuts in southern Europe in 1951. Strains of the fungus isolated from cankers on recovering trees had a different appearance in culture and were not as virulent as strains recovered from active cankers. This phenomenon was termed hypovirulence, and is now known to be conferred by a mycovirus that infects the pathogen and can spread to uninfected strains, thereby allowing diseased trees to recover. Transmission of the mycovirus requires hyphal fusion, which can only occur between genetically compatible strains of the fungus. In Europe, interstrain compatibility is common, and natural spread of hypovirulence led to recovery of diseased trees in some areas (**Figure 2**). This has been augmented with artificial inoculations of active cankers with hypovirulent strains of *C. parasitica* to provide effective biological control of chestnut blight. As a result, chestnut is still profitably cultivated in Spain and Italy. Hypovirulence has not proven to be an effective control measure in the USA, where the genetic structure of fungal populations is much more diverse. This limits compatibility between strains, and thereby restricts transmission of the mycovirus. As a result, hypovirulence is not widespread in the pathogen population and the recovery observed in Europe has not occurred in North America.

Pitch Canker

Pitch canker is caused by *Fusarium circinatum*, an asexual form (anamorph) that also produces a sexual stage by the name of *Gibberella circinata*

Figure 2 Callus tissue grows over 'healed' cankers that were inoculated with hypovirulent strains of *Cryphonectria parasitica*. Figure 3 Pitch canker on *Pinus radiata*; multiple infections caused by *Fusarium circinatum* lead to death of the affected branch distal to the girdling canker. Diseased branches are identifiable as naked tips or by the associated killed (brown) needles, where these have not yet fallen.

(teleomorph). Although the sexual stage is readily produced under laboratory conditions, it is rarely, if ever, seen in nature. Pitch canker was first described in the southeastern USA where it came to be regarded as a chronic problem affecting a number of southern pine species in plantations, seed orchards, and nurseries. In 1986, the disease was discovered in California as a cause of extensive damage and mortality to planted *Pinus radiata* (common names: Monterey pine and radiata pine). Soon thereafter, pitch canker was reported in both native forests and plantations in Mexico, in pine seedling nurseries in South Africa, and among planted pines in Japan. More recently, pitch canker has been documented as a cause of seedling mortality in Chile and Spain.

The nature of the damage caused by pitch canker varies with the tree species and the circumstances under which it is growing, but commonly involves dieback in the canopy to varying extents (**Figure 3**). Death of a branch tip results from a girdling canker on the current year's growth. Disease severity increases due to multiple tip infections and independent infections on larger branches. Complete girdling of the main stem can occur as well, most often probably as a result of multiple coalescing cankers rather than a single infection. Resin accumulates in and around infection sites, this being especially pronounced on older branches and the trunk of the tree (**Figure 4**). Cones and pollen-bearing strobili may also be infected.

Although pitch canker is a relatively minor problem for plantation forestry in the southeastern USA, it represents an evolving and increasingly serious problem in other parts of the world. In California, native *P. radiata* forests have been badly affected, and damage to the extensive landscape plantings of this species is a continuing problem. Although *P. radiata* has suffered by far the most damage from this disease, most pines native to California are also susceptible, and some of these have become severely diseased where they are exposed to the pathogen. Perhaps the greatest concern about pitch canker lies in its potential to attack exotic pine plantations in the southern hemisphere, where *P. radiata* is a critically important species.

Figure 4 Resin streaming from multiple cankers on the main stem of *Pinus radiata* caused by *Fusarium circinatum*. Reprinted with permission from Gordon TR, Storer AJ, and Wood DL (2001) The pitch canker epidemic in California, *Plant Disease*, 85: 1128–1139.

Although pitch canker was first described in the southeastern USA, it is not known if this constitutes the site of origin of the pathogen, or if it was introduced there. One other possibility for the aboriginal home of the pitch canker pathogen is Mexico, which is a center of diversity for the pine genus and where the population of *F. circinatum* is genetically quite diverse. In any case, most accounts of pitch canker in the southeastern USA suggest that the disease has 'stabilized' in this area, being widespread but rarely severe. On the other hand, where the pathogen is a more recent arrival, its geographic range may still be expanding. Thus pitch canker is regarded as an endemic problem in the southeastern USA but an invasive pathogen in California, South Africa, Chile, and Spain.

Factors in Susceptibility

The potential for pitch canker to pose problems for forest trees can be assessed by considering the basic elements required for a pathogen to cause disease: a susceptible host and a permissive environment. This is well illustrated by *P. radiata* which, as a species, is highly susceptible but does include some resistant individuals (**Figure 5**). In addition, some trees that become infected may eventually recover from pitch canker. This results from a loss of symptomatic branch tips through breakage in the vicinity of the canker and a lack of new infections, which has been attributed to systemic induced resistance. Thus, the damage caused by pitch canker to a stand of *P. radiata* will be determined, in part, by the proportion of trees that manifests inherent and/or induced resistance to the disease.

Figure 5 A stand of *Pinus radiata* that includes many pitch canker-infected trees, one of which (large tree on the right) has been killed by the disease. An adjacent tree (left of the dead tree) has remained free of symptoms due to genetic resistance.

Where trees are fully susceptible to pitch canker, disease development may be constrained by environmental limitations. The pathogen requires a wound and ambient conditions that allow wounds to remain moist long enough for infections to become established. In the southeastern USA, weather-related events are regarded as the important cause of wounds for infection, whereas in California pine-associated insects appear to be the most important wounding agents. Where aboveground damage caused by pitch canker is a problem, atmospheric moisture is plentiful during periods of moderate temperatures. Such conditions are provided by warm summer rains in the southeastern USA, and by rain and fog along the California coast. Movement of the disease to more northerly locations in North America may be limited by progressively lower temperatures. In California, drier conditions in more inland areas are likely to be restrictive. It is noteworthy, however, that most of the approximately 4 million ha planted to *P. radiata* elsewhere in the world are in regions where the climate should be conducive to development of pitch canker.

As noted earlier, pitch canker can be a problem in seedling nurseries. Under these conditions it infects roots and may kill seedlings at or before emergence or almost anytime thereafter. In very young seedlings, symptoms of the disease are not distinctive, but in older seedlings (1–3 years) tree death is associated with girdling of the main stem near the soil line, where the accumulation of resin is similar to what is seen in the aerial phase of the disease. Where *F. circinatum* is operating as a soilborne pathogen, the environmental limitations described above are not likely to pertain.

From a global perspective, management of pitch canker should emphasize prevention, by avoiding importation of the pathogen into areas where forest resources would be at risk from this disease. Although *F. circinatum* can survive in association with various infected plant materials (and in soil), seed probably represents the most efficient vehicle for dissemination. Seed can be infested externally or internally and may give rise to seedlings that die quickly or survive without symptoms for 6 months and possibly much longer. Sowing infested seed will contaminate soil, which may thereafter serve as a reservoir of the pathogen, and subsequent shipment of symptomless seedlings provides an ideal mechanism for establishment of the disease in plantations or landscapes.

Genetic Resistance

In the long term, genetic resistance to pitch canker may have a role to play in disease management. In native forests, practices that promote regeneration may facilitate natural selection for more resistant genotypes, which are known to be represented within *P. radiata* populations, for example. In managed plantings, it may be prudent to avoid highly susceptible pine species altogether, in favor of those less prone to severe damage. However, where industries are heavily committed to *P. radiata*, as in Chile, New Zealand, Australia, and Spain, it should be possible to enhance the level of resistance in improved varieties. This can be accomplished through vegetative propagation of known resistant clones, but it is as yet unknown how many different genetic combinations may confer resistance. As a consequence, it may not be possible to deploy an array of clones that is sufficiently diverse to avoid undue risk of catastrophic failure due to selection for more virulent strains of the pathogen. Likewise, the heritability of resistance has not been established so the prospects for increasing resistance through family-level selection cannot yet be assessed. Research is needed to better understand the genetic basis for resistance to pitch canker and facilitate its application to disease management.

Diplodia Shoot Blight and Canker

Diplodia shoot blight and canker, caused by *Diplodia pinea* (syn. *Sphaeropsis sapinea*) is common in temperate regions worldwide. This pathogen infects conifers in both the Pinaceae and Cupressaceae, including various species of *Cedrus* (cedar), *Juniperus* (juniper), *Picea* (spruce), *Pinus* (pine), and *Pseudotsuga* (Douglas-fir). The disease is most frequently seen on two- and three-needled pines, on which tip dieback is the most common symptom (**Figure 6**). Cankers caused by *D. pinea* are characterized by elongated, depressed areas on branches or stems, often with resin flow on the outer bark. When the bark is removed, resin-soaked wood is visible (**Figure 7**). In older infections, callus growth may be observed around the edges of the canker. Where young branches are infected, needles and shoots stop expanding and are quickly killed, later appearing stunted and necrotic. Infected stem tissues are initially water-soaked in appearance, later becoming purplish-brown and necrotic. Repeated tip and/or stem infections can lead to branch death. The seedling phase of the disease, called collar rot, is characterized by similar infections, which may girdle the stem and cause mortality of seedlings.

Economic Importance

Diplodia shoot blight and canker is seldom damaging to trees planted within their natural range and as such it is rarely important in native forests. On the other hand, exotic pine species in plantations or in landscape plantings can be severely affected. For example, this disease has caused economic damage to *Pinus patula* (Mexican weeping pine) and *P. radiata* in plantations in the southern hemisphere (**Figure 8**) and to both exotic (e.g., *P. nigra* and *P. sylvestris*) and native (*P. resinosa* and *P. banksiana*) pines in the north central USA.

Two subgroups of the pathogen have been described, morphotypes A and B, which are differentiated on the basis of colony morphology and growth rate in culture as well as by isozyme profiles and DNA polymorphisms. The two morphotypes also exhibit differential aggressiveness to pine, with A being more aggressive. Recent work indicates the two morphotypes should be considered separate species, with the A morphotype being associated with the binomial *D. pinea* and the B morphotype designated as a new species, *D. scrobiculata*.

Life Cycle

The fungus produces spores in fruiting bodies (pycnidia), visible with a hand lens, on needles, fascicle sheaths, cone scales, and bark. Even apparently symptomless trees may harbor spores formed on cone scales. Pycnidia typically form in the spring of the year following infection. Spores contained in pycnidia are transparent at first and later become brown. These are released during wet weather and are spread by rainsplash or wind-driven rain. Spores can infect expanding needles and shoots, and second-year cones, where surface wetness persists for 12 h at 12–36°C. Infection of mature current-year and older shoots and stems can occur through fresh wounds, such as those caused by insects, hail, or pruning.

This fungus is also considered an endophyte because it can be associated with symptomless infections. Such infections are thought to become damaging when the host is predisposed by some form of abiotic or biotic stresses. Drought stress in particular has been well-documented to induce damage in *D. pinea*-infected trees. The ability of *D. pinea* to exist within its host as a latent pathogen suggests that this fungus has a long history of association with pines. The observation of more severe disease on off-site or stressed trees and on exotic species in plantations fits the pattern described above for weak parasites that become opportunistic pathogens when conditions are altered to the detriment of the host.

Management

Management of diplodia shoot blight and canker in plantations depends primarily on avoidance of the disease. Careful selection of the planting site and of a timber species appropriate for that site are important to minimize stress. High soil fertility should be avoided as this has been shown to aggravate the disease in some situations. Should the disease reach severe levels within a commercial stand, replanting or early harvest may be warranted. In nurseries, seedling beds should not be established in the vicinity of older trees as these may serve as a source of inoculum. Seedlings can be protected by frequent fungicide applications until shoots and needles are mature. On Christmas-tree farms, fungicides may also be employed to protect trees, but control depends primarily on avoiding shearing operations during wet weather.

Conclusion

The three canker diseases described above illustrate ways in which movement of plants and pathogens can lead to new or significantly altered host–parasite relationships, with devastating consequences. Chestnut blight in North America offers an extreme example of an exotic pathogen preadapted for virulence, where susceptibility of the host was complete and the result was disappearance of a dominant tree species throughout a vast forest ecosystem. Pitch canker is also caused by an exotic pathogen, but one that has not found a host as devoid of resistance as the American chestnut was to the blight pathogen. Susceptibility to pitch canker is the rule in *P. radiata* and mortality has been widespread, but a small percentage of individuals proved to be highly resistant and many others have sustained relatively minor damage. This, combined with remission in some severely diseased trees, suggests that the host–pathogen relationship will stabilize in a way that allows *P. radiata* to remain a defining feature in forests that bear its name. Likewise, chestnut blight in Europe show signs of stabilizing, not through a response of the host but because the pathogen is itself debilitated by a parasite. Thus, various mechanisms can serve to constrain the aggression of an invasive species, imparting a resilience to forested ecosystems that has no doubt been critical to their persistence.

Diplodia pinea offers a contrast to chestnut blight and pitch canker in that native forests suffer little damage from it. In this case, too, introduction of the pathogen into new areas has created problems, but primarily for exotic plantation forestry. Thus, movement of the host to suboptimal sites is the primary reason *D. pinea* is a damaging pathogen. The genetic constitution of most potential hosts prevents aggressive growth of *D. pinea*, except where trees are compromised by stress. In a broad sense, all three canker-causing pathogens are opportunists that differ in the nature of the opportunities they have exploited.

In terms of management, these diseases illustrate the importance of prevention, especially where this can be achieved on a regional scale by limiting new pathogen introductions. Unfortunately, historical barriers to the spread of plant pathogens, such as spatial gaps in host distribution, are increasingly likely to be breached through steadily increasing trade and travel. Ever-present threats include not only known major pathogens but also untold numbers of minor pathogens that await their opportunity to flower into full virulence. Thus, the implementation of any new and effective measures to limit more widespread distribution of plant-associated microbes offers great potential to reduce the risk of major new disease problems for forest resources worldwide.

Insect Associated Tree Diseases

J N Gibbs, Aberyail, Llangynidr, UK
J F Webber, Forestry Commission Research Agency, Farnham, UK

Introduction

The causes of tree diseases range from the simple – with one principal damaging agent – to the complex – where a number of damaging agents interact.

A key role for insects in some simple diseases is that of vector for a pathogen. This is particularly important for certain fungal diseases. However, insects also play a vital part in the dissemination of some tree-pathogenic nematodes, phytoplasmas, xylem-limited bacteria, and viruses.

In complex tree diseases insects may play a variety of roles. At an early stage, leaf-eating insects may act as agents of stress. At a later stage it may be bark- or wood-inhabiting beetles that deliver the final death blow to the tree.

Fungal Diseases Vectored by Insects

Among the fungi, there are three main taxonomic groups: the Oomycotina, the Basidiomycotina, and the Ascomycotina (plus the closely allied Fungi Imperfecti). The majority of fungal pathogens with known insect vectors are either Ascomycotina or Fungi Imperfecti, and most of the ascomycetes fall within two genera of the family Ophiostomataceae – *Ophiostoma* and *Ceratocystis*. In addition, most of the imperfect fungi are *Chalara*, *Leptographium*, or *Verticicladiella*, genera that would be expected to have *Ophiostoma* or *Ceratocystis* perfect states. The nature of the insect–fungus relationship with this group of pathogens is discussed in some detail later in this article. Among other ascomycetes, recent attention has focused on the role of insects as vectors of *Fusarium circinatum*, the cause of pitch canker. This major pathogen, first recognized in the eastern USA, was reported from California in 1986. Studies there on *Pinus radiata* have focused on the twig-feeding bark beetles *Pityophthorus* spp., but other beetles, including the cone beetle *Conophthorus radiata*, have also been implicated. In southern Europe, a cone-feeding insect, the seed bug *Orsillus maculatus*, has been found to transmit the important canker pathogen *Seiridium cardinale* to *Cupressus sempervirens* cones. Once the cones are colonized by the fungus they become a source of inoculum for branch infection. Interestingly, it seems that when *S. cardinale* arrived in Europe, it took over a long-established relationship between the insect and a nondamaging fungus *Pestalotiopsis funerea*.

Although the Basidiomycotina include many fungal pathogens of trees, the only indubitable case of insect transmission concerns the *Amylostereum* species that are transmitted by woodwasps in the genera *Sirex* and *Urocerus*. In most parts of the world these organisms do little damage but in Australia and New Zealand, *Sirex noctilio* and *Amylostereum areolatum* can cause significant losses in *Pinus radiata* plantations, especially during periods of drought.

The fungus is carried by the adult siricids in a pair of small invaginated intersegmental sacs protruding into the body. These are connected by ducts to the anterior end of the ovipositor. During oviposition (**Figure 1**), spores of the fungus are 'injected' into the sapwood of trees and developing mycelium then invades the wood around the oviposition hole and larval tunnels. As is commonly the case with xylem pathogens, a zone of reduced moisture content develops around the tissue occupied by *Amylostereum* and this ensures that the *Sirex* eggs hatch and the larvae develop in relatively dry wood. In addition, host resinosis is reduced in colonized tissue, and this also favors larval development. Female larvae, from the second instar onwards, carry the

Figure 1 *Sirex* woodwasp, vector of basidiomycete *Amylostereum* ovipositing on pine. Courtesy of Forest Commission.

Figure 2 A soil tent (arrowed) produced by ants, causing *Phytophthora megakarya* infection of cocoa pods. Courtesy of CM Brasier.

fungus in deep skinfolds called hypopleural organs sited in the abdomen. The young adult then acquires the fungus during eclosion when, by reflex actions, it breaks up the hypopleural organs in the cast-off larval skin. Interestingly, inoculation with the fungus alone has relatively little effect and the insect's mucus secretions are believed to play an important part in 'conditioning' the tree for invasion by *A. areolatum*.

The only oomycetes known to be insect-vectored are *Phytophthora palmivora* and *P. megakarya*. They cause black pod disease of cocoa and can also cause stem cankers and wilt of flower cushions. Although these fungi can be disseminated via rain splash and contact with plant litter, several species of ants have been found to act as vectors. Transmission occurs when ants collect particles of soil contaminated with *Phytophthora* and build them into tents on the cocoa plants, including on the pods (**Figure 2**). These can then become infected with the pathogen, which appears to be capable of invading both wounded and uninjured pods.

The Ophiostomoid Pathogens of Standing and Freshly Felled Trees and their Insect Dispersal

Because of their economic importance, diseases caused by this group of fungi have been subject to detailed research, evaluation of which has thrown much light on the principles underlying the process of insect transmission.

Two contrasting patterns of host invasion can be found in the Ophiostomataceae and these have a significant influence on the nature of the relationship with potential insect vectors. In the vascular wilts the fungus shows extensive vertical distribution in the xylem elements (vessels or tracheids), but is unable to colonize xylem parenchyma, the medullary rays, the cambium, and the inner bark (phloem tissue) until the host becomes moribund. Examples from temperate regions of the world include Dutch elm disease caused by *Ophiostoma ulmi* and *O. novo-ulmi*, oak wilt (*Ceratocystis fagacearum*), and black stain root disease (*Verticicladiella wageneri*), which affects pines and Douglas-fir. A tropical example is takamaka wilt in the Seychelles caused by *Leptographium calophylli*. By contrast, in the vascular stains the fungus invades the rays, ray parenchyma, and inner bark at the same time as it colonizes the xylem elements. Some vascular stain diseases occur in standing trees. Examples are the *Ceratocystis* canker of deciduous trees caused by *C. fimbriata* and the pathogenic bluestain, caused by *C. polonica*, that develops in Norway spruce following trunk invasion by *Ips typographus*. Another pathogenic bluestain occurs in *Pinus contorta* in western North America following attack by the mountain pine beetle *Dendroctonus ponderosae* (**Figure 3**). Here two fungi, *C. clavigera* and *O. montia*, are carried to the trees on the beetles and are strongly implicated in overcoming host resistance. Other bluestains only develop if the trees lack active host resistance following felling or windblow. A European example is the stain caused by *Leptographium wingfieldii* that develops in *Pinus sylvestris* logs following attack by *Tomicus piniperda*.

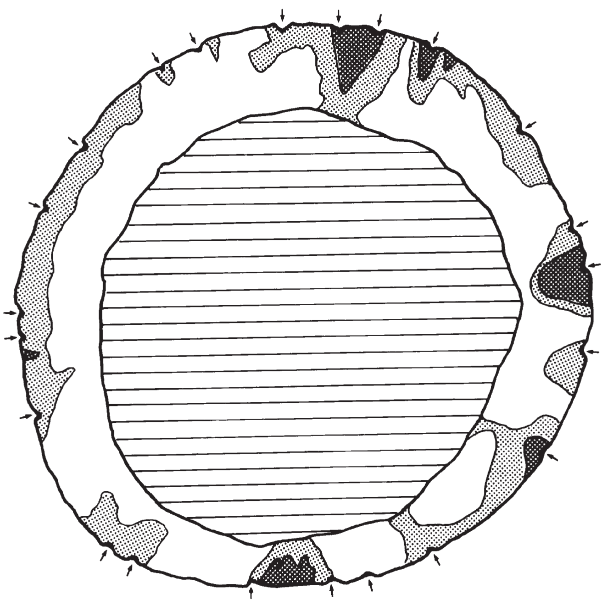

Figure 3 Cross-section of xylem of a lodgepole pine a few weeks after it has been successfully colonized by *Dendroctonus ponderosae*. Arrows show the position of egg galleries. The zone of blue-stained wood and the surrounding zones of wood with reduced moisture are shown with different degrees of stippling. The heartwood is hatched. Some of the patterns are due to the presence of other egg galleries above or below the section. Reproduced with permission from Reid RW, Whitney HS, and Watson JA (1967) Reactions of lodgepole pine to *Dentroctonus ponderosae* and blue stain fungi. *Canadian Journal of Botany* 45(7): 1115–1126.

Establishment of the Link Between Insect and Ophiostomoid Fungus in the Diseased Tree

Specialized plant pathogens are characterized by an expanding phase of parasitic growth in the living host and a declining phase of saprotrophic growth in the dead host. This is because qualities which fit the fungus for parasitism tend to put it at a disadvantage when it comes to prolonged survival in competition with other microorganisms. Any potential vector must have a life cycle that is completed before the disappearance of the fungus, and some likely candidates can prove to be of no significance.

An example is provided in myrtle wilt, a vascular stain disease of *Nothofagus* in Tasmania caused by *Chalara australis*. Very large numbers of the mountain pin hole borer, *Platypus subgranosus*, breed in trees killed by the fungus but while the *Platypus* has a 2–22-year life cycle, *C. australis* survives in the stems of dead trees for only 12–18 months. Hence, the lack of synchrony between the two species prevents the borer from vectoring the pathogen.

Of course, it is not enough for the fungus just to survive in the tree. It also needs to produce propagules that are suitable for insect dispersal. The ophiostomatoid fungi are typically very well adapted for this purpose, as illustrated in **Figure 4** for the Dutch elm disease pathogen *Ophiostoma novo-ulmi*.

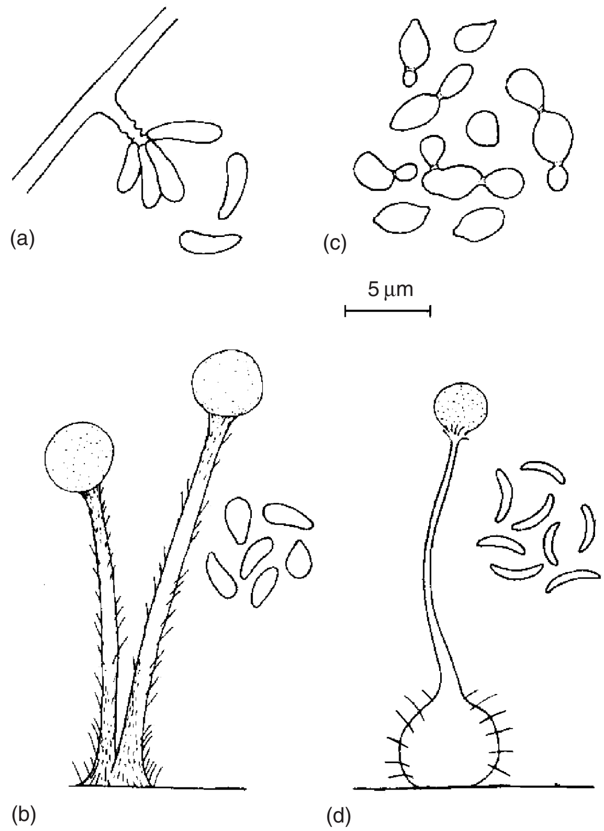

Figure 4 Spore forms and fruit bodies in *Ophiostoma novo-ulmi*. The scale applies to the spores only: (a) conidial or sporothrix stage; (b) stalk-like coremium (c. 1 mm tall) and coremiospores; (c) budding yeast-like stage; (d) flask-shaped perithecium (0.5 mm tall) and ascospores. The coremium and the perithecium are particularly well-adapted for insect dispersal. Courtesy of CM Brasier.

Transport of Ophiostomoid Fungi from Diseased to Healthy Trees

By definition a vector must move from a diseased to a healthy tree, or at least from a diseased part to a healthy part of the same tree. Scolytid beetles act as vectors of Dutch elm disease because, following emergence from their pupal chambers, the young adults often fly to feed in the twig crotches of healthy trees (**Figure 5**) before seeking out suitable fresh bark for breeding.

The method of spore transport, the behavior of the vector and the environmental conditions during dissemination can all influence the chances of successful disease transmission. With some vectors, spores are simply carried externally on the insect's exoskeleton and so are directly exposed to desiccation and ultraviolet radiation during flight. Studies on *Scolytus scolytus* in the UK during the 1980s showed that the mean percentage of beetles carrying *O. novo-ulmi* was over 89% in the pupal chambers but only 17% after emergence and flight.

Although fungi are much better protected if they are contained within the specialized carrying organs, mycangia, possessed by many bark and wood-boring beetles, it is a matter of record that few of the fungi transported in this way have much ability to cause tree disease or bluestain.

Temperature may also play an important part in disease transmission by regulating insect behavior. Although most vectors are commonly assumed to fly, the threshold temperatures for flight can often be quite high – at least 20°C in the case of the Dutch elm disease scolytid vectors. Indeed, the very temperatures which encourage insect activity can often be detrimental to the fungi they transport. For this reason, crawling may be more important than is generally recognized, and is crucial in the dissemination of *Verticicladiella wageneri* by various root-inhabiting beetles and weevils, which actively seek out stressed and diseased roots for oviposition.

Transfer and the Establishment of Infection with Ophiostomoid Fungi

Once the vector has reached a potential host tree, successful transfer of the fungus to susceptible plant tissue and the initiation of sustained disease again

Figure 5 (a) Larger European elm bark beetle *Scolytus scolytus*, vector of Dutch elm disease; (b) feeding grooves (arrowed) produced by *S. scolytus* on *Ulmus procera*. Courtesy of Forestry Commission.

depend on several factors. These include the nature of the infection court, and the quantity of inoculum that is introduced to it.

Wounds are required in all known cases of infection by the Ophiostomataceae involving insect transmission, and, where bark beetles and weevils are involved, the insects are able to make the wounds themselves. However, with other kinds of insects, such as the sap-feeding nitidulids that vector the oak wilt pathogen *Ceratocystis fagacearum*, there is a dependence on wounds made in other ways, e.g., through the use of pruning tools or tree-climbing irons.

The depth of the wound may also be important. With the vascular wilt diseases like Dutch elm disease and oak wilt, the wound must reach the wood if the pathogen is successfully to penetrate and invade the xylem elements, whereas with a vascular stain disease like the *Ceratocystis* canker of fruit trees, a wound exposing live inner bark is all that is required.

The arrival of viable fungal spores in a suitable wound does not necessarily lead to disease. Infection depends on the number and physiological condition of the spores, and on the effects of competing microorganisms. Simultaneous host invasion from many infection points may also be necessary to overwhelm the resistance of a host which might otherwise be able to check the development of a single infection. This has been shown to be important with the vascular stain pathogen *Ophiostoma polonica* on Norway spruce, where doubling the number of inoculation points produced an almost eightfold increase in the amount of wood which succumbed to the pathogen.

Relationships in the Brood Galleries Between Insects and Ophiostomoid Fungi Causing Vascular Wilt Diseases

In a vascular wilt disease like Dutch elm disease, the pathogen can move rapidly away from the point of infection as spores are carried along in the transpiration stream. The result is that symptoms arising from a single infection can appear rapidly throughout the crown. Bark beetles can successfully establish breeding colonies in the trunk and major branches of such trees and, as the larval brood develops, there is the opportunity for a link to be reestablished with the fungus in the xylem. At the same time colonization of the inner bark can also take place from propagules of the pathogen still present on the parent beetles as the latter begin to establish breeding galleries. The subsequent ecological interactions between the beetle larvae and the various ‘sources’ of the fungus are quite complicated.

The survival of the fungus on the parent beetles also means that it can establish itself in brood galleries that are made in the bark of logs or windblown limbs from healthy trees. Young beetles emerging from such material can be just as effective in spreading the pathogen as beetles emerging from diseased trees. Failure to recognize this point greatly hampered early attempts to eradicate Dutch elm disease from the USA in the 1930s.

Insects as Agents for Fertilization in the Ophiostomoid Fungi

It is important to realize that, in the Ophiostomataceaea, as in many other groups of fungi, spore dispersal may be as important, or more important, for fertilization as for infection or substrate colonization. This is because they comprise two mating types and these have to be brought together for the sexual stage of the fungus to be produced. There may also be a link between dissemination for fertilization and dissemination for transmission. For example, in *C. fagacearum*, the cause of oak wilt, the switch from asexual spore to sexual spore production following fertilization prolongs the period over which inoculum is available for disease transmission.

Pine Wilt Disease: Caused by a Nematode, Vectored by Longhorn Beetles

The pine wood nematode *Bursaphalenchus xylophilous* is a native of North America where it causes little damage. However, following its introduction to Japan and subsequently to other countries in Asia, it has caused enormous losses to the native pines. Transmission is by several species of *Monochamus* (longhorn beetles in the Cerambycidae), and, as with the scolytid vectors of Dutch elm disease, these insects can introduce the pathogen both during maturation feeding and during oviposition (**Figure 6**). Within the vector, the nematode exists as a special larval stage, the dauerlarva, but once in the xylem of the healthy tree, the dauerlarvae molt to reproductive adults that mate and begin egg-laying. The first-stage larvae molt while still in the egg and then hatch as second-stage larvae that feed on host parenchyma cells. The larvae molt to third and fourth larval stages and then to adults that continue feeding and breeding. Once the tree dies, the nematodes survive on fungi (principally ophiostomoid bluestain fungi) before forming an overwintering stage. In the same trees, *Monochamus* larvae develop through various instars before pupating and emerging as adults in spring. The overwintering form of the nematode changes into dauerlarvae and these enter the tracheae of the callow *Monochamus* adults via the thoracic spiracles.

Diseases Caused by Phytoplasmas, Xylem-Limited Bacteria and Viruses and their Insect Vectors

These diseases are caused by a loose grouping of tree pathogens that share the characteristic of being unable to replicate except within living host tissue. *Inter alia*, this means that transmission from one host to another is essentially a passive operation. Insects

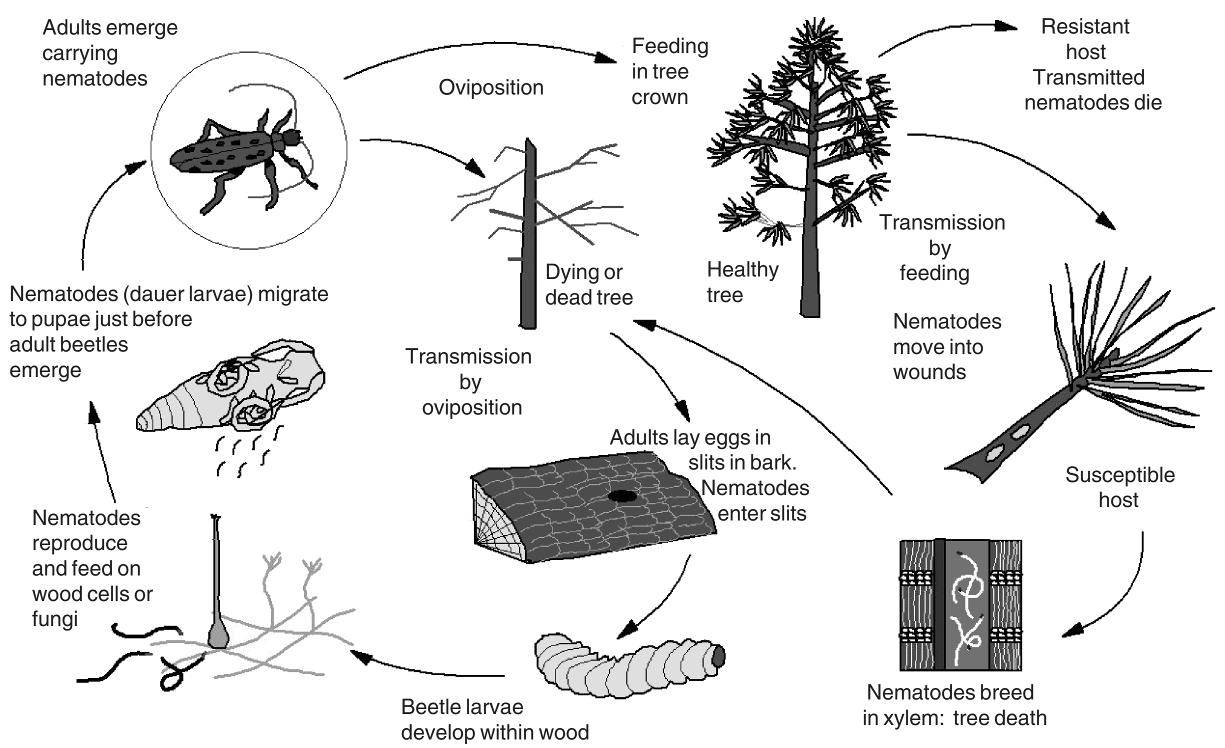

Figure 6 Diagram of the pine wilt disease cycle showing transmission of the nematode both by twig feeding and oviposition. Courtesy of HF Evans.

implicated in the process are all in the Homoptera, a group (suborder) that contains sucking insects such as aphids, leaf-hoppers, psyllids, and spittlebugs. However, only in comparatively few cases are the vectors known with certainty. Phytoplasmas, formerly known as mycoplasma-like organisms (MLOs), have the general characteristics of bacteria but lack cell walls. They can only invade the phloem where they replicate in the sieve tubes. Symptoms typically involve a yellowing of the foliage, followed by progressive dieback. Shoot proliferation resulting in the formation of witches' brooms may also occur. Important examples include elm and ash yellows in North America, lethal yellowing of coconut (widely distributed in the tropics) and, recently, sudden death of cabbage tree in New Zealand.

Detailed knowledge of the role of insects in transmission has been obtained from studies on elm yellows where the white-banded leafhopper, *Scaphoideus luteolus*, is known to be a vector. The pathogen is picked up by the insect during feeding on phloem sap in the leaf veins. It multiplies in the insect's salivary glands and is transmitted to the phloem of healthy trees during further feeding. Almost a year can elapse between infection and the development of symptoms. A planthopper *Myndus crudus* appears to be the principal vector of lethal yellowing of palms. This insect often lives among the roots of various grasses by day but migrates to palm trees at night.

The xylem-limited bacteria are smaller than other plant-pathogenic bacteria and, as the name indicates, are restricted to the host xylem. Strains that cause diseases of trees have been given the name *Xylella fastidiosa*. Symptoms in genera such as elm, plane, and oak include delayed leaf expansion, late-season leaf scorch, and dieback. Given the biology of the pathogen, it follows that their vectors are all xylem-feeding sucking insects. Many species have been identified through studies of the pathogen in the economically important Pierce's disease of grapevine but those involved in transmission to trees are not yet known. However, it is probable that nymphs as well as adult insects will be able to acquire and transmit *X. fastidiosa*. It is suggested that the bacteria form a plaque in the foregut and are flushed out by the sucking pump.

Many of the above-mentioned diseases were originally thought to be caused by viruses. When it comes to tree diseases caused by the true viruses (viruses consist of a nucleic acid core and a protein coat), very few have important insect vectors. One exception is plum pox where up to 20 species of aphid are thought to be involved in transmission.

Role of Insects in Complex Tree Diseases

Tree diseases of complex cause often go under the names of diebacks or declines. A good model for this type of disease involves various agents of stress acting on the tree which is then so much altered that it becomes vulnerable to organisms of secondary action, i.e., organisms that would be unable to cause significant damage to a healthy tree. Defoliating insects very often act as agents of stress, preventing the tree from carrying out photosynthesis and hence causing a depletion in essential food reserves. For example, the introduced gipsy moth (*Lymantria dispar*) plays this role in the condition known as oak decline in the northeastern USA, and so does the native oak roller moth (*Tortrix viridana*) in the somewhat similar condition in northern Europe known as oak dieback. Similarly, sucking insects can act as agents of stress by removing large quantities of sugars from the phloem. Thus in the condition known as beech bark disease, the scale insect *Cryptococcus fagisuga* builds up huge populations on the trunks of beech (*Fagus sylvatica* in Europe and *F. grandifolia* in North America) and renders the bark vulnerable to attacks by fungi (*Nectria* spp.) that would not normally be capable of damage.

Insects often also act as organisms of secondary action. Thus many beetles that are incapable of initiating a successful attack on a healthy tree will quickly establish breeding galleries in one that has been altered by various agents of stress. In North American oak decline, for example, it is the two-lined chestnut borer *Agrilus bilineatus* that often delivers the coup de grâce to a tree weakened by successive gipsy moth defoliations. Similarly many of the conifer bark beetles can cause mortality in trees weakened by drought.

Heart Rot and Wood Decay

F W M R Schwarze, EMPA, St. Gallen, Germany

Introduction

In natural ecosystems, there is a dynamic equilibrium between the accumulation of woody biomass and its breakdown. In this way, a permanent cover of trees or shrubs is maintained, while the carbon and minerals that they have fixed are recycled. At the same time, the survival of a range of woodland plants is fueled by the energy released in the breakdown of wood. Decay fungi play a major role in the processes of breakdown since, alone among microorganisms, they have evolved the means to break down large volumes of wood completely.

The balance between trees and decay fungi represents the state of play in a coevolutionary battle that has lasted for hundreds of millions of years, and in which wood has been the main prize. The success of trees as a dominant form of land vegetation has depended on their being able to maintain a perennating woody structure, which is their means of attaining both height and longevity. This defensive strategy protects the woody stem against loss of integrity of both its water-conducting and its mechanical properties. A range of agents, especially decay fungi, whose mode of attack is the degradation of the woody cell wall, can cause such damage.

Colonization of the Standing Tree

Heart rots were for a long time regarded as the primary cause of decay in standing trees. Whilst it is now clear that this is a considerable oversimplification, it remains true that in high forest and mature amenity trees heart rots are still a major cause of economic loss and deterioration. Based on the concept that either the distribution of water and its mutual relation with aeration are primary determinants of colonization patterns, five distinctive colonization strategies are recognized:

- heart rot
- active pathogenesis
- specialized opportunism
- unspecialized opportunism
- desiccation tolerance.

Most heart rot fungi have a stress-tolerant colonization strategy, i.e., they colonize the tree via exposed heartwood or ripewood (**Figure 1**). Although the heartwood of many tree species does exhibit a high concentration of antifungal extractives (e.g., polyphenols, tannins), heart rot fungi have adapted to the adverse conditions (low oxygen concentrations, high carbon dioxide concentrations, low moisture content). Thus, those features that render functionally intact sapwood nonsusceptible to decay are avoided. Moreover, after colonization of the tree via infection courts such as logging scars, branch stubs, fire scars, broken tops, pruning wounds, and severed roots, decay fungi can degrade the heartwood without inducing the host response system of the tree.

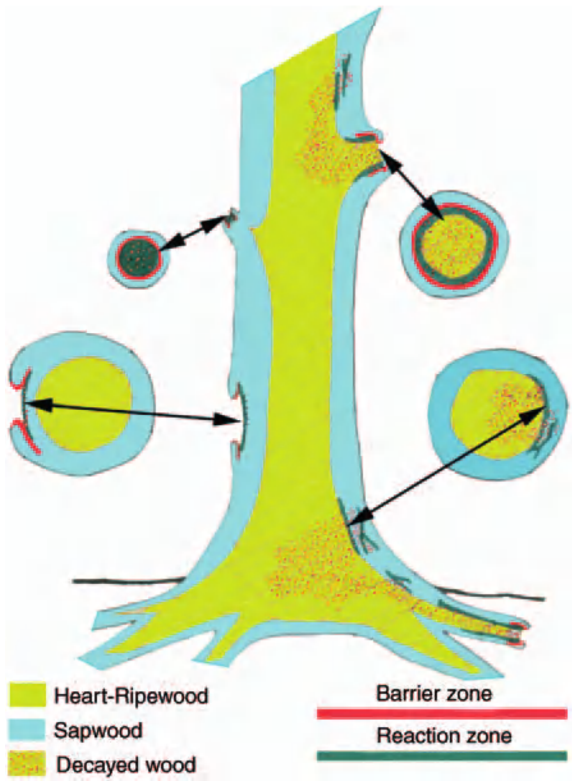

Figure 1 Infection points for decay fungi and associated host response mechanisms within the tree.

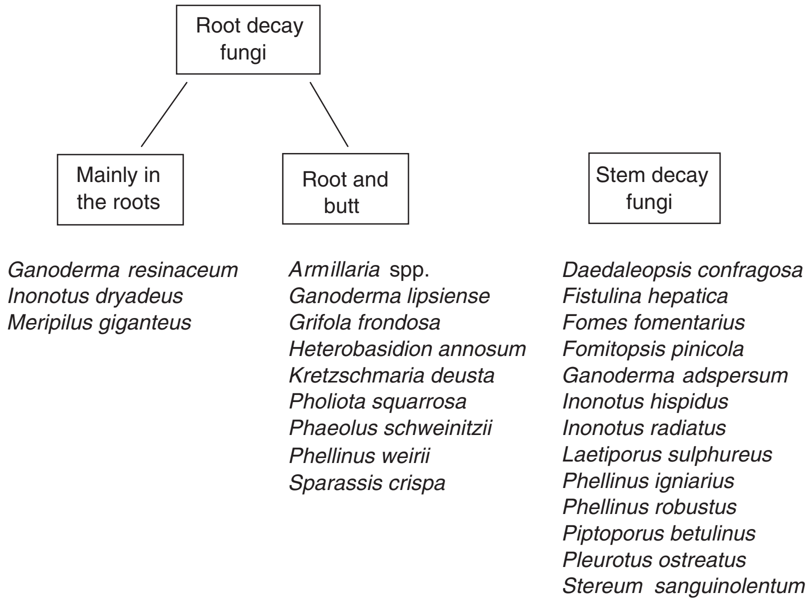

Figure 2 Classification of decay fungi according to the position of rot within the tree. Reproduced with permission from Schwarze FWMR, Engels J and Mattheck K (1999) *Hozzersetzende pilze in Baümen – Stralegien der Holzzersetzung*. Rombach, Freiburg, Germany.

Wood decay fungi are separated into top rots and root or butt rots depending on which part of the tree is affected. Important agents of decay in trees are listed in **Figure 2**. Top rot decay fungi are found in the wood of the upper parts of trees. They seldom progress very far into the roots and therefore do not spread from one tree to another via roots. Root and butt rot fungi colonize the lower stem and roots of trees. Some parasitize the cambium of roots while others remain within the central xylem and can be classified as saprophytes.

The Construction of the Woody Cell Wall

A full understanding of the interactions between decay fungi and living trees requires studies at various levels; anatomical, physiological, and biochemical. In order to understand the alterations caused in woody cell walls by decay fungi, the micromorphological aspects of the sound wall will therefore be briefly described.

Conifer wood is relatively homogeneous in structure and consists primarily of tracheids, uniseriate xylem rays, and, in some genera, also axial parenchyma and epithelial cells surrounding resin canals. Tracheids are dual-purpose cells combining properties of both mechanical support and water conduction. By comparison, dicotyledonous wood is more heterogeneous, and its mechanical and water conducting functions are served by vessels, while fibers or fiber tracheids mainly supply strength and support. Parenchyma is a more prominent feature in dicotyledonous wood than in coniferous wood, with most genera having multiseriate xylem rays and varying amounts of axial parenchyma.

The structure of woody cell walls can be seen in **Figure 3**. The cell wall proper consists of a thin primary wall, to which a much thicker secondary wall consisting of three layers (S_1, S_2, and S_3) is added after the initial formation of the cell. As in plant cells generally, the walls of adjacent cells are bonded together by a layer termed the middle lamella (**Figure 3**). The main structural component of the walls of juvenile wood cells is cellulose, whose long threadlike molecules are aggregated in microfibrils which provide the tensile strength of wood and are held within a matrix of other polysaccharides, known loosely as hemicellulose. The cellulose microfibrils in the various secondary layers show different orientations in relation to the cell wall axis (**Figure 3**).

During the maturation of wood cells, all the layers of the wall together with the middle lamella become to a greater or lesser extent impregnated with lignin, a hard polymer that provides stiffness and resists compressive forces. Of these, the two phenylpropanoid units guaiacyl and syringyl are the most important monomers of the lignin of trees. Conifer wood lignin consists almost exclusively of guaiacyl monomers, whereas hardwood lignin consists of approximately equal proportions of guaiacyl and syringyl. The proportions of these monomers vary between individual cell types. For example, water conducting cells such as the vessels and tracheids, and the middle layer in the cell walls, have a very

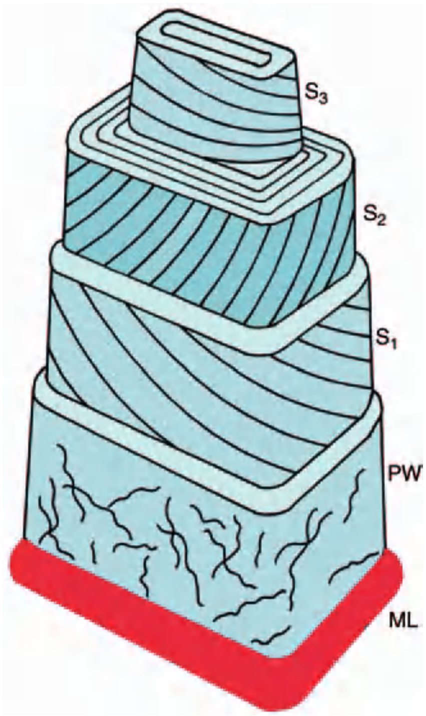

Figure 3 Conventional cell-wall model which distinguishes five cell-wall layers. These are the middle lamella (ML), the primary wall (PW), and the three-layer secondary wall (S): outer (S_1), middle (S_2), and inner secondary wall layer (S_3). The sloping lines indicate the angle of cellulose microfibrils. high concentration of guaiacyl and thus are particularly resistant to most soft-rot fungi.

Types of Wood Decay

Brown Rot

Brown rots, in which cellulose and hemicelluloses are broken down with little or no overt breakdown of lignin, are caused exclusively by basidiomycetes. This class contains many families, though the majority of the brown rot fungi belong to the family of the Polyporaceae. Moreover, they are predominantly associated with conifers, whereas most white rot fungi are associated with broadleaved trees. The correlation of brown rots with conifers coincides with the predominantly northern distribution of these fungi compared with the preferential tropical distribution of white rots. In brown rot, cellulose and hemicelluloses are broken down in the wood substrate, while lignin remains preserved in a slightly modified form. In contrast to white rot fungi, most brown rot fungi lack extracellular phenoloxidases. Because of the preferential degradation of carbohydrates, the decayed wood acquires a brittle consistency, breaks up into cubes, and finally crumbles into powder. The modified lignin gives the decayed wood its characteristic color and consistency.

The breakdown of cellulose by brown rot fungi has been postulated to involve not only enzymes but also a nonenzymic system. In this system, hydrogen peroxidase and iron cause oxidative reactions in the cellulose molecule, thereby enhancing the activity of enzymes (endocellulases) which split the molecule at random points along its length. As a result, the cellulose microfibrils are cut into short lengths, so that a dramatic loss of tensile strength occurs within a very short period of exposure to the brown rot process. The enzymes can then make energy and carbon available to the fungus by further breaking down the remaining short chains and their constituent glucose subunits.

Brown rot fungi cause some alterations of lignin, but lack the enzymes to break it down substantially. Their hyphae cannot erode the lignified cell wall from the lumen outwards, especially since the innermost layer of the wall, the S_3, is especially resistant to physical penetration (**Figure 4**). Thus the cellulose-degrading secretions of brown rot fungi have to diffuse into the cellulose-rich S_2 layer within the cell wall. Sufficient diffusion can occur from even a single hypha to cause breakdown of a substantial proportion of the cell wall material (**Figure 4**). The partial alteration of lignin may facilitate this diffusion, since the intact cell wall is thought to be impervious to large molecules such as enzymes. However, the molecules of the nonenzymic system, which break open the cellulose chain, are thought to diffuse through the cell wall even when lignin is unaltered.

The ontogeny of wood decay by brown rot fungi is uniform, apart from a few exceptions such as *Fistulina hepatica*. The reason for this is presumably the adaptation of these fungal species to the relatively simply structured softwood of conifers, and their restricted ability to degrade lignin. In contrast, white rot fungi, which preferentially occur on broadleaved trees, exhibit an extraordinary diversity in the ontogeny of wood decay.

White Rot

White rots are caused both by basidiomycetes and by certain ascomycetes. The common feature of all these fungi is that they can degrade lignin, as well as cellulose and hemicelluloses. However, the relative rates of degradation of lignin and cellulose vary greatly according to both species of fungus and the conditions within the wood. As with brown rots, there is additional variation related to the preferential decay of different zones within the annual ring. The adaptation of white rot fungi to the much more heterogeneously structured wood of broadleaves, plus their ability to degrade all the cell wall constituents extensively, leads to a multiplicity of different patterns of wood decay. Within this range of variation, two broad devisions are widely accepted: selective delignification and simultaneous rot. White rot fungi degrade lignin by an oxidative process which involves phenoloxidases such as laccase, tyrosinase, and peroxidase. They degrade cellulose in a less drastic way than brown rot fungi, since their cellulolytic enzymes attack the molecule only from the ends, splitting off glucose or cellobiose units. This reduces tensile strength only gradually, unlike the breakdown of cellulose in brown rots, which occurs at random points.

Selective delignification In selective delignification, lignin is degraded earlier in the decay process than cellulose or hemicellulose. The hyphae, which are responsible for secreting the lignin-degrading enzymes, grow in the cell lumina in some cases, so that the lignin is dissolved out of the adjacent cell wall. In other cases, the hyphae penetrate the compound middle lamella between the cells and delignify it so that the cells tend to separate. As indicated above, cellulose is left relatively unaltered during selective delignification, at least in the early stages of decay. The resulting residual material is stringy in texture, having lost much of its stiffness and hardness while retaining considerable tensile strength. This contrasts very much with brown rots in which cellulose is removed while lignin remains, leaving a very brittle residue.

Many of the fungi that cause selective delignification tend to do so in discrete pockets which show up paler than the surrounding wood due to the high concentrations of cellulose that remain within them. An example of this 'white pocket rot' is caused by *Phellinus pini* or *Grifola frondosa*. When present in otherwise dark-colored heartwood, such pockets are particularly striking, showing up as bright, white scattered zones. It is not surprising that this remarkable pattern was one of the first types of decay investigated.

The different patterns of cell wall degradation during selective delignification can be observed in

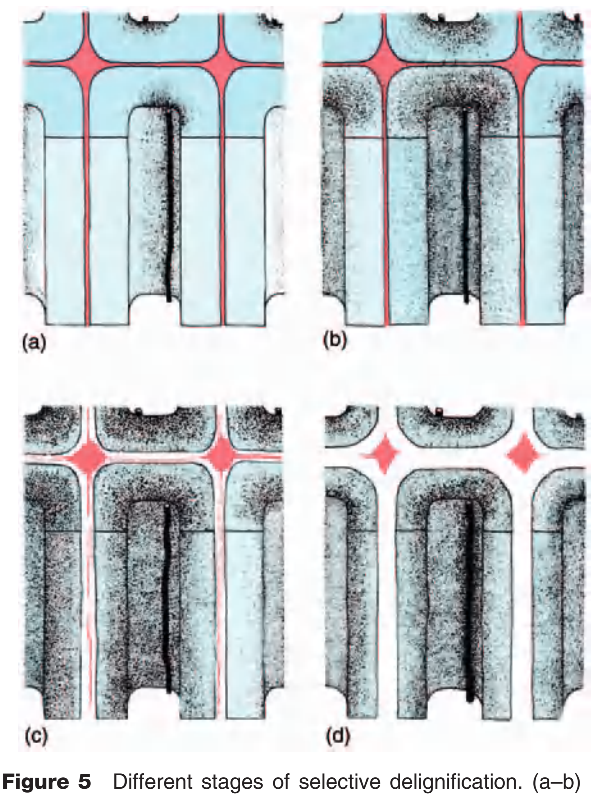

Figure 5 Different stages of selective delignification. (a–b) In early stages enzymes diffuse into the secondary wall from hyphae of *Heterobasidion annosum* growing in the cell lumen. Delignification extends from the secondary wall into the middle lamella. (c–d) During advanced stages, preferential degradation within the highly lignified middle lamellae results in the separation of single cells from one another. Cellulose remains intact during initial stages of decay. Reproduced with permission from Schwarze FWMR, Engels J and Mattheck K (1999) *Hozzersetzende pilze in Baümen – Stralegien der Holzzersetzung*. Rombach, Freiburg, Germany.

Figure 5. Initially degradation of the middle lamella, occurring in conjunction with extensive lignin degradation in the secondary wall, is apparent. At an advanced stage individual cells become separated from their matrix. Moreover, extensive delignification may occur in the S_2 layer, leading to the accentuation of radial structures within the secondary wall (S_2).

Although selective delignification is usually associated with cellulose degradation in wood, extreme forms of this type of decay are well known. From the temperate rainforests of southern Chile a type of wood decay which is called *palo podrido* is known. This is a name for decayed tree stems which are used as cattle fodder in southern Chile. Chemical analyses have shown that the wood of some decayed tree stems consists of 97% cellulose and merely 0.9% lignin. Native peasants in southern Chile use the term *palo blanco* for this incredibly white wood, whereas *palo podrido* is a general term for delignified wood.

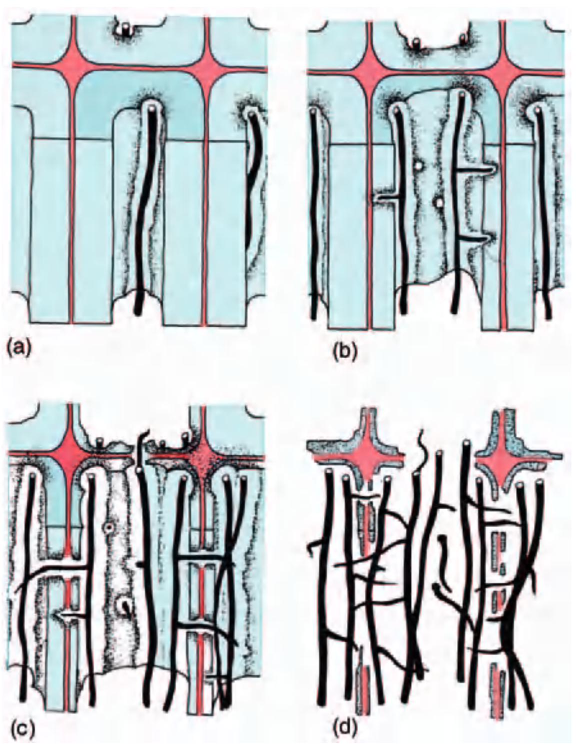

Figure 6 Different stages of simultaneous rot. (a) In early stages, degradation of the secondary wall occurs in the immediate vicinity of the hyphae. (b) The cell wall is progressively broken down from the lumen outwards. Individual hyphae of *Fomes fomentarius* penetrate into the cell wall at right angles to the cell axis. (c) The cell wall becomes increasingly thinner, and numerous boreholes appear between neighboring cells. (d) At an advanced stage, degradation of the compound middle lamella commences. Reproduced with permission from Schwarze FWMR, Engels J and Mattheck K (1999) *Hozzersetzende pilze in Baümen – Stralegien der Holzzersetzung*. Rombach, Freiburg, Germany.

Simultaneous rot In simultaneous rot, lignin and structural polysaccharides including cellulose are degraded at similar rates by enzymes secreted by hyphae growing in the cell lumen (**Figure 6**). This form of degradation takes place close to the hyphae involved, and results in the formation of erosion troughs where they lie on the cell wall. Fungi causing a simultaneous rot comprise a large group of species which occur commonly in hardwoods, but only rarely in softwoods. The enzymes that they secrete are able to decompose all substances of the lignified cell wall. As the degradation of cellulose, hemicelluloses, and lignin occurs at nearly the same rate, the term simultaneous rot is appropriate, although the general term white rot is often applied. The coalescence of the erosion troughs induced by numerous hyphae results in a general cell wall thinning from the lumen outward (**Figure 6**). Unlike selective delignification, simultaneous rot can lead to a fairly brittle fracture because of the loss of tensile strength from cellulose degradation.

Soft Rot

Soft rots are considered to be chemically more similar to brown rots than to white rots, since they strongly decompose cellulose while leaving lignin only partially altered. Another common feature of both brown rot and soft rot fungi is the demethylation of methoxyl groups. However, the degradation of wall materials at the hyphal contact surface in soft rots is more reminiscent of white rot than of brown rot.

Although soft rot fungi are also able to degrade the lumen surface of the wood cell wall adjacent to the hyphae by erosion (type 2 attack) the formation of cavities within the S_2 layer of the secondary wall (type 1 attack) is the characteristic mechanism of cell wall degradation. Soft rot cavities are initiated by fine penetration hyphae formed from hyphae in the lumina of wood cell walls. The penetration hypha grows through the innermost S_3 layer of the cell wall to the cellulose-rich S_2 layer where it either branches and grows axially within the cell wall following the orientation of the cellulose microfibrils (**Figure 7**). Fine hyphae that exhibit branching continue hyphal extension for a short period, but then cease apical growth. At this stage a cavity is formed within the secondary wall around the fine hypha, which increases in diameter as the cavity develops. This is then followed by a further phase of apical growth at the hyphal tip, producing a needlelike proboscis hypha. This process repeats itself many times over, leading to the formation of a spiral chain of cavities within the wood cell wall, all orientated to the angle of the cellulose microfibrils and each showing different stages of cavity expansion (**Figure 7**). The repetitive start and stop pattern of apical hyphal

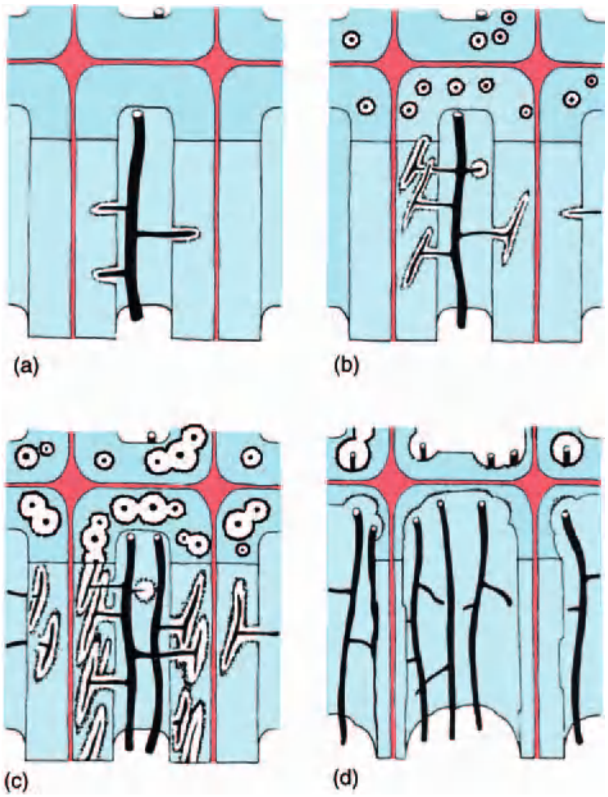

Figure 7 Different stages of soft rot type 1. (a) Penetration of hyphae into the secondary wall. (b) Branching and growth of the hyphae parallel to the alignment of the cellulose microfibrils in the S_2 layer. (c) Enzymatic degradation of the secondary wall around the hyphae results in the formation of cavities with conically shaped ends. (d) At an advanced stage of degradation by *Kretzschmaria deusta* the secondary wall is completely broken down, whereas the compound middle lamella persists. growth of results in gradual breakdown of the wood cell wall as the cavities expand and the secondary wall is destroyed.

Traditionally, soft rots has been attributed to deuteromycete and ascomycete fungi (e.g., *Chaetomium* spp.) and have been generally thought not to be caused by basidiomycetes. A major supposed difference between soft rot fungi and wood-degrading basidiomycetes in general is that until recently only the latter were considered to occur deep within large volumes of wood and in the living sapwood of trees. Fungi of the types that are commonly associated with soft rot are active only in the outer layers of dead wood or timber, although they can progress inwards as the surface layers become eroded. In living trees, the most significant role so far attributed to soft rot fungi has been the decay of the bases of dead branches, which results in a form of natural pruning.

Various ascomycetes are known to cause limited amounts of decay in living trees, particularly members of the Xylariaceae such as *Hypoxylon* spp. However, one member of this group, *Kretzschmaria deusta* (syn. *Hypoxylon deustum*) is exceptional in being able to cause deep-seated and extensive decay in large volumes of wood. It causes a distinctive pattern of decay in all its host species, in which many fine dark zone-lines can be seen. The ability of *K. deusta* to function as a soft rot fungus in living trees is of considerable interest, since this type of decay has not been previously thought to occur within living trees. However, one important aspect of the soft rot decay mechanism is that once fungal hyphae have penetrated into the cell wall and branched along the orientation of the cellulose microfibrils, they are able to avoid toxic compounds that may be present in the wood cell lumen. This can apply to wood preservative chemicals impregnated into the wood, but equally to natural products and extractives deposited in the lumen.

Soft rot caused by basidiomycetes Recent work has shown that the cavity-forming soft rot decay process is not exclusive to members of the lower acomycetes and deuteromycetes, but can be demonstrated in some wood-decay basidiomycets. Thus, diamond-shaped or rhomboid cavities have been found in the cell walls of wood decayed by basidiomycetes causing white or brown rots. As in true soft rots, such cavities may follow the helical course of cellulose microfibrils. However, soft rot patterns have not until recently been found in the wood of living trees degraded by basidiomycete decay fungi. Observations showed that, the basidiomycete *Inonotus hispidus*, which occurs on living trees of several genera, causing a white rot of the heartwood and sapwood, could produce internal cavities both in artificially incubated wood blocks and naturally infected wood of London plane (*Platanus* × *hispanica*) and of ash (*Fraxinus excelsior*). Other conditions that seem to favor soft-rode mode of degradation in living trees by *I. hispidus* are found within reaction zones, i.e., regions where the living cells of sapwood have reacted to fungal invasion.

Development of Decay within the Tree

As the growth of decay fungi can effectively only be observed at the anatomical level, microscopical investigations of their modes of action are essential for a better understanding of their behavior within reaction zones.

Many studies attempting to explain the limitations of colonization at the host–pathogen interface have been restricted to the description of discoloration and decay patterns in wood. Alex Shigo's CODIT-model ('compartmentalization of decay in trees') proposed that, following fungal colonization of the xylem of trees, decay columns are confined within defined compartments in the wood. Such compartments have recognizable boundaries within xylem between a region of decay and surrounding sound wood. Different types of boundary have been identified representing regions of anatomical modification and deposition of materials. Within these zones, tyloses or gummy deposits are found blocking the lumina of vessels and fibers adjacent to parenchyma. In many cases, toxic phenolic substances are present, so that hyphal growth is both physically and chemically deterred within the cell lumina, which would otherwise provide easy pathways for fungal colonization and surfaces for cell wall erosion (**Figure 8**). In response to wounding, reaction zones are apparent as areas of discoloration between healthy and infected tissue. Material deposited by the host as a defense mechanism and barrier to invasion is therefore viewed as a form of containment against ingress of air and subsequent colonization by decay fungi. Dynamically, the invasion of living sapwood at a reaction zone margin has been envisaged as a continuous process, the host tissue passing through the sequence functional sapwood, drier transition zone, reaction zone, incipient decay, and decayed wood. More recently, evidence has been obtained showing that in some

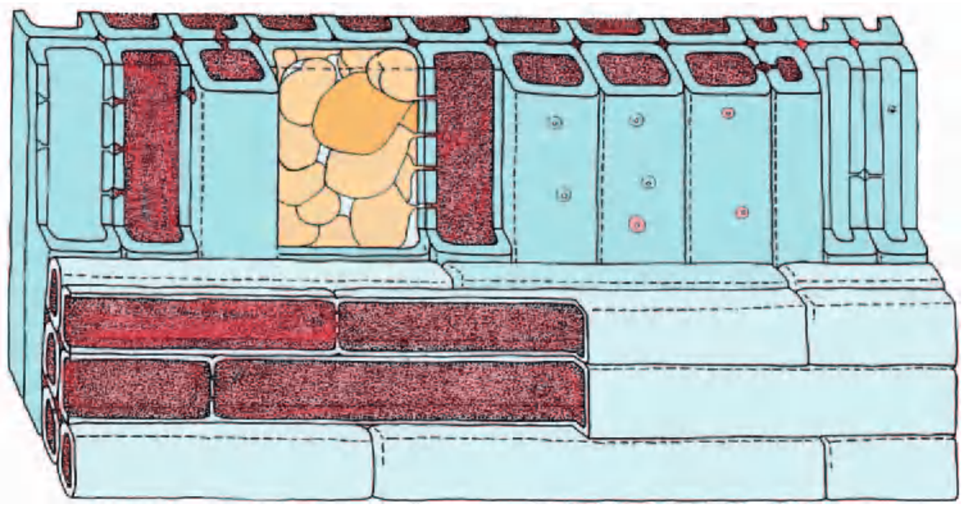

Figure 8 Schematic diagram illustrating the modified wood structure within a reaction zone of beech. Tylose formation is apparent within vessels. The inner cell wall of axial parenchyma cells is encrusted with a polyphenolic layer, whereas cell lumina fiber tracheids are occluded with abundant polyphenolic deposits. angiosperms this sequence of continuous pathogen advance does not seem to occur. Thus, it appears that rather than forming a dynamic barrier, reaction zones essentially act as static boundaries to decay. Furthermore, this is supported by the presence of reaction zone relicts within decayed wood, indicating that the invasion of functional xylem tissues by decay fungi in these trees is discontinuous.

The fact that reaction zones can be breached by fungi and the nature of the mechanisms by which this occurs have particular relevance in understanding the invasive potential of decay fungi in standing trees. Knowledge of these mechanisms greatly improves interpretations of the dynamic interactions at the host–pathogen interface. It seems that some decay fungi can partly escape the adverse conditions within reaction zones by switching their mode of action towards hyphal colonization within the cell walls. Reaction zone penetration by *Inonotus hispidus* in London plane (*Platanus* × *hispanica*) is accomplished by forming soft-rot-like tunnels through the cell wall (**Figure 9**). A soft rot mode of growth within reaction zones apparently enables hyphae to circumvent impedances within the cell lumina. Invasion of reaction zones in beech (*Fagus sylvatica*) by *Ganoderma adspersum* is characterized by the preferential degradation of polyphenols (**Figure 10**). In contrast, *Kretzschmaria deusta* defeats reaction zones in beech by soft rot and preferential degradation of the secondary walls without decomposition of polyphenols

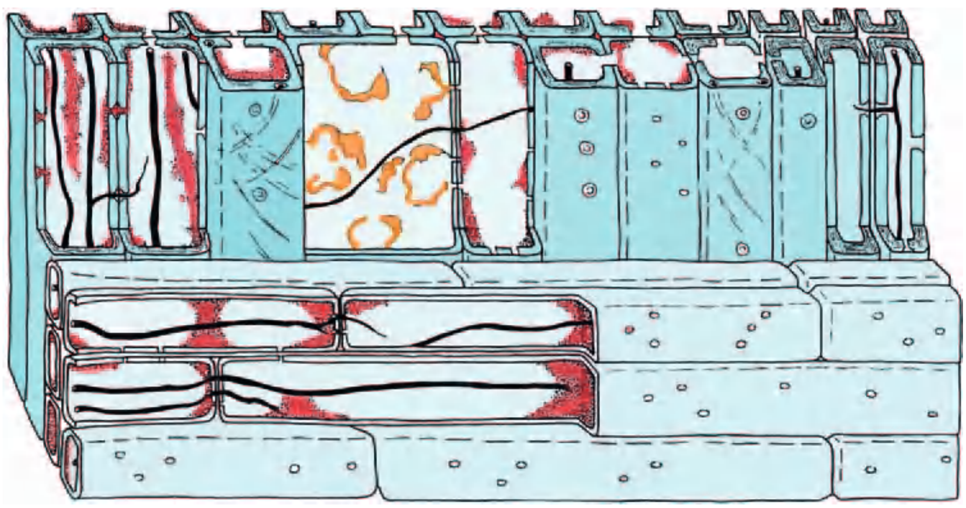

Figure 10 *Ganoderma adspersum* initially degrades polyphenols allowing subsequent hyphal growth through the cell lumina. At advanced stages of decay the fungus causes a selective delignification of the cell walls. Reproduced with permission from Schwarze FWMR, Engels J and Mattheck K (1999) *Hozzersetzende pilze in Baümen – Stralegien der Holzzersetzung*. Rombach, Freiburg, Germany.

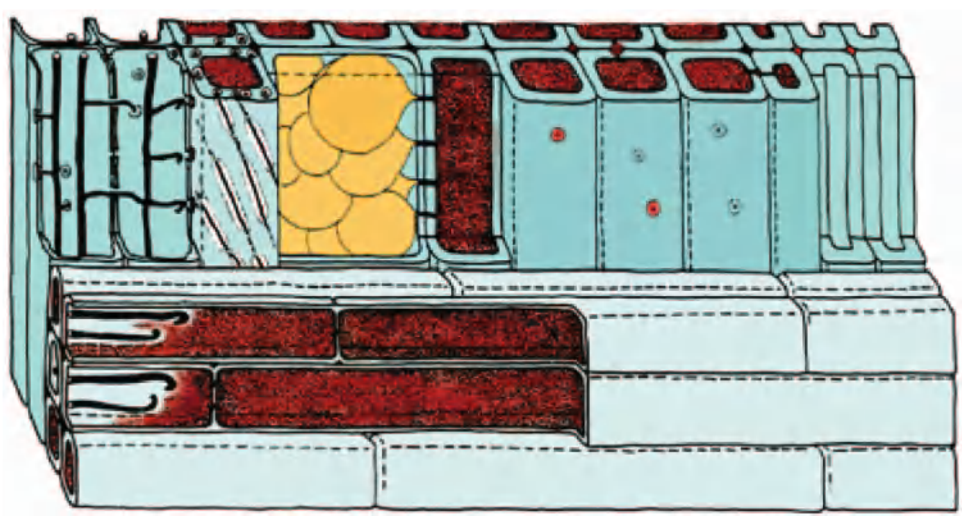

Figure 11 *Kretzschmaria deusta* defeats reaction zones by a soft rot mode without significant degradation of polyphenols. Reproduced with permission from Schwarze FWMR, Engels J and Mattheck K (1999) *Hozzersetzende pilze in Baümen – Stralegien der Holzzersetzung*. Rombach, Freiburg, Germany.

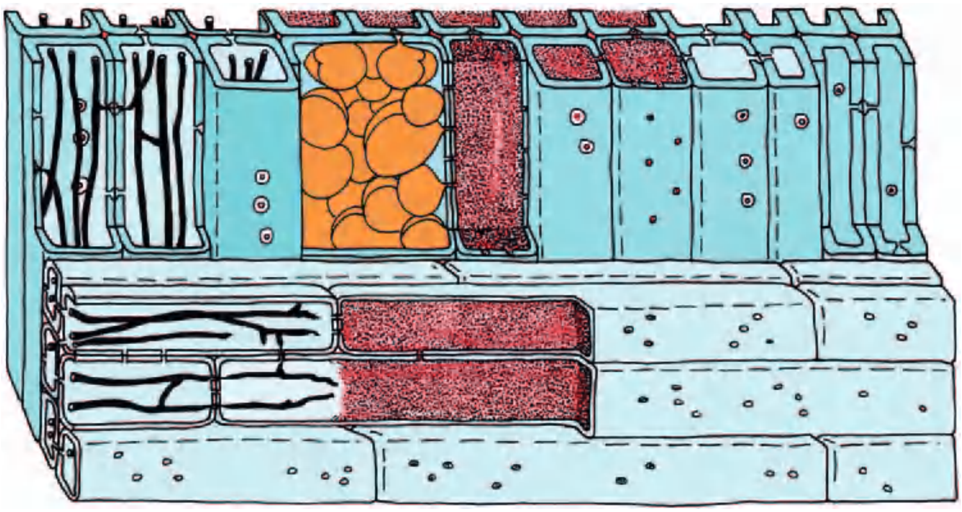

Figure 12 Hyphae of the brown rot fungus *Fomitopsis pinicola* can readily colonize and degrade cell walls of the unaltered sapwood. Due to their limited enzymatic ability they cannot readily penetrate reaction zones in beech. Reproduced with permission from Schwarze FWMR, Engels J and Mattheck K (1999) *Hozzersetzende pilze in Baümen – Stralegien der Holzzersetzung*. Rombach, Freiburg, Germany.

(**Figure 11**). Failure of *Fomitopsis pinicola* to invade and defeat reaction zones in beech is apparently related to the limited enzymatic ability and inflexible behavior of brown rot fungi (**Figure 12**).

On the basis of these observations, it is postulated that *I. hispidus* and other basidiomycetes have the ability to cause a soft rot either in addition or alternatively to their more typical mode of action, i.e., a white rot may be a common phenomenon, which may play a significant role in lesion expansion for a range of other decay fungi. By contrast, more aggressive decay fungi may have a broader enzymatic potential capable of degrading polyphenols deposited in the wood cell lumina.

The relative aggressiveness of decay fungi seems to be a function of their ability to degrade both lignin and polyphenolic compounds formed in response to lesion expansion in the wood. The fact that less-invasive fungi appear to avoid polyphenolic deposits by tunneling into the cellulose-rich regions of the wood cell wall and do not display an ability to penetrate through the lignin-rich middle lamella adds weight to this view.

Disease Affecting Exotic Plantation Species

M J Wingfield, University of Pretoria, Pretoria, Republic of South Africa

Introduction

Tree pathogens in natural forests are typically in balance with their environment. This delicate balance can easily be disturbed through the introduction of an exotic pest or pathogen (*see* **Pathology**: Diseases of Forest Trees). In natural forests, pathogens play an important role in maintaining genetic diversity of the tree species in these ecosystems. They are also important in removing weak trees from the forests and contribute to decomposition of forest biomass. Thus, management of natural forests, especially for commercial forestry, is complicated and often poorly understood.

Plantation forestry is a relatively modern undertaking and has been practiced for just over 100 years. These forests are primarily propagated to produce solid-wood products for construction, fuelwood, or secondary products such as charcoal, pulp, and paper. Demand for some of these products has grown rapidly during the course of the last century and huge commercial industries are now based on plantation forestry.

Plantations are established either using native or exotic species. In the northern hemisphere, the tendency has been to establish plantations of native species such as loblolly (*Pinus taeda*) and slash (*P. elliottii*) pines in the southeastern USA, scots pine (*P. sylvestris*) in Europe and various species of *Populus* in North America and Europe. In contrast, huge plantation areas have been established in the tropics and southern hemisphere using primarily exotic species of *Pinus*, *Eucalyptus*, and *Acacia*. These include *Pinus radiata* in Australia, Chile, and New Zealand, *P. patula* in Southern Africa, *P. taeda* in Brazil, hybrids of *P. elliottii* and *P. caribaea* in Australia and South Africa, *Eucalyptus grandis* and hybrids of this and other species in Brazil, South Africa and Southeast Asia, *E. globulus* and *E. nitens* in Chile, and *Acacia mangium* in various parts of Southeast Asia.

There are fundamental differences between natural forests and trees grown and managed intensively in plantations. Natural forests are typically made up of a mixture of species. In some ecosystems, such as the boreal forests, this can be a relatively small number of species, while others such as tropical forests include a great diversity of species. This is very different to the composition of plantations of exotic species where uniform families or even single genotypes are planted across extensive areas.

The establishment of plantations of exotic tree species in the tropics and southern hemisphere has been hugely successful. Growth and yield generally surpass those obtained in plantations using native species and the performance of the exotic trees has been likened to that of weeds. Although the reasons for the superior performance of exotic trees in plantations can be debated, there is substantial evidence to suggest that this is strongly linked to the so-called pest and pathogen release hypothesis. Here, the trees have been released from their natural enemies and are able to grow vigorously in the absence of competition. Indeed, in many cases, a problem with exotic tree species is that they commonly ‘escape’ from plantation lands and establish themselves as serious weed plants in natural ecosystems.

The absence of pests and pathogens has provided forestry companies growing exotic trees with a valuable window of opportunity. However, pathogens have gradually appeared in these plantations and in some cases they have resulted in considerable loss. These losses are usually exacerbated due to the large areas planted to single species where the trees are often genetically related. There are thus examples where the tree species being grown has had to be abandoned due to the appearance of a serious disease problem.

Examples of Diseases in Exotic Plantations

Diseases affecting exotic plantation forestry occur in two distinct categories. These include those caused by exotic pathogens, which have usually originated on the trees or related tree species in their areas of origin. Alternatively, they are caused by pathogens native to the new environments in which the trees have been established. In some instances, the pathogens are well known in their areas of origin or elsewhere in the world and their appearance in new environments might even have been predicted. However, in many situations, native pathogens are unknown in their areas of origin because they are not associated with an obvious disease problem or a commercially important species of tree. This often means that the source of a pathogen affecting exotic tree species is unknown and complex molecular genetic studies are required before its origin can be discovered.

Generally, when plantations of exotic tree species have been established in areas where very closely related native species grow naturally, serious disease problems have emerged. Thus, although different, the exotic tree species are sufficiently similar to the native trees to enable pathogens to move on to them. For example, where European *Pinus* spp. have been planted in areas of the USA that has a diverse ecosystem of native *Pinus* spp., serious disease and pest problems have been experienced on the exotics. Likewise, where *E. globulus* has been planted as an exotic in western Australia, these trees have been severely infected by a wide range of pathogens, presumably originating on nearby native *Eucalyptus*.

Diseases Caused by Native Pathogens

There are many examples of diseases of exotic plantation trees that are caused by native pathogens. Amongst the first of these to be discovered were root pathogens such as species of *Armillaria*, *Ganoderma*, *Heterobasidion annosum*, and *Phytophthora* that tend to have wide host ranges. However, in recent years, numerous examples of native stem and shoot pathogens that infect exotic plantation trees have emerged. Some of these were thought to be reasonably host-specific but this is clearly not the case. Now it is of particular concern that these 'new' pathogens that have become adapted to infect the exotic species might be accidentally introduced into areas where the trees are native. Such situations where native trees are invaded by exotic pathogens could lead to epidemics of a magnitude equivalent to chestnut blight and Dutch elm disease, discussed elsewhere (*see* **Pathology**: Insect Associated Tree Diseases). This section includes a selection of examples of native pathogens that have caused serious disease problems in plantations of exotic tree species.

***Armillaria* root rot** Armillaria root rot is a well-known disease of woody plants that can be caused by one of numerous species of *Armillaria*. Most of these fungi have wide host ranges and are best known in the northern hemisphere, where disease centers in native forests caused by single clones of the pathogen can become very large. *Armillaria* spp. such as *A. ostoyae* have thus gained notoriety for representing the largest and oldest living organisms on earth.

Armillaria spp. are native in natural woody ecosystems, generally killing weakened trees and moving through the soil via bootlace-like rhizomorphs. When trees have been felled to provide land for planting exotics, stumps are colonized by the *Armillaria* spp. The fungus thus acquires energy (inoculum potential), enabling it to infect healthy trees adjacent to the colonized stumps. Large numbers of newly planted seedlings can be killed in this way and it can be virtually impossible to establish stands without removing the source of inoculum.

In more established trees, infection centers usually originate from colonized stumps of felled trees. Infection passes from one tree to another via root contacts or by rhizomorphs. This can result in large disease centers that continuously increase in size, during the rotation.

Armillaria spp. have been amongst the first pathogens noted after the establishment of exotic tree species, generally but not exclusively in plantations of *Pinus* spp. For example, *A. limonea* and *A. novae-zealandiae* have resulted in serious losses to newly established stands of *P. radiata* in New Zealand. Similarly, *A. limoneae* and *A. luteobubalina* are associated with *P. radiata* establishment problems in Chile. In South Africa, *A. fuscipes* has caused serious losses in newly established plantations of various *Pinus* spp., but especially *P. elliottii* and *P. patula*.

Eucalyptus rust Rust diseases are caused by a group of pathogens generally known to be highly host-specific. These fungi tend to have complex life cycles and many have both primary and alternate hosts, which bear different parts of these life cycles. Amongst the three most important genera of trees grown as exotics in plantations, *Pinus* spp. have the largest number of rust diseases. It is thus interesting that none of these have appeared on exotic *Pinus* spp., grown in the tropics and southern hemisphere. *Eucalyptus* is a very large genus including more than 600 species, mostly native to Australia. It is thus interesting that no rust diseases are known on these trees in their native environment.

Puccinia psidii that causes eucalyptus rust is an unusual pathogen. This fungus is native in South and Central America where it occurs on various genera and species of native Myrtaceae. The fungus has, however, developed the capacity to infect *Eucalyptus* spp. In countries such as Brazil and Uruguay it has caused severe damage to these trees, especially in young plantations of susceptible species. As trees become older, they are less severely damaged by the pathogen and thus, established plantations are not considered at risk due to rust.

The eucalytpus rust pathogen is widely considered to be amongst the most important threatening organisms linked to forestry. This is collectively because rust fungi have powdery spores that facilitate spread, and the fact that some native Myrtaceae, especially in Australia, are highly susceptible to this pathogen. Accidental introduction of *P. psidii* into that country could have disastrous consequences for the natural environment.

***Ceratocystis* wilt** *Ceratocystis* species are well-known pathogens of woody plants and many cause important wilt diseases. Examples include the causal agents of oak wilt, *Ceratocystis fagacearum*, and sapstreak of sugar maple and other hardwood trees caused by *C. virescens*. These fungi are primarily dispersed by casual insects such as flies and picnic beetles (Coleoptera: Nitidulidae), which are attracted by the fruity aromas produced by the fungi, sporulating on infected trees. The insects are attracted to the sap produced by fresh wounds, and in this way the fungi enter the vascular systems of trees (*see* **Entomology**: Sapsuckers). Because infections lead to the blockage of sap flow, these fungi tend to kill trees relatively rapidly.

Ceratocystis wilt is a relatively newly discovered disease in plantations of exotic trees. *C. albofundus* was the first species belonging to the group shown to cause a rapid wilt disease of trees. This fungus infects wounds on exotic *Acacia mearnsii* (black wattle) and *A. dealbata* (green wattle) in South African plantations. Large numbers of trees can be killed rapidly and this is the most important disease of *A. mearnsii* in South Africa. There is good evidence to show that *C. albofundus* originated on native Proteaceae in South Africa. This is unusual given that Proteaceae are very distantly related to *Acacia* spp. The fungus has not been found in Australia and might pose a threat to native *Acacia* spp. in that country.

Ceratocystis fimbriata is a well-known wilt and canker pathogen on many forest and fruit trees. This fungus has recently been discovered to cause rapid wilt and death of *Eucalyptus* spp. in Brazil, Uruguay and the Congo. Phylogenetic studies have shown that the fungus in the former two countries is probably native, but it appears to be exotic in the Congo. There is no evidence that *C. fimbriata* occurs in Australia. Thus, strains of the fungus that infect *Eucalyptus* elsewhere in the world are clearly threatening to native stands of these trees.

Diseases Caused by Introduced Pathogens

Many pathogens found on exotic plantation trees are thought to have been introduced from the areas of origin of these trees. As mentioned previously, these assumptions could be incorrect given that the origin of most pathogens has not been established experimentally. Relatively large numbers of foliage pathogens occur on exotic plantation trees such as *Eucalyptus* and they are assumed to have been introduced into the new areas on contaminated seed. Many are relatively unimportant and have been afforded little attention.

Most of the more serious diseases of exotic plantation trees are caused by introduced pathogens. Some have been present in exotic plantations for many years and others have appeared relatively recently. New introductions continue to occur regularly and this is a trend that is not likely to change. The following examples have been selected based on relative importance and to reflect differences in infection strategy and host range.

Diplodia canker and dieback of pines In most countries where species of *Pinus* have been established as exotics in plantations, *Diplodia* canker and dieback caused by *Diplodia pinea* (also known as *Sphaeropsis sapinea*) was the first disease to be recorded. This is apparently due to the fact that the fungus is seed-borne and was, therefore, introduced into new areas probably close to the time of plantation establishment. The fungus is found in every country where pines are grown as exotics. Contemporary studies have shown that those countries that have restricted the importation of seed have populations of the pathogen with lower levels of genetic diversity than those where more regular seed introductions have been made.

For many years, *D. pinea* was thought to be a secondary, wound-infecting fungus. In contrast, recent research has shown that the fungus is a common latent pathogen in asymptomatic pine tissue. Onset of disease is closely linked to environmental stress such as drought, cold, poor site-species matching, and hail damage. The fungus is perhaps best known in South Africa where the highly susceptible *Pinus patula* is widely planted and commonly damaged by hail storms. A combination of latent infections by the pathogen, together with the susceptible species and hail damage, can lead to the death of very large areas of trees.

Dothistroma needle blight In exotic plantation forestry, *Dothistroma* needle blight caused by *Dothistroma septospora* is perhaps the best-known disease. This is due to the tremendous damage that it has caused to *P. radiata* plantations in Africa, South America, Australia, and New Zealand, particularly during the 1960s and 1970s. Many plantation programs based on this tree species were abandoned, especially those in Africa where the climate was highly conducive to infection by *D. septospora*.

Dothistroma septospora is native to the northern hemisphere where it is well known and occurs in both its sexual and asexual forms. In many areas, the fungus is relatively unimportant but there are examples of severe damage to plantations and ornamental *P. ponderosa* in the USA and *P. nigra* where it is grown as an exotic in the USA and plantations in some parts of Europe. The fungus was first discovered in exotic *P. radiata* plantations in Africa in 1957 and it rapidly spread to other areas such as Australia, New Zealand, and Chile, where *P. radiata* was being intensively propagated. The disease remains important in these areas and wide-scale aerial spraying continues to be used to reduce the impact of the disease.

Mycosphaerella leaf blotch on Eucalyptus Many species of *Mycosphaerella* infect the leaves and green branches of *Eucalyptus* spp. In exotic plantations, these fungi have been amongst the first to be recorded associated with disease. Although there is no experimental evidence to substantiate this, observations regarding disease occurrence suggest that these fungi are seed-borne and that they have been widely distributed together with seed used for plantation establishment.

Most *Mycosphaerella* spp. on *Eucalyptus* appear to be relatively unimportant. However, some species, such as *Mycosphaerella nubilosa*, have caused serious defoliation of juvenile leaves of *E. globulus* in South Africa and West Australia. *Eucalytpus nitens* is also severely damaged by this fungus in South Africa. *Mycosphaerella nubilosa* is well-known on native *Eucalyptus* in Australia and this is certainly the origin of the fungus. In contrast, *Phaeophloespora destructans*, which phylogenetically is an asexual state of a *Mycosphaerella* species, is of unknown origin and causes serious shoot and leaf blight on various *Eucalyptus* spp. including *E. grandis*, *E. urophylla*, and *E. camaldulensis* in Indonesia, Thailand, and Vietnam. This fungus was first found in Sumatra and it has gradually spread southwards. It was possibly introduced into the area from Australia or other parts of Indonesia where *E. urophylla* is native, or it has moved on to *Eucalyptus* from some other host. Irrespective of its origin, *P. destructans* has become one of the most important pathogens of *Eucalyptus* and it now threatens plantation programs elsewhere in the world.

Pitch canker Pitch canker has become one of the most important diseases threatening exotic pines in plantations. The disease (*see* **Pathology**: Stem Canker Diseases) is caused by *Fusarium circinatum*, which is known in its sexual state as *Gibberella circinata*. This fungus was discovered for the first time in the southeastern USA in 1945 on *P. virginiana* and it has caused occasional outbreaks of disease in that area. More recently, the fungus appeared in California where it was discovered causing branch and stem cankers on *P. radiata* planted along streets and in parks. The disease has spread rapidly to trees in natural stands where it has caused very serious damage and possibly threatens *P. radiata* in its native range.

The pitch canker fungus requires wounds to infect trees. These wounds can arise from physical damage to trees, for example, by wind and forestry operations. Insects are also associated with infection and these include cone- and shoot-infesting bark beetles (Scolytidae) and weevils (Curculionidae), as well as lepidoptera that damage shoots. When infections reach the main stems, parts of trees above the stem cankers and often whole trees will die. The name ‘pitch canker’ refers to the deep resin impregnation of the wood associated with infections.

The pitch canker fungus was first discovered in exotic pine plantations in South Africa in 1991. In this situation, it caused extensive losses to *P. patula* seedlings in a major pine production nursery. The fungus has subsequently spread to virtually all pine-producing nurseries in this country and it has also recently been associated with serious losses associated with the establishment of new lands. The pitch canker disease, typified by infections on aboveground parts of trees, has not been seen and, strictly speaking, pitch canker disease does not occur in South Africa.

A situation very similar to that in South Africa has recently been discovered in Chile. Here, *P. radiata* plants in nurseries are severely damaged by *F. circinatum*. The disease affects seedlings in containers and open-rooted nurseries, and most importantly, valuable clonal hedges used to produce clonal cuttings. Infections of established trees in plantations have not been seen in Chile. However, the presence of various primary insects, such as shoot moths known to be associated with pitch canker in the southeastern USA, suggests that it is only a matter of time before the disease appears in plantations.

An early hypothesis from the southeastern USA was that the pitch canker fungus might have originated in Haiti. Recent studies using DNA-based markers have shown that the fungus in California probably originated in the eastern USA. The fungus in South Africa most probably originated in Mexico, where the disease is now well-known on native *Pinus* spp. Pitch canker is known to occur in Japan, and has recently been found in Korea and in Spain. All indications are that *F. circinatum* is spreading around the world, presumably on seed, which is known to carry the fungus. Countries such as New Zealand and Australia, with substantial resources of susceptible *P. radiata*, have instituted rigorous legislation to prevent the introduction of the pathogen.

Phytophthora root rot Phytophthora root rot is a well-known disease of woody plants and can be caused by numerous species of *Phytophthora*. These fungi are unusual in that they belong to a group of organisms that are not strictly fungi (Kingdom: Stramenopila). They are soil-borne and produce structures enabling them to survive in the soil for extended periods of time. They also produce motile spores that are water-borne and move through the soil–water interface. Contamination of new areas can occur easily through the movement of soil or contaminated irrigation water.

Phytophthora spp. generally infect the feeder roots of plants and give rise to a slow decline as these infections move towards the root collars of trees. In exotic plantation forests, they are often moved into newly established areas with infected plants from nurseries. Trees can die during the first year after planting but more commonly die after 2 years or more. Disease distribution tends to be scattered in plantations. Where highly susceptible trees are planted in infected lands, they too become infected.

By far the best known *Phytophthora* species is *P. cinnamomi*. This fungus has a very wide host range and is thought to be native to Papua New Guinea, although the origin of the fungus has been deeply debated. It has caused serious losses in plantations and wind breaks of *P. radiata* in Australia. In South Africa, important species of *Eucalyptus* such as *E. fastigata*, *E. fraxinoides*, and *E. smithii* have been severely damaged.

Management of Diseases in Plantations

Many opportunities exist to reduce the impact of diseases in exotic plantations. Thus, quarantine measures to prevent the introduction of new pathogens are among the most important approaches to disease management. Eradication of pathogens after early detection might, in some cases, also be possible. Chemical control has been very successful in the case of some foliar diseases such as *Dothistroma* needle blight, where aerial spraying of fungicides has been used for many years.

Of all the approaches to disease control in exotic plantations, minimization through breeding and selection of pathogen-tolerant planting stock is most important and widely used. Considerable success has been achieved in reducing the impact of diseases through matching species to sites and planting species tolerant of the diseases, in areas where these diseases occur. Classical forest genetics has contributed substantially to the improvement of exotic plantation forestry as well as to disease resistance. Large industrial corporations that are involved in plantation forestry have generally invested in forest genetics programs and especially in ensuring access to a wide range of provenances of desired tree species. Breeding programs have also moved rapidly towards producing hybrids between species. They have thus been able to capitalize on hybrid vigor and to gain the advantages of a mixture of traits not available in single species. Hybrids have also been very useful in combatting various disease problems.

Contemporary trends are to produce clones of the best-performing genotypes and, after thorough testing, to deploy them on sites where they will grow best. Consequently, in some areas, plantation forestry has become technologically advanced, using techniques such as tissue culture and somatic embryogenesis to multiply clones. Management of clonal forests is complicated and, from a disease standpoint, maintaining reliable plantation records and establishing safe numbers of clones to plant is important. Thus, large corporations rely on geographic information systems to determine planting strategy and to ensure effective disease avoidance or resistance.

Genetic modification of exotic plantation trees to improve traits including disease tolerance and resistance is being actively pursued at the experimental level. Various genes associated with disease resistance are available and these have been transformed into trees such as *Eucalyptus* and *Pinus* that are widely grown as exotics in plantations. Tissue culture protocols are widely available for these trees, thus facilitating genetic modification. Clonal forestry and experience in deploying relatively small numbers of genetically identical clones for short rotations will also positively influence opportunities to deploy genetically modified trees. However, rotations longer than those associated with agronomic crops and the fact that forest trees are wind-pollinated, potentially producing clouds of genetically modified pollen, have raised concern. As soon as the potentially negative impacts of deploying genetically modified trees have been resolved, it is likely that these trees will play an important role in minimizing the impacts of disease.

Biological control of insect pests is well established in exotic plantation forestry but has not been used commercially to reduce the impact of pathogens. There is, however, considerable opportunity in this field and recent advances in the manipulation of fungal viruses for pathogen control deserve notice. Certainly, as diseases in forest exotic forest plantations become increasingly important, and together with the negative environmental impact of most chemical fungicides, it is likely that interest in biological control will increase.

Future Prospects

Plantations of exotics, particularly in the tropics and southern hemisphere, have yielded outstanding productivity during the last 100 years. Separation of the trees in these plantations from their natural enemies has been an important component of this success. However, disease and pest problems in exotic plantations have gradually increased due to the accidental introduction of new pathogens and the adaptation of native pathogens to be able to infect the exotic trees.

In the future, it is likely that increased investments will be needed in order to reduce the impact of pathogens in plantations of exotic trees. These will be essential if the impressive productivity that has been associated with these plantations is to be maintained. New technologies, including those associated with molecular genetics and computer science, are likely to become increasingly important in ensuring the long-term sustainability of exotic plantation forestry.

PLANTATION SILVICULTURE

Contents

Forest Plantations

J Evans, Imperial College London, Ascot, UK

Definition

Forest plantations embrace a range of forest types, with the common feature that the majority of the trees present were established by planting (or deliberate seeding). However, this simple statement belies the fact that when mature, many planted forests can appear similar to natural forest formations. While a geometrically shaped forest monoculture of a nonnative species is plainly artificial, many old and famous forests in Europe appear natural and reveal little of their mainly planted origin. Examples include the New Forest (UK), parts of the Black Forest (Germany), parts of the Forêt de Compiègne (France), and almost all the forests of Denmark.

There is no internationally agreed definition of a forest plantation, or 'planted forest,' the expression now widely used to embrace the continuum of forest types where forest origin is known to be by planting or direct seeding. Successive international experts meeting on The Role of Planted Forests in Sustainable Forest Management in Chile (1999) and New Zealand (2003) have recommended that the question of definition be considered. This is because the boundary between planted and natural forests is often indistinct and, among countries, there are different degrees of management, and different objectives for planted forests and a complementarity between natural and planted forests.

International agreement on a definition is not finalized, but harmonization of definitions is led by the United Nations Food and Agriculture Organization (FAO) in collaboration with several other bodies. Here discussion is confined to the more obvious types of forest plantations over which few will argue, where use of formerly nonforest land, or regularity of shape, or choice of species, or intensity of management, readily points to their artificial origin. This will include afforestation, which is the act or process of creating forest land by planting trees where forest historically did not exist such as grasslands, or to stabilize sand dunes, and reforestation, where the act or process of changing previously deforested lands back to forest land is mainly by planting trees. This commonly occurs where forest is logged or clear-felled and the next crop, of the same or a different species, is established by planting.

History

Planting trees has a long history and is recorded from ancient civilizations, e.g., the Old Testament portion of the Bible. But planting trees as a way of regenerating forests used, for example, for timber production and as a means of afforestation, is more recent. In the UK significant planting dates from the sixteenth century, and the practice only became commonplace across Europe by the eighteenth century. The nineteenth century saw plantation establishment as one means of 'modern' organized forestry and in Germany it became fashionable as an efficient way of growing a uniform crop of trees. The twentieth century saw major plantation establishment, initially in temperate and Mediterranean climatic regions and, since the 1950s, to an increasing extent in the tropics and subtropics.

Tree introductions have facilitated plantation development. Many successful plantations were built on experience gained from arboreta and trials of exotic (introduced) species. Both in temperate and tropical environments, this approach yielded species that have proved amongst the most successful of all plantation species, outstanding examples of which are conifers from the Pacific Northwest of America into western Europe, *Pinus radiata* from California into southern-hemisphere countries such as Australia, Chile, New Zealand, and South Africa, teak (*Tectona grandis*) from India, Myanmar (Burma), and Thailand into many tropical countries, and several Australian eucalypts in the tropics and subtropics. Together these trees form many millions of hectares of productive forest plantations far from their native habitats.

Today forest plantations of all types probably amount to some 187 million ha or about 6% of all closed forest in the world. Exact figures are uncertain owing to variable standards between countries of recording forest plantation statistics, including the vexed issue of definition.

Future Developments

There is already a substantial resource of planted forest, and current establishment of new plantations at an annual rate of several million hectares will soon result in such forest becoming the main source of wood products. This is predicted to occur in about 30 years' time if current rates of planting continue, and possibly a little sooner if massive afforestation arises from carbon sequestration initiatives. A total forest plantation resource of 300 million ha would satisfy the great bulk of world wood requirements for the foreseeable future.

An increasing area of planted forest is only one anticipated development. The nature of planted forests is also likely to shift in balance from: (1) domination by exotic species to greater emphasis on native ones, though exotics will always play an important role; (2) a largely industrial focus to industrial, rural development, rehabilitation, and environmental roles; and (3) a single-use to multiple-use forest.

Types of Plantation

Industrial Plantations

Industrial plantations are the arable crops of forestry; their principal objective is to grow a product, usually timber, efficiently. The main purposes include fuel production – firewood and charcoal, pulpwood for paper and cardboard, panel products, sawtimber (lumber), and sometimes veneers. Commonly one plantation supplies several of these products in the course of a rotation. Other products may also arise, whether as other round timber products, or in nontimber benefits such as amenity or even biodiversity enhancement where a plantation is growing on an impoverished site. But the dominant objective is to grow a commercial product.

While most industrial plantations are successful they have largely failed in one area: the growing of high-grade cabinet timbers for furniture and similar quality uses. In temperate countries this arises from the very long rotations required and in the tropics from silvicultural difficulties with growing mahoganies and related species of Meliaceae, because of shoot borers, and the complexity of domesticating dipterocarps, merantis, and rosewoods.

Some industrial plantations of trees are grown for nontimber forest products (NTFPs) used in naval stores, gums, and resins. Although extensive, rubber plantations (*Hevea brasiliensis*) have not generally been considered as plantation forestry since their main product is rubber latex. Today such plantations are now also exploited for their wood, which is finding a ready market in the manufacture of less bulky furniture.

Industrial purpose dominates management in terms of species choice (usually only one), stocking density, thinning prescriptions, rotation length to maximize financial returns or grow crops to a particular market specification, and clearcutting silvicultural systems for efficiency of harvest.

Social and Community Plantations and Woodlots

Planting trees is one way of compensating for loss of natural forests as a means of providing domestic products such as building poles, fencing materials, firewood, and even fodder for livestock. It was widely promoted in the 1970s and 1980s in countries of the African Sahel, in India and elsewhere usually in the drier tropics, but was not always successful. Sometimes choice of species was poor, sometimes tenure and ownership of land or even of the planted trees were unclear, but commonly the problems lay in a failure to involve the local community or villagers adequately in the decision-making process.

Today tree planting for social and community needs is embraced as part of rural development forestry and is subject to participatory processes to place it firmly in local people's control. In India these are sometimes termed 'communities of protection' or community-based forest management (CBFM) in the Philippines, while in Ethiopia many planting projects begun as food-for-work initiatives during the 1980s' famine have become a village resource. Collectively these kinds of plantation projects now often form part of joint forest management (JFM) initiatives.

Social and community plantations possess many of the same features as industrial crops: they are often, but not exclusively, single species and they tend to be block plantings, though size may be as little as 0.01 ha. As well as supplying one or more products they may confer benefits of shade and shelter, amenity, and even soil erosion control.

Environmental Planting and Buffer Zones

Some plantations have been established to harness their protective functions. While it is almost always better to conserve natural woodland cover for purposes of erosion control and catchment management, where little or no forest exists tree planting can be a useful complement to the other activities, such as terracing and check dams. This can generate conflict over water use – trees generally consume more water than other land uses, and exceptionally plantations have even been used to dry swampy areas as a way of reducing stagnant water in which malaria-carrying mosquitoes breed so prodigiously.

Not all plantation species are suitable for environmental planting. For example, plantations of teak and some eucalypts develop a thin or no litter layer, are prone to ground fires, and suppress understory vegetation, all of which makes them ill-suited for soil erosion control.

Buffer zone planting is where trees are deliberately planted to take pressure away from natural forest. Trees are established in the zone around natural forest to provide an alternative source of forest products, both woody and NTFPs. In this way pressure on natural forest is eased. Also this zone assists wildlife conservation by enlarging the area of woody cover and generally discouraging people from encroaching into natural forest. It is important that such buffer zone plantings are properly managed and, for example, include fruit trees to benefit local people.

Substantial development of plantations has also taken place to combat desertification, to stabilize dunes, to act as shelterbelts and windbreaks, and related benefits.

Rehabilitating Degraded Land and Restoring Natural Forest

Since about 1990 a number of cases have demonstrated that, under certain conditions, the recreation of a woodland environment by planting trees can act as a precursor for recovery, restoration, or regeneration of natural forest formations. Plantations suppress vigorous weeds, especially grasses; internally they bring a more equable microclimate; and generally they provide conditions often more conducive to regeneration of trees. In this sense plantations are an intermediate stage between (say) farmland and natural forest and help the process of forest restoration. The importance of such restoration often makes it eligible for funding from the Global Environment Facility (GEF).

A prominent example are the thousands of hectares of *Cordia alliodora* plantations in Ecuador which have led to successful natural regeneration in the understory of native rainforest hardwoods of *Virola* and *Brosimum* spp. In Ethiopia plantings of exotic pepper trees (*Schinus molle*) eucalypts (mainly *E. camaldulensis*) and silky oak (*Grevillea robusta*) on a woodland scale have led to rapid recolonization and recovery of native acacia (*Acacia abyssinica* and *A. tortilis*) and *Erythrina variegata* within the plantation area.

Enrichment Planting

Degraded natural forest is sometimes enriched by planting desirable tree species. Where the proportion of planted trees constitutes less than 50% of the forest, it is not considered to be a plantation. As a silvicultural system it is less common today than 30 years ago owing to expense in maintaining planted trees and, generally, indifferent success.

Carbon Sequestration

To date few plantations have been deliberately established to store carbon as one means of mitigating the rise in atmospheric carbon dioxide, which is partly responsible for global climate change. It is likely that carbon trading and financing under clean development mechanism (CDM) schemes will emerge and lead to increased investment in afforestation and reforestation. Should such plantations be established, and predictions are as high as 100 million ha worldwide in the next 50 years, the object of management will be to maximize carbon sequestration. Such plantations could potentially supply wood products, and possibly other benefits as well, but will inevitably have substantial land-use and people-related impacts.

Amenity Planting

Some tree planting has the principal objective of providing esthetic and recreational values to the urban and periurban environment. Such plantations may also provide some timber products and, where the previous land was impoverished, will enrich wildlife values too.

Plantation Silviculture

Characteristics

A feature of almost all forest plantations is that, at least for the first rotation, they are established in even-aged blocks usually of one species (monoculture). While there are many exceptions, these features of even age and single species simplify management but may increase the risks of damage from biotic and abiotic sources.

Plantations also tend to be regular in shape, with boundaries commonly following the artificial and often straight legal boundary to a property or area of land.

Species Choice

The first consideration is the objective of the plantation and what the main purpose of tree planting is. This, along with issues such as intensity of management, will largely determine what species are selected.

Much care is taken to match tree species with plantation site conditions. Commonly introduced (exotic) species are used when they offer greater productivity than the native alternatives. Many examples were cited earlier. It is clear that choice of species alone is insufficient to achieve optimum productivity, and seed origins and provenances from across the range of a potentially suitable species, as well as the fruits of selection and breeding programs, require investigation.

Understanding site is equally important and sophisticated analytical tools now exist, such as climatic mapping and environmental analysis, to characterize site and its potential for tree growth.

Establishment, Management, and Protection

Forest nurseries Almost all planted forests, as the name implies, are established by planting trees. These are young trees, usually grown in a forest nursery for 6 months to 3 years, depending on species and locality, to produce a plant typically 15–50 cm tall which is hardened off and taken to the planting site, which is often many kilometers from the nursery (**Figure 1**). This contrasts with most arable farming where seeds are sown where the plant is to grow.

Forest nurseries raise plants using one of two main methods: (1) either beds are prepared in the ground in which seed is sown into finely cultivated soil, and the seedlings are cared for, conditioned, and lifted to produce bare-root plants, sometimes called 'transplants'; or (2) seeds are sown individually into containers filled with a special soil-mix in which

Figure 1 Extensive plantations of spruce, mainly *Picea sitchensis* in Northern England 50 years after afforestation began. © J. Evans, 2004.

the young plants grow and are subsequently taken to the planting site still with a small root ball attached. Plants grown in containers have many names, usually depending on the kind of container system used: 'containerized plants' is sometimes used as the generic term. Typically bare-root methods are cheaper per plant, but containerized plants are more robust, surviving better in adverse conditions such as drought experienced at the time of planting.

A few plantations, such as poplar and quite often teak, are planted by inserting hardwood cuttings called 'sets' or 'stump plants.' Woody material of these species readily roots, thus allowing this form of vegetation propagation to be used.

Site preparation Sites for planting are usually degraded land or poor-quality pasture unfit for agriculture and of little conservation or other importance. Clearing existing natural forest simply to provide a site for tree planting is today strongly deprecated and is contrary to certification schemes, e.g., Forest Stewardship Council (FSC) principles governing plantation development. Of course, reforestation is a different case.

The planting site itself may need one or more of the following operations – vegetation clearance, cultivation, tillage, bedding, drainage, fertilizing, and fencing – before planting can begin. Assessment of such needs depends on local experience and evidence from research trials and is frequently one of the largest expenses in establishing a plantation. Prescriptions cannot be laid down, but the aim of such work is to undertake the minimum preparation and protection necessary to secure high tree survival and vigorous growth over a whole rotation.

Tree planting Planting is not a difficult operation, but must be done with care to insert roots into mineral soil. In most situations containerized seedlings or transplants should be inserted to root collar depth, but occasionally where water stress is a problem, deeper planting may be done to ensure root contact with moist soil. It is important that all trees are planted vertically and not left leaning at an angle. Planting takes place at the start of the wet season in the tropics and subtropics or in the fall or spring in temperate latitudes prior to leaf flush. Typically, 1000–4000 trees are planted per hectare depending on the object of the plantation.

Newly planted trees must be protected from browsing damage and from vigorous weed competition to allow trees to become well established. Weed control may be required from 1 to 5 years. Some plantations may need a single application of fertilizer to aid growth or correct a nutrient deficiency but the practice is not required on many sites. Phosphorus is the most commonly limiting nutrient for satisfactory tree growth and on many tropical sites a small quantity of the micronutrient boron is required. Application of pesticides at the time of planting is, unlike farming, the exception rather than the rule when tree plantations are planted on formerly nonforested sites. Pesticide use is sometimes required when replanting a former forest site, such as a second rotation crop, to control insects such as weevils, and in the tropics, termites and leaf-cutting ants.

If more than 20% of newly planted trees die, additional trees may be planted, a process with many names, including 'infilling,' 'blanking' and 'beating-up.' It is not worth doing more than once since delayed plantings invariably fail to catch up with the original trees and are destined to become suppressed.

Once plantations are established and are no longer suffering weed competition or damage from browsing animals, the next operation is frequently cleaning, i.e., the removal of unwanted woody growth.

Thinning and pruning Once the canopy has closed, plantations may be subject to regular thinning until the trees have reached desired final crop size. Thinning aims to remove poor trees to favor the best remaining ones and normally begins once a stand has reached 8–10 m height. Each thinning removes one-quarter to one-third of trees present at intervals of 3–10 years, depending on age and vigor of the stand, until rotation age is reached.

Pruning of side-branches may be done on the lower bole, up to 6–8 m, to produce high-grade knot-free timber. It is carried out in stages at around the time of first and second thinning.

Rotations and Regeneration

Plantations are grown for a purpose, and it is this purpose that determines rotation length. Some plantations may be managed to maximize their economic return, but more commonly trees are grown until they reach a size that is optimum for the intended market. Clearly, firewood plantations will be grown on a shorter rotation than trees grown for sawtimber (lumber) or veneer when large trees are required. Also, in plantation management, a few trees may be left much longer than the usual rotation for reasons of amenity or wildlife benefit.

In the tropics rotations can be as short as 2–3 years for small-sized products, 5–20 years for industrial products such as woodpulp, and 10–40 years for lumber-sized material. In temperate conditions rotation lengths are commonly two to five times as long.

Most plantations are clear-felled and sites replanted, the latter operation taking advantage of any genetically improved stock or even a change of species since the previous crop was established. Some plantations are regenerated naturally using seed from the preceding final crop trees or, where the species is suitable and small-sized products sought, from coppicing, i.e., forming the new crop from stump shoots (sprouts) of the felled trees. Coppicing is common for firewood and pole crops such as many eucalypt plantations in the tropics.

Plantation Yields and Productivity

Growth Rates and Yields

Because a suitable species is carefully matched with the planting site and because trees are spaced evenly to occupy the site and all are harvested, plantation productivities are usually considerably greater than that of natural forest (**Figure 2**). The typical range of yields is: 3–20 $m^3 ha^{-1} year^{-1}$ in temperate plantations, 5–35 $m^3 ha^{-1} year^{-1}$ in Mediterranean climates, and 5–50 + $m^3 ha^{-1} year^{-1}$ in the tropics and subtropics.

The main factors causing the above wide variation in plantation growth rates are tree species, fertility and exposure of site, and length of growing season, namely adequate summer warmth in high latitudes or sufficient moisture in Mediterranean and tropical regions where severity (length) of dry season is critical. Within these general climatic parameters moisture (rainfall amounts) often determines good and poor years for tree growth.

Maximum productivity from a site is also affected by stocking and for how long trees are grown. Long rotations to achieve large tree sizes for specified markets may diminish site productivity potential since older trees, while not overmature biologically, slowly decline in growth rate.

Figure 2 Plantation of native *Cordia alliodora* on abandoned ranch land in Lcuador which has led to good regeneration of other native hardwoods. © J. Evans, 2004.

In the future yields can be expected to increase owing to genetic improvement ranging from simply choosing a better provenance to possible use of genetic modification technology.

Problems with Plantations

Monoculture and Risk of Pests, Diseases and Other Threats

The uniform conditions of growing one tree species in large even-aged blocks may expose plantations to greater risk of damage from pests and diseases. Ecologically the potentially large food resource, the close proximity of trees to pass on infection, and even direct root contact beneath ground all suggest greater risk and potentially rapid build-up of a threatening pathogen or pest. Where an exotic (introduced) species is used, some freedom from damage is often observed in the first rotation, but this is often transitory. For example, extensive plantations of lodgepole pines (*Pinus contorta*) in Scotland (UK) grew well on very inhospitable sites throughout the 1950s and 1960s but in 1977 began to be devastated by a hitherto benign insect species associated with native Scots pine (*Pinus sylvestris*), *Panolis flammea*. The severity of damage was so great that lodgepole pine is no longer planted.

Other well-known examples include defoliation by the psyllid *Heteropsylla cubana* of the once widely planted multipurpose tree species *Leucanea leucocephala*, and *Sirex* wood wasp infestation of *Pinus radiata* plantations in Australia and recently in South America. Fungal pathogens causing serious damage such as defoliation, wood decay, or root mortality are the blights on poplar, fomes (*Heterobasidion* spp.) damage to many conifers, and *Phytophthora* spp.

All these and many other threats place plantations at considerable risk. However, experience teaches that most are containable provided that good silviculture limits risk of stress to trees through careful matching of species with site and related operations, and provided that adequate research can inform integrated pest/pathogen management programs and strategies. Only occasionally has a species been precluded owing to the threat of a devastating pest or disease, e.g., *Dothistroma* damage to *Pinus radiata* planted in the tropical highlands, and psyllid damage to *L. leucocephala*.

Abiotic Damage

The uniformity of plantation conditions can render them particularly vulnerable to fires, storms, frosts, droughts, and related events. In the late 1990s one-sixth of the entire Usutu Forest in Swaziland in southern Africa, a plantation of some 72 000 ha, was destroyed by either fires or hail damage, necessitating massive replanting programs. In the UK the threat of windthrow in forest plantations determines rotation length on many more exposed sites, with the aim of cutting trees just prior to the time they are predicted to blow down.

Sustainability of Yields Over Time

With significantly greater productivity than most natural forest, the question of sustainability of plantation yields becomes important. Could the more intensive silviculture lead to declining yields in the long term? It is difficult to answer this question categorically, and the situation will vary with site, because few plantations have been grown successively for more than two rotations and almost none for more than three rotations. However, what evidence does exist suggests that productivity is unlikely to decline; indeed, it may increase with improvements in genetic stock of plants. In one of the most intensively studied examples in Swaziland there is no evidence of yield decline after three whole rotations of pines grown for pulpwood, and even some signs of improving productivity.

There are some well-publicized exceptions to the above, namely plantations of *P. radiata* in South Australia, *Cunninghamia* in subtropical China, and *Picea abies* in Germany. In each case research has either demonstrated or at least pointed to causal factors that explain the yield decline. Such factors include excessive compaction of soil when harvesting trees, failure to conserve organic matter, and inadequate attention to invasive weeds, especially grasses. On no site does the growing of a single tree species in monoculture itself appear to be a primary cause of the problem. Indeed, in the case of South Australia, current growth rates of pine plantations now greatly exceed that of the previous rotations.

Outlook

As noted, there is already a substantial resource of planted forest which continues to expand and is destined to become the main source of wood products. What must be hoped is that this will include not only industrial grades of lumber but also high-quality timbers to replace diminishing supplies from natural forest. What must also be hoped is that much of future planting in developing countries will be fully integrated into rural development and local people's aspirations to contribute in the many ways plantations can to sustainable livelihoods.

Other emerging trends include increased planting of trees outside the forest, such as in agroforestry, partnerships between corporate enterprises and smallholders, rehabilitation of degraded land, and environmental protection roles.

Plantations as a way of growing trees efficiently appear sustainable. They will fully come to play the enormous role they can only if environmental, political, and social imperatives are addressed alongside those of sound silviculture.

Stand Density and Stocking in Plantations

K Theron and B V Bredenkamp, Department of Forest Science, University of Stellenbosch, South Africa

Introduction

In the third volume of the classical work *Schlich's Manual of Forestry* (1925), it is stated:

> To every method of treatment, as determined by the objects of management, corresponds a normal density of the growing stock. The degree of density may be defined as overcrowded, crowded, open, very open, interrupted, irregular, etc. Such terms are indefinite and subject to different interpretations.

Over 75 years later the terms describing the degree of site occupancy by trees are still being misinterpreted, essentially because many foresters use 'stocking' when referring to 'stand density.' These terms are not synonymous and are well defined. Stand density is an absolute measure that quantitatively expresses the number or count of trees on a unit of land, for example x stems per acre (spa) or y stems per hectare (s ha^{-1}). If trees are well spaced so that death from competition mortality is precluded, then stand density will remain constant over fairly long periods of time.

Stocking, on the other hand, is a relative measure of the degree of site occupancy with due regard to the objectives of management, and it is often expressed as a percentage of full site occupancy. At a certain stage of its development a stand may be well stocked for the production of sawtimber. In other words, that particular stand density is well suited to meet the objective of growing timber with dimensions to meet the needs of the sawmiller. That very stand will at the same time be understocked for the production of pulpwood and overstocked for the production of veneer logs. Further, because trees are continually increasing in size, stocking changes over time while stand density in terms of stems per unit area is held constant.

Basal area per unit area of land is commonly used as a quantitative measure of stocking.

The control of stand density through planting at the required spacing and spatial arrangement, suppression of ingrowth, and thinning to allow room for growth is a primary tool of forest management to achieve optimal stocking for a particular crop of trees. A collection of stands that are fully stocked is a prerequisite for the concept of a normal forest.

Determination of Optimal Stand Density

The effects of stand density on growth parameters of trees and stands of trees have been studied intensively. Much of the initial work in this field was based on an extravagant set of 27 installations of field experiments in South Africa, established mainly in the late 1930s, and known as the correlated curve trend (CCT) experiments. The results quantified many of the effects of stand density for the first time and provide an excellent example to illustrate many of the points below. The aim of the CCT experiments was a replicated installation of the experiment on each of a good, an average, and a poor site for 10 tree species grown commercially in each region where that particular species was grown in that country, in order to consolidate all spacing and thinning research. The aims were not fully met in terms of replication but an ambitious research program ensued.

At each installation large plots were established at between eight and 12 different spacings applied at random and a further eight or 10 plots were grown according to a strictly specified thinning regime. To avoid complications induced by seedling mortality and competition from weeds, the different spacings were achieved by planting at a uniform (high) stand density followed by frequent thinnings in advance of the onset of competition. This practice proved to be contentious and the current generation of spacing experiments, known as the standardized sample size (SSS) CCT experiments, does not employ it.

The premise behind the CCT experiments was that, apart from accident and disease and factors such as grass competition and differences in exposure, the following hold true:

1. In any given locality the size attained by a tree of a given age must be related to the growing space previously at its disposal; all other factors influencing its size are fixed by the locality.
2. Trees planted at a given (stand density) will, until they start competing with each other, exhibit the absolute or normal standard of growth for the species and locality. (In the original publication the term stocking was incorrectly used to denote stand density and in this section it is replaced by stand density within parentheses.)
3. Trees planted at a given (stand density) and left to grow unthinned will exhibit the absolute or normal standard of growth for the species, locality and the particular density of stock in question.

The first results from the CCT experiments in five pine species, based on observations when the oldest trees were 9 years old, were published in 1947. These early results were 'remarkable and, in a sense, unexpected.' The conclusions drawn were:

1. The age at which competition commences for a stand of given (stand density) is independent of species, site, or climate.
2. The degree of competition (using diameter at breast height (dbh) increment as index) is the same for a given age and (stand density) irrespective of species and site.
3. As (stand density) decreases, dbh and mean height increase; total volume at first increases and then decreases.

The experiments referred to in these conclusions were established under widely different climatic and site conditions by different people. Data were collected by nine research officers independently of each other (due to staff changes during World War II) and yet final thinnings in advance of competition were completed in all experiments within a few months of each other.

With hindsight, it is apparent that some licence was taken. The conclusions applied to five particular pine species as originally no other genera were tested. What was considered to be a poor site in the 1930s would be viewed differently today. Afforestation has spread into marginal areas where the sites are poorer and certainly drier and modern site amelioration techniques make afforestation of sites originally classified as 'poor' quite 'average.' The conclusions being considered 'independent of species, site or climate' thus applied to a fairly narrow range of conditions.

In the CCT experiments all treatments were allocated to plots at random with some restrictions in order to group plots of similar size.

Stand density has also been studied with systematic designs. The circular (wagonwheel) designs known as Nelder experiments (**Figures 1–3**) address either changes in growing space or changes in the shape of the growing space available to the tree in separate installations. In the former case trees are planted progressively further apart along the 'spokes' of an imaginary wheel, with the result that each position further from the hub of the wheel outwards represents a lower stand density while the shape of the growing space is maintained as essentially square. In the second case the trees are planted progressively closer together along the spoke, resulting in growing spaces that vary from square near the hub to spaces with increasing rectangularity the further the location is from the hub.

The 'Scotch plaid' experimental design is based on a rectangular grid and incorporates both increasing growing space and increasing rectangularity of growing space in each installation (**Figure 4**).

Many other experimental designs have been used around the world.

The Effects of Changing Growing Space on Trees

An increase in growing space results in an increase in dbh. Even if trees were grown at a high stand density that resulted in a reduced dbh, a thinning will result in an increase in dbh increment. The rate of that increase depends on the degree of suppression prior to the release (**Figure 5**). This effect is also observed in stands where stand density was reduced by competition-induced mortality.

The height of an individual tree is less affected by stand density than it is by site quality. However, tree height is not unaffected by stand density, and across a range of stand densities there is one that will be optimum for height growth of a particular species. Stand density that is too high or too low will impact negatively on height growth but within the limits of stand density used in plantation forestry there is essentially no effect on top or mean height.

Because stand density has a marked influence on dbh and a minimal influence on height, it has a marked influence on stem taper. The higher the stand density, the less the taper will be.

Increasing stand density results in a decrease in the diameter and length of branches and in some species there is also a decrease in the number of branches per unit length of the tree bole.

The higher the stand density, the poorer stem form will be. Trees grown under conditions of suppression tend to be more crooked than those that are free-growing and there is some evidence that the proportion of trees that are forked will also increase with increasing stand density. However, some species, such

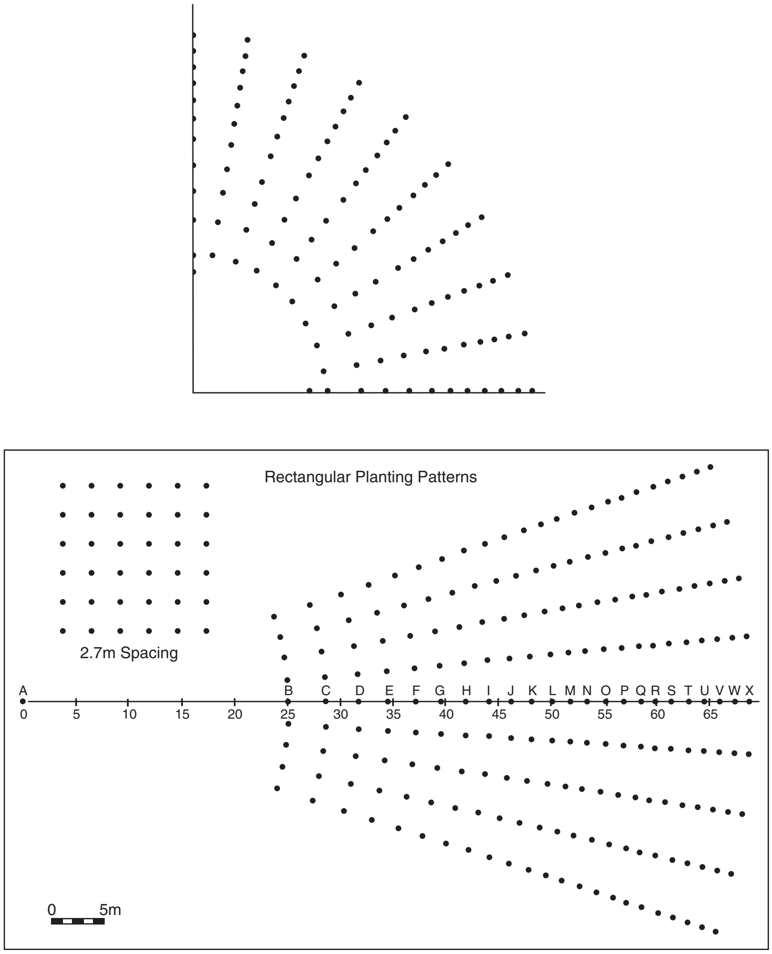

Figure 3 Nelder experiments: segments of variable-density plots (design 1b). Source Nelder JA (1962) New kinds of systematic designs for spacing experiments. *Biometrics* **18**: 283–307 (top) and Bredenkamp BV (1982) Rectangular espacement does not cause stem ellipticity in *Eucalyptus grandis*. *South African Forestry Journal* **120**: 7–10 (bottom).

as *Acacia melanoxylon* and *A. auriculiformis*, must be grown at high stand densities to avoid crook.

As a reduction in stand density increases diameter growth, the proportion of early or spring wood is increased, resulting in a reduction in timber density. There is little evidence to support the popular belief that this results in a reduction in timber strength or quality. Attempts of foresters to reduce the size of the juvenile core through reduced planting spacing and delayed first thinning generally fail to reach their objective. However, in the case of *Pinus patula* where the juvenile core may consist of as many as 20 annual rings, delayed thinnings can restrict the size of the juvenile core.

The Effects of Changing Growing Space on Stands of Trees

As stand density has such a marked impact on the dbh of the individual tree it also has a major impact on stand mean dbh. Mean dbh is controlled almost exclusively by stand density.

High stand density results in an increase in the variation of dbh. Dbh distributions are most uniform when stand density is low and most heterogeneous under conditions of suppression.

If mean height of a stand is defined as the height of the tree with average dbh (mean cross-sectional area), then mean height is affected by stand density because of the influence on dbh. Top height, which can be defined in many ways, is less affected. Top height is sometimes considered to be unaffected by stand density and is thus used to express site quality as the top height of a stand at a given index age; however, at extremes of stand density, top height is also affected.

As stand density controls dbh and affects height, the most important variables determining tree volume, stand density has a major effect on stand volume. If the object of management is merely the production of fiber, then the optimum stand density

is the highest stand density the site can support without inducing mortality due to competition. However, if a specific crop is being cultivated, there will be an optimum stand density for that crop and that optimum will be at a much lower level than in the case with production of fiber.

The Effects of Rectangularity of Growing Space

The effects of rectangularity of the growing space, measured as the ratio of the distance between rows to the distance between the trees within the rows, on the volume production of trees and stands is negligible, if any. Between-row spacing of as much as six times the within-row spacing has been shown to have essentially no effect on the growth or the shape of the cross-section of the bole. There are however effects on branching. In general, branches oriented with the row curve away from competing branches from adjacent trees and grow towards clear space between the rows. No influence of rectangularity of growing space on the number of branches has been reported.

Spacing and Stocking Practices Around the World

Initial stand densities have been markedly reduced since the 1970s. The wider initial spacings are mainly due to increasing availability of genetically improved planting stock; better site preparation, planting, and tending; improved forest protection, and the advantage of enabling shorter rotations.

Practices differ very widely among countries. In some cold temperate countries trees are planted at 10 000–18 000 trees ha^{-1}. In the UK most conifers are now planted at densities of 2500 stems ha^{-1} whereas in the 1930s about 4500 stems ha^{-1} were planted. In southern-hemisphere countries it is now normal to plant between 600 and 1100 stems ha^{-1} where high-quality sawn timber is produced. Where pulpwood, poles, firewood, or mining timber are required, stand densities are up to 2000 stems ha^{-1}. *Populus deltoides* grown for matches is often established at 400 stems ha^{-1}. Initial stand densities of less than 400 stems ha^{-1} are mainly found in agroforestry situations.

When Very Close and Very Wide Spacings Are Used

The general goal of initial spacing is to provide sufficient trees from which eventually to select a final crop of evenly spaced and acceptably formed trees, within the restraints of site and other factors. For a given spacing, growth responses are heavily dependent on species and site factors.

Appropriate initial spacings and thinnings enable foresters to achieve the end-use objective. For the production of small-sized timber such as pulpwood, poles, and mining timber, volume production in a stand must be maximized, i.e., initial spacing is relatively close and no thinnings, or only light thinnings, are required. For the production of sawtimber and veneer, initial spacings are wider and heavy thinnings are required to produce final crop trees with big diameters in a relatively short time.

Initial spacings are generally relatively wide for fast-growing species of good tree form, where tree establishment costs are high. In the case of *P. deltoides* grown for matchwood, where minimum sizes for peeling preclude the use of timber for thinnings, initial spacings are even up to 5×5 m. Other factors to consider are mechanization, water run-off required by downstream users, and susceptibility to diseases and pests that increase with an increase in stress on trees.

Improved genetics and good silvicultural practices have reduced the need for high initial stand densities. However, where young trees are exposed to severe winds, wide spacings increase the incidence of wind damage. New Zealand evidence suggests that initial stand density of *Pinus radiata* should not be less than 600 stems ha^{-1} to ensure adequate mutual protection.

The appropriate stand density after a thinning depends largely on the amount of foliage a given species can support on a given site. The residual basal area may vary from 9 to 40 $m^2\,ha^{-1}$ with higher stand densities with evergreens, shade-tolerant species, and good sites. On sites that are so poor that the root systems compete severely but crowns cannot close, stand densities should be exceptionally low.

Effects of Spacing on Site Capture

When trees are free-growing and not competing with each other, diameter growth is less than the maximum possible. As basal area increases, competition sets in amongst trees, but total growth per hectare continues to increase, although at a decreasing rate until the maximum growth is reached, i.e., the site is fully utilized. With further increases in stand density, the stand increment remains similar over a wide range of stand densities. Therefore, individual trees grow slower in diameter as stand density increases. When competition is so severe that trees lose vigor and become more prone to disease and insect attack, increment becomes less than the maximum.

During the first year or more after establishment of a plantation, when the trees are small, the site is not fully utilized. Only later do roots and crowns spread sufficiently to compete with neighboring trees for light, moisture, and nutrients.

In even-aged monocultures a site can support only a certain number of trees of a given species and size. The maximum number of trees that can be carried decreases with age as the trees grow larger, rapidly at first but slowly towards the end of the rotation. On dry and infertile sites, competition amongst trees will occur before their crowns start to compete for light. Where soil moisture and nutrients are in abundance, competition for light may set in before the roots are in severe competition.

The most vigorous trees are most likely to survive the competition, i.e., the tallest are generally the largest in all dimensions. The weaker trees become increasingly suppressed and eventually die. This process is called natural thinning. In very dense stands, competition is so severe that dominant trees also grow slower. This can be avoided by timely thinnings.

The trees of monoculture plantations are generally uniform in spacing and size and therefore also in vigor. Either their crowns or roots will start to compete rather suddenly and then or soon afterwards will be the ideal time for the first thinning. The initial spacing should preferably be wide enough so that the trees to be thinned will have grown to merchantable size.

The earliest a plantation can be thinned without loss of increment varies with the rate of growth, which is determined by site quality, initial spacing, genetics, and intensity of silvicultural practices. It can be as early as age 2 years for *Tectona grandis* planted at 2 × 2 m in the tropics. In the UK it varies from 20 to 35 years for most conifers, but can be more than 50 years in colder climates.

If the thinning cycle is very long, thinnings are generally heavy and the site may not be fully utilized for some years after a thinning.

Thinning weight, i.e., the number of stems, or basal area, or volume per ha removed during a thinning, expressed as a percentage of the main crop before thinning, is generally between 20% and 60%. Lighter thinnings are regarded as uneconomical. Heavier thinnings leave stands more prone to wind damage and unacceptable increment due to incomplete site utilization.

The most beneficial silvicultural regime for a stand would include frequent light thinnings. These are economically not justifiable. The frequency and intensity of thinnings are thus driven more by economics than good silviculture. However, end-use potential and wood quality also play a role.

Spacing in Agroforestry, Tanbark and Biomass Plantings and Other Unconventional Stands

Spacing is manipulated to produce material which will best meet the market demands and also yield optimal profits. In all forestry stands, including agroforestry, crops are usually thinned or clearfelled before competition becomes so severe that mortality sets in.

In agroforestry, tree seedlings are often planted at the same time as food crops. Spacing between tree rows is often wider than in monoculture plantations to delay the shading of the food crop or forage grown for grazing by the trees. Trees may also be thinned and pruned so that food cropping can continue beyond the tree establishment stage.

In some agroforestry systems trees are planted in strips to provide shade or shelter to the agricultural crops or animals grazing among the trees. Such plantings may occupy less than 5% of scarce farmland.

In alley cropping, nitrogen-fixing shrubs and trees are grown in wide rows to allow cultivation of four to six rows of food crops in between. Spacing between trees varies from less than 2 m to as wide as 5 m.

In semiarid areas as few as 20 trees ha^{-1} are planted where annual crops are grown. Partial shade conditions are sometimes also created in moist areas where perennial agricultural crops, e.g., tea and coffee, are grown, by planting 50–200 trees ha^{-1}.

For woodlots, initial spacing between trees is normally closer than for commercial plantations. On good sites, trees grown for firewood may be planted as close as 1 × 1 m and if grown for poles at 2 × 2 m, to maximize yields. Rotations are typically only 3–6 years.

Acacia mearnsii plantations grown for the production of tanbark are planted at 2200 trees ha^{-1}. When established by means of direct sowing or natural regeneration, many thousands of seedlings ha^{-1} must be removed in one to three successive thinnings to retain 1200–1600 stems ha^{-1} until clearfelling at ages 8–12 years.

In recreational areas, soils are often compacted by the many visitors, thus placing stress on the trees. Therefore, spacing between trees should be wide to minimize competition amongst them.

How Spacing Interacts with other Establishment Practices (e.g., Plowing, Drainage)

The spacing at which trees are planted in plantations is usually determined accurately. For practical reasons, e.g., mechanized operations, locating young trees when weeding, and for line thinning, rows should be straight. Likewise, when natural regeneration is used, respacing or precommercial thinning should be done so that the remaining trees are in rows. Where plantations are established on level, stone-free ground, straight lines can often be seen in a number of directions. However, on many sites it is difficult to achieve precision because of steep slopes, rocks, and old stumps.

Costs of some forestry operations, e.g., weeding and extraction of thinnings, can be reduced by using tractor-mounted equipment and other big machinery. It is therefore sometimes desirable to have rectangular spacings that allow enough space between rows to accommodate such machines. For example, instead of planting approximately 1200 trees ha^{-1} at a spacing of 2.9 × 2.9 m, the distance between the rows can be increased to 3.5 m and the distance between trees in the row reduced to 2.4 m to maintain the same number of trees per hectare.

Weeds are likely to be suppressed more rapidly in closely spaced stands because of quicker canopy closure. However, this should not be the major objective of close initial spacings because the additional costs of establishing more trees usually far exceed the savings incurred on weeding operations.

After a number of coppice regenerations in *Eucalyptus* plantations for example, reestablishment with nursery-raised plants is usually necessary. It is then preferable to plant in the rows of the killed stumps rather than between the rows, to enable easy future access, e.g., for firefighting.

Use of Thinnings to Manipulate Stand Density and Achieve Optimal Stocking

Artificial thinning is the removal of a proportion of individual trees from a stand before clearfelling. It is generally understood to take place after the onset of competition. However, precommercial thinnings may take place before trees start to compete with each other. Thinnings are mostly prescribed as stems ha^{-1} or basal area to remain at a given age.

In stands that are to be thinned, more trees are established than the required final crop, mainly to ensure sufficient trees from which the final crop can be selected, but also to utilize the site better.

The main objectives of thinnings are to:

- provide the remaining trees more space for crown and root development to encourage stem diameter increment and thus reach the desired size sooner
- remove trees of poor form so that final crop trees are of good quality
- manage relatively uniform growth in order to enhance wood quality and sound end-use potential
- prevent severe stress that may induce pests, disease, and stand instability
- provide an intermediate financial return from sales of thinnings.

Thinning schedules are therefore based on both biological and economic considerations. Skillful thinning can increase economic yields although the site is not fully utilized throughout the entire rotation, because veneer and sawlog prices generally increase significantly with increased log diameters.

An infinite number of combinations is possible between initial spacing, timing and intensity of thinning, final density, and rotation length. A unique thinning regime is therefore possible to fit every case of management and market circumstances.

Tending

G Kerr, Forestry Commission Research Agency, Farnham, UK

Published by Elsevier Ltd., 2004

Introduction

Tending generally aims to improve the composition, structure, condition, health, and growth of forests, in both single cohort and multicohort stands, to achieve management objectives. The scientific basis of a range of tending operations is described with reference to stands arising from artificial regeneration (planting (*see* **Afforestation**: Stand Establishment, Treatment and Promotion - European Experience) or direct seeding), natural regeneration (natural seeding (*see* **Silviculture**: Natural Stand Regeneration) or coppicing (*see* **Silviculture**: Coppice Silviculture Practiced in Temperate Regions)), or a mixture of both approaches. As with any silvicultural treatment, tending must be conducted with a clear understanding of the way in which the vegetation and site will develop after treatment. If the work is conducted with little foresight costs can be incurred with few, or possibly negative, effects on the development of the stand.

Tending Operations

The nomenclature of tending is an area of silviculture where terminology can be parochial and confusing. For example, the term 'singling' has many different meanings and 'formative pruning' can be translated into French in a number of different ways. For clarity, the terminology used here follows *The Dictionary of Forestry* (see Further Reading). The range of operations considered is illustrated in **Figure 1** and described below.

Brashing

Brashing is the removal of live or dead branches on a tree stem from ground level up to a height of about 2.5 m. It is usually applied to planted single cohort stands at or just after the time of crown closure. The direct effects of brashing on a stand of trees are insignificant in terms of growth and timber quality. However, there can be indirect effects: increased access aids early identification of damage or health problems, and facilitates subsequent intermediate treatments.

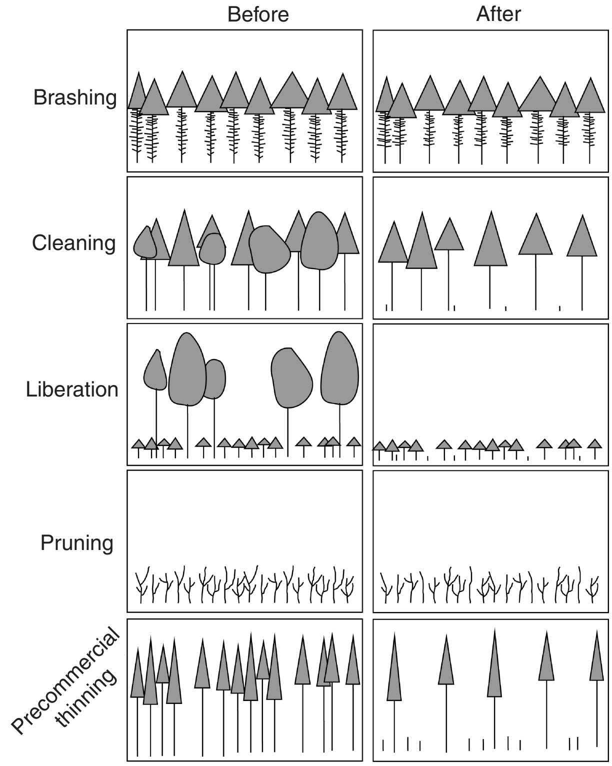

Figure 1 Diagrammatic representation of the effects of tending operations on forest stands.

Cleaning

Cleaning is a release treatment made to free selected trees from less desirable individuals that overtop them or are likely to do so (**Figure 2**). Cleaning has significant direct effects on the growth rate of selected trees because it increases access to resources. The main limiting resource is often assumed to be light in single cohort stands because cleaning has obvious effects on the canopy. However, on many sites greater access to light, water, and nutrients will all be important even though on some sites a single factor can be limiting, for example on dry sites greater access to moisture may be most critical. The main indirect effect of cleaning is the removal of 'undesirable' species and this may reduce the biodiversity of the stand. This is an important consideration if social or environmental management objectives are a priority, and in such woodlands there is no need for the undesirable species to be eliminated.

Liberation

Liberation is a release treatment to free a young cohort from competition with much larger sized trees. In many circumstances a liberation cutting corrects a problem not addressed by earlier silviculture. For example, the larger trees may be of species

Figure 2 Cleaning would now be desirable in this stand of northern hardwoods where pin cherry (*Prunus pennsylvanica*) is now dominant.

Figure 3 Pruning *Pinus radiata* to produce knot-free timber.

and sizes that could not be utilized from a previous felling and were left to reduce harvesting costs. The influence of these trees on the cohort of younger trees will depend on their number, basal area, and distribution. The presence of such trees is not always negative and they can increase species richness, improve vertical structure, and provide shelter for the younger trees; they could be girdled to increase standing deadwood.

Pruning

Pruning is the removal, close to the branch collar, of side branches and multiple leaders from a standing tree (*see* **Plantation Silviculture**: High Pruning). It is widely practiced to simulate natural branch mortality and increase the timber quality of selected trees. A secondary function of pruning is to act as a semipermanent way of marking tree selections to guide future thinning decisions. In general it is only used on 'young' trees where some degree of genetic improvement has been possible (**Figure 3**), otherwise it is really a remedial treatment for stands where production of quality timber is an important objective but establishment has not provided enough trees to achieve this.

Precommercial Thinning

Precommercial thinning is the removal of trees not for immediate financial return but to reduce stocking and concentrate growth on the more desirable trees. The effects are similar to cleaning except that, because the trees are generally older, they are dominating the site to a greater extent and the risk of losing control of the vegetation, to coppice regrowth or regeneration of pioneers, is much less. In addition, although precommercial thinning can remove less desirable species, with consequent effects on stand diversity, it is usually associated with removal of poorer phenotypes of the more desirable species.

Weeding

Weeding is a release treatment that eliminates or suppresses undesirable vegetation. The most likely need is in the period between establishment and first thinning to remove climbers such as *Clematis* spp., *Lonicera* spp., and kudzu (*Pueraria lobata*).

General Points

When tending operations are being considered the trees are established and safe from the normal adverse influences common to the site. However, trees will still need to be protected from a range of biotic and abiotic factors. A special case of this is the grey squirrel (*Sciurus carolinensis*) in the UK and Ireland. Grey squirrels can cause significant damage to a range of broadleaved species and trees are most vulnerable to damage when they are 10–40 years old (**Figure 4**). It is interesting to note that this behavior of the grey squirrel is very different to that in its native North America.

The future changes in appearance, species composition, productivity, and structure of a stand are largely governed by the spatial arrangement and height distribution of trees in the phase of growth between establishment and first thinning. Tending operations are an initial opportunity to influence this development. However, the costs of the operations can be high and, relative to decisions concerning establishment and thinnings, the long-term effects of some tending operations are uncertain. Hence, when forestry practice is subject to economic scrutiny tending operations are vulnerable. For example, in traditional French silviculture regenerating oak (*Quercus robur* and *Q. petraea*) has traditionally used a series of weeding and cleaning operations, but recently there has been much pressure for rationalization and the number of operations carried out has been significantly reduced. Similarly when regenerating northern hardwoods on the Allegheny plateau in northwest Pennsylvania, USA, almost no tending operations are carried out (**Figure 5**).

Figure 4 Grey squirrel (*Sciurus carolinensis*) damage to *Fagus sylvatica* in the UK.

Stand Development

There are several classification schemes to describe stand development. A convenient one to set tending operations in context is shown in **Figure 6**. The model describes how the stand structure of a forest changes following disturbance (*see* **Silviculture:** Forest Dynamics).

After harvest or disturbance young trees regenerate on the site and this is classified as the stand initiation phase. As the young trees grow they form a dense canopy which eliminates further regeneration and

Figure 5 Naturally regenerated northern hardwoods (mainly *Prunus serotina*); little tending will take place before the first thinning.

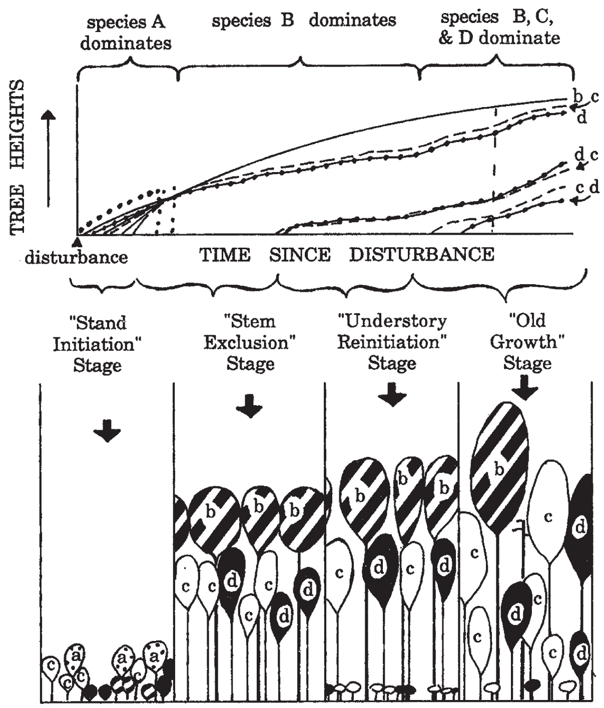

Figure 6 Schematic stages of stand development after disturbance. All trees forming the forest regenerate soon after the disturbance; however, the dominant tree type changes as stem number decreases and vertical stratification of species progresses. The height attained and the time lapsed during each stage vary with species, disturbance, and site. Reprinted from Oliver CD and Larson BC, *Forest Stand Dynamics*, update edn, Copyright © 1996 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons Inc.

existing stems start to die; the stand is in the stem exclusion stage. When openings form in the canopy as a result of a reduction in canopy competition, conditions for regeneration of the understory improve during the understory reinitiation phase. Eventually large trees in the main canopy die, younger trees in the lower canopy are released, and the stand develops into the old growth phase that has an all-aged structure with an irregular canopy. In single cohort stands, tending operations take place in the latter stages of the stand initiation phase and the beginning of the stem exclusion stage. Stocking is one of the primary factors that influences the development of stands moving from the stand initiation phase to the stem exclusion phase (*see* **Plantation Silviculture**: Stand Density and Stocking in Plantations). Hence the changes described below will occur sooner in an area with dense stocking, from successful direct sowing or natural seeding, compared with a planted area where costs usually prohibit stocking levels that will induce mortality quickly.

During the stand initiation phase tree crowns will not be in contact and, although the trees will be in competition for light, water, and nutrients, they can physically expand their crowns. At the point of crown closure, or soon after, the leaf area index reaches a maximum and the trees totally dominate the area. After crown closure, which is the start of the stem exclusion phase, trees begin to alter their shapes in response to the competitive environment. Foliage in the lower crown dies; as a result branch mortality commences and the growth rate of each tree decreases and the stem shape becomes less tapered. During this period of intense competition between trees (i.e., involving intimate physical crown contact) the stand is in the plastic phase as stem shape changes (**Figure** 7). During this phase the future crown classes of individual trees as dominants, codominants, intermediates, emergents, or suppressed is governed by a complex interaction of factors.

As the stand continues to develop the foliage area of the crowns remains constant but it moves further from the forest floor. At a point where the trees are fully utilizing site resources, or a where there is a constraining factor (e.g., water on a dry site), volume growth will slow dramatically, trees will become unstable due to high height : diameter ratios, height growth will stop, and possibly ‘stagnation’ will result. Stagnated stands contain trees that are very stressed and which therefore can be much more vulnerable to a range of biotic and abiotic damaging agents.

As mentioned above, the time taken for a single species, single cohort stand to stagnate is influenced mainly by stocking. This is illustrated in **Figure** 8a; stand A is initially dense but is cleaned at age x and has a precommercial thinning at age y to ensure that it does not enter the zone of stagnation. Stand B has a much lower density of trees at the end of establishment phase and this means that it will not stagnate in the period when tending operations are being considered. **Figure** 8a is a theoretical consideration and the zone of stagnation is narrow and well defined. However, in reality other factors in addition to stocking determine when, or even if, a stand stagnates; these include the inherent variability of the site, variation in age of regenerated trees, and genetics. This is illustrated in **Figure** 8b where the zone of stagnation is wider and entry into it is later compared with theory. If the stand is also multispecies a further significant factor is added that will delay the onset of stagnation, particularly if the tolerances of shade of the various species are different. In summary, and reality, although theoretically many stands with no intervention will develop towards a stagnant state there are many factors that slow this process.

In multicohort stands there are, by definition, two or more sizes of trees present and at some point in the development of the stand one of the cohorts will be

Figure 7 Dense oak stand (*Quercus robur* and *Q. petraea*) in the plastic phase of growth.

in the phase where tending operations may be required (**Figure 9**). Most growth per tree and usually per hectare occurs in the tallest cohort and manipulation of this will have the most direct effect on yield (*see* **Silviculture**: Unevenaged Silviculture). The taller cohort will also have a high degree of control over site resources: light, water, and nutrients. The lower cohort(s) can therefore reach a stage where a resource limits growth quite quickly. This is illustrated in **Figure** 8c where the zone of stagnation is less well defined and much wider, and trees can enter into it at much younger ages compared with single cohort stands. Hence, a primary concern in the management of multicohort stands is to ensure that younger trees do not lose vigor because of the ability of taller trees to dominate competition for site resources.

One area where understanding of stand development is lacking is in the ability of trees to recover from stagnation caused by periods of competition well beyond the normal intervention cycle (tending or thinning). For example, a common observation is that European ash (*Fraxinus excelsior*) will stagnate relatively quickly and generally does not recover. In contrast, European silver fir (*Abies alba*) takes much longer to stagnate and, after release many years later, can quickly resume a height growth trajectory determined by the site rather than its past competitive position. This is illustrated in **Figure 10**: at age *x* species A responds quickly to release but species B is slower. Later, at age *y*, both species respond to intervention less well although the decline in species B is much more marked than with species A. At present, understanding of these growth patterns is confined to general descriptions at the species level without much knowledge of the mechanisms involved.

Application of Operations to Guide Stand Development

The main guiding principles in the application of tending operations are:

1. To avoid conditions where the stand may stagnate.
2. To steer the stand towards the structure and composition that will achieve management objectives.
3. To achieve cost effectiveness.

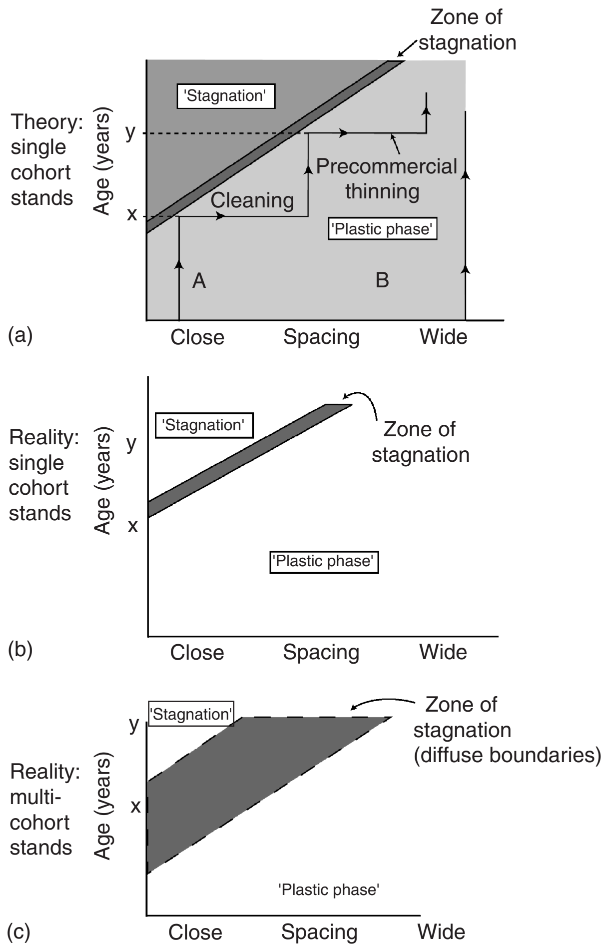

Figure 8 Relationship between tending regimes, stand development, and the zone of stagnation.

Different tending operations can influence stand development to a lesser or greater extent. Brashing and pruning can achieve specific objectives but, as discussed earlier, their influence on stand development is limited. However, cleaning, liberation, and precommercial thinning can have a significant effect on stand development.

The following points should be considered with respect to guiding stand development using tending operations:

1. How did the stand develop into its present condition?
2. What would be an appropriate operation now?
3. How will the stand develop after tending?

How Did the Stand Develop into its Present Condition?

No tending operation should be undertaken without some understanding of how the stand developed into the situation where intervention was required. For example, if drastic early cleaning is required this may reflect ecological conditions suboptimal for the selected trees or some other failure of establishment. In these situations the most important question to answer is: can the situation be remedied at acceptable cost? If not, the forest manager may have to adjust plans to take account of these changed circumstances rather than spending large sums of money fighting the natural processes that are operating on the site.

Specifying an Appropriate Operation

The structure and stage of development of the forest stand generally dictates whether the operation should be a cleaning, liberation, or precommercial thinning. However, the timing of the operation is less clear-cut and often the decision involves consideration of a number of factors such as labor and logistics, in addition to biological criteria. An example where an understanding of stand development is important for deciding the timing of a tending operation is with cleaning, where the species being removed can coppice. If the operation is carried out too early and the coppice is not killed using herbicides, there is a danger that the coppice shoots will grow into the canopy and have deleterious effects on the selected trees. In these situations it is invaluable to have some knowledge concerning the implications of delaying operations, if only to ensure that the products removed from the stand could be marketed in some way to offset the cost of the operations.

Another example of where knowledge of the effects of varying the timing of an operation is important is in cleaning hardwoods out of conifer natural regeneration. An interesting case study of this has been documented on a young stand of longleaf pine (*Pinus palustris*). In the trial the treatments were to remove the hardwoods when the pine was aged 1, 2, 3, 4, or 8 years and a control (untreated); the density of the pine was equalized in all treatments at age 4. By age 30, pine density ranged from 1482 to 1976 ha^{-1} in released plots and there were few differences in terms of diameter, height, and volume due to the different timings of the operation. However, there were significant differences with the untreated plots; competition had reduced the number of pines to 632 ha^{-1}, and the trees were smaller, with 8–10 times less utilizable volume. In conclusion, release was necessary, but delaying it at least for a few years did not diminish long-term volume production.

In most cases where a liberation cutting is required the trees to be cut will have little timber value,

Figure 9 Tending of groups of young trees in multicohort stands can be important if they are very dense.

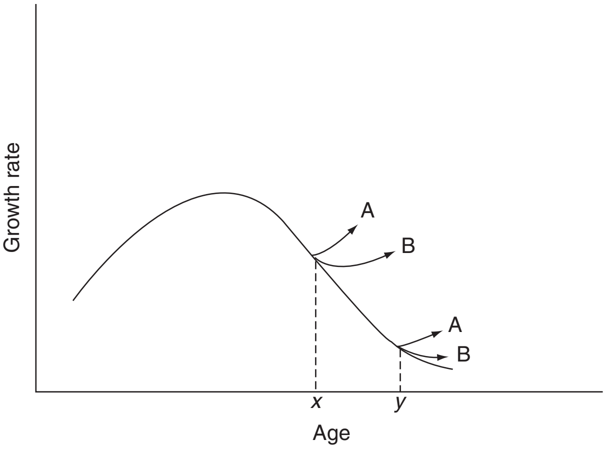

Figure 10 Changes in the responsiveness of two species to tending at different ages.

especially if they have been left with a lot of growing space so that they develop wide, spreading crowns and have all the characteristics of a 'wolf tree'. The main factor influencing when they can be removed is the physical impact of felling and extraction on the younger ones. The effects on the younger trees and the cost of the operation can be minimized by killing the trees with safe and judicious use of herbicides. This can have a positive affect of creating (or increasing) a resource of standing deadwood but this must be balanced against any possible risk to people using the forest, especially if they have been invited or encouraged into the forest for recreation. If the liberation is by cutting this will have most benefit and damage the younger trees least if it is done when the younger trees are small (less than knee high) and when the weather is not cold and frosty, to reduce the possibility of young trees snapping.

The question of how to remove the competitive effect of trees is perhaps more straightforward compared with the timing of the operation. The competitive effects of trees can be removed by cutting or killing using herbicides, or a mixture of both. If trees are to be cut a major consideration is the limitations of the equipment available; this can also influence when the operation is carried out. Herbicides can be used to kill trees by spraying foliage or by applying the herbicide to a cut in the stem. There are many factors to consider with the safe and judicious use of herbicides. A combination of cutting and herbicides can also be used, for example, to prevent coppice regrowth after cleaning.

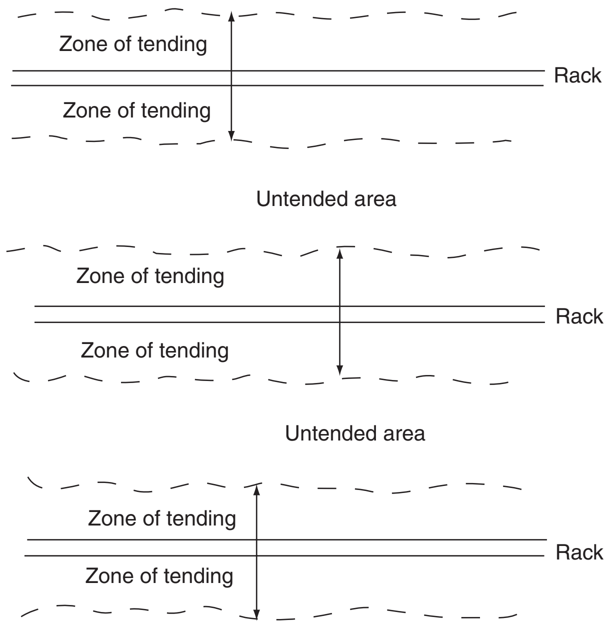

Figure 11 Rack cutting in young naturally regenerated stands to reduce costs.

If a decision has been taken that in order to fulfil management objectives a stand must be cleaned or have a precommercial thinning this will usually apply to the whole stand. However, if as with most tending operations, this is done at a cost to the landowner, treating a proportion of the stand is one way of reducing costs. Two examples of how this can be done are rack cutting and selective release.

Rack cutting This is commonly used in Denmark, France, and Germany. Parallel racks, 1 m wide, are cut every 12–16 m (*n*) through natural regeneration at an early age. Cleaning and respacing is then carried out 3–4 m (1/4*n*) on both sides of the rack, so that roughly only 50% of the crop is treated (**Figures 11** and **12**). The racks improve access and so reduce the cost of respacing, while dividing the stand for management purposes.

Selective release One method of achieving this is the cleaning and releasing of two stems (about 2 m apart), at intervals of approximately 7–8 m through the stand so that they can develop to pole size. Each favored tree is cleared to a distance of 1.2–1.5 m radius and the intervening matrix is untouched.

Prediction of How the Stand will Develop After Tending

The most likely source of information on how any one stand will react to the tending operation is by accumulated experience of treating similar stands on equivalent sites. There are a few models that can be used by the forest manager to help decision making; perhaps the best-known are those for *Pinus radiata* grown as plantations in New Zealand (**Figure 3**).

Figure 12 Cleaning oak (*Quercus robur*) in France showing racks (see also **Figure 11**).

Conclusion

Tending is the application of intermediate treatments after establishment but before the first thinning. The main guiding principles in the application of these operations are: (1) to avoid conditions where the stand may stagnate; (2) to steer the stand towards the structure and composition that will achieve management objectives; and (3) to achieve cost effectiveness. Factors influencing decisions concerning tending in single cohort and multicohort stands are different because in the latter large trees significantly influence the availability of light, water and nutrients to younger trees.

Tending operations can significantly improve stand productivity; but as they are labor intensive they may not always be cost effective and are therefore under pressure in forest management systems.

Thinning

P Savill, University of Oxford, Oxford, UK
J Evans, Imperial College London, Ascot, UK

Introduction

Thinning is an operation that artificially reduces the number of trees growing in a stand with the aim of hastening the development of the remainder. It is normally carried out several times and starts a few years after the canopy closes. The trees removed are usually the same species as the trees favored. In many situations in forestry about 3000 trees ha^{-1} may be planted, or when natural regeneration is relied upon, the number may be 250 000 or more. The mature stand contains no more than 300 trees ha^{-1}, and with some broadleaved species fewer than 100. Thus, a minimum of around 90% of all trees established at the start of a rotation are removed before the end in thinnings.

Competition can be manipulated by foresters either by the spacings used at establishment (in planted forests), or by thinning after the trees have grown for some years, or both. Thinning is carried out for a number of reasons:

1. To reduce stand density and hence to reduce competition, leaving the remaining trees more space for crown and root development. This promotes stem diameter growth and usable sizes are reached more quickly.
2. To remove dead, dying, and diseased trees, or any others that may cause damage to the remaining healthy ones.
3. To remove trees of poor form: crooked, forked, or coarse trees, so that future growth is concentrated only on the best trees.
4. To provide the owner with some revenue though, if this is not possible, as in some early thinnings, in the expectation of greater returns later in the rotation.
5. More occasional reasons include maintaining light beneath the canopy to encourage grass growth for grazing, for providing poles for building, or for amenity, recreational, or ecological reasons.

Responses of Crops to Thinning

Thinning a stand reduces the number of trees competing for light, soil moisture, and nutrients. This has a number of effects on the remaining trees:

1. Natural mortality (or self-thinning) is reduced because the remaining trees have better access to the resources needed for growth.
2. The lower branches of the crowns receive more light, and so remain alive for longer, hence the trees have deeper crowns than in unthinned stands.
3. The increased space round a tree after thinning promotes the growth of shoots, foliage, and roots. The crown expands outwards to occupy the gap left in the canopy where the neighboring tree was felled. The resulting greater photosynthetic area increases growth.
4. Diameter growth increases significantly. Height growth is little affected.
5. Because thinning mainly affects diameter growth, the stems in thinned stands taper more rapidly than in otherwise similar unthinned stands.

6. Provided a reasonably intact canopy is maintained, total cumulative production per unit area does not vary very much within a wide range of thinning treatments. Production is spread over fewer crop trees where thinning is frequent and heavy, meaning that they grow faster than where the same increment per unit area has to be spread over many more trees.
7. The removal of suppressed trees, which may often be on the verge of death, has a negligible effect on volume growth but if a proportion of the most vigorous trees are felled, there is an immediate reduction in growth because the remaining trees are not able to make full use of the resources of the site. However, over a range of treatments, there is no permanent loss of increment. The stand not only recovers its normal level of growth, but also, over time, makes good the production lost when the increment was below normal immediately after thinning. The length of the recovery cycle is proportional to the volume removed in thinning; the heavier the thinning, the longer the period of recovery.
8. If there is a large standing volume of timber and live branches, as in a stand which has not been thinned, it will consume more assimilated carbon for respiration than where lower volumes are maintained through thinning, hence cumulative net production will be reduced in dense stands. The reduction will become more marked as the volume of standing timber increases.
9. There are two ways in which thinning practices can significantly reduce total cumulative production. The first is by consistently removing the most successful trees in the stand, the dominants, which are those most able to respond, and leaving the less efficient, smaller trees to grow. The second occurs if the intensity of thinning is so great that the site is not being efficiently used. There may often be sound economic reasons for carrying out both these practices.
10. Other responses to thinning include delayed natural pruning, since the extra light allows lower branches to survive for longer. The branches grow thicker and, unless pruned, result in larger knots in the wood.

Time of First Thinning

First thinnings should be carried out before live crowns become too small. They should normally occupy 30–40% of the stem height of broadleaved species, and 40–50% for conifers. If thinning is delayed, as is often the case, because it is more profitable to fell larger trees, the future development of a stand can be impaired.

The earliest a stand can be thinned without a loss of potential production varies according to the rate of growth in fully stocked stands. It can be as early as age 12 years for Maritime pine (*Pinus pinaster*) in southwest France, and 15 for Douglas-fir (*Pseudotsuga menziesii*) in the Massif Central. In Britain, it varies between ages 20 to 35 for most conifers, and can be up to 50 years or more in the much harsher climate of Sweden. At this time in most regions the total standing volume per hectare varies between about 70 $m^3 ha^{-1}$ for light-demanding species, such as larch (*Larix*), to about 100 $m^3 ha^{-1}$ for more shade-tolerant ones.

Thinning Intensity and Thinning Cycle

In an analysis of British thinning experiments it has been shown that the proportion of growing stock that can safely be removed annually without decreasing future production is close to 70% of the maximum mean annual increment over what is termed the 'normal thinning period.' This period occurs during the time when current annual increment is at its highest and ends shortly before the age of maximum mean annual increment. Annual thinning yields before and after the normal thinning period are lower. An example for a Norway spruce (*Picea abies*) stand with a maximum mean annual increment of 20 $m^3 ha^{-1} year^{-1}$ is shown in **Figure 1**. Here it is possible to remove 14 $m^3 ha^{-1} year^{-1}$ (i.e., 70% of 20) between the ages of 25 and 55 years without prejudicing future production. If a stand is thinned at this 'marginal intensity,' by the end of the rotation about half the total cumulative production will have been removed in thinnings and the other half remains for the final harvest (**Figure 2**). By contrast, in an unthinned stand of the same species, age, and growth rate, the standing volume will be about 10% less than this cumulative total because competition will have caused some of the trees to die and hence some potentially useful production to be lost, as well as losses through increased respiration. In terms of basal area, 25% or more must be removed per hectare before any substantial increases in diameter will occur to the remaining trees. In practice, there may be good economic or other reasons for thinning more heavily or more lightly than the marginal intensity (**Figure 3**).

Thinning can vary in intensity: it can be light or heavy, or not carried out at all, but commonly, something close to the marginal thinning intensity is adopted in most places. The thinning intensity has three related aspects: (1) the time of first thinning

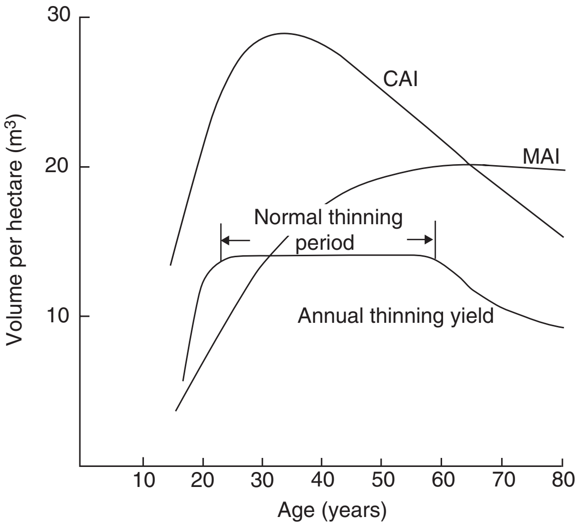

Figure 1 Relationships between age, and mean annual increment (MAI), current annual increment (CAI), and annual thinning yields for yield class 20 $m^3 ha^{-1} year^{-1}$ Norway spruce (*Picea abies*) thinned at the marginal intensity. Figure 2 Cumulative production in thinned and unthinned Norway spruce (*Picea abies*) of yield class 20 $m^3 ha^{-1} year^{-1}$ and planted at 2500 stems ha^{-1}. Reprinted from Savill P, Evans J, Auclair D, and Falck J (1997) *Plantation Silviculture in Europe.* With permission from Oxford University Press.

(see above); (2) the standing volume removed in a single thinning (the thinning weight), and (3) the frequency of thinning (the cycle). The thinning weight and cycle are not independent in relation to intensity. For example, if a regime stipulates that 60 $m^3 ha^{-1}$ (weight) should be thinned every 3 years (cycle), then the average annual rate of removal is

Figure 3 Fourth thinning of Mexican cypress (*Cupressus lusitanica*) in a well-grown plantation in Kenya. © J. Evans, 2004.

20 $m^3 ha^{-1}$. However, this rate of removal (intensity) could also be achieved by felling 100 $m^3 ha^{-1}$ on a longer cycle of 5 years. In each case the thinning intensity is the same.

A stand could be thinned every year but it is normally more profitable to obtain the benefits of scale, by thinning occasionally and heavily rather than frequently and lightly. Cycles are commonly adjusted to remove 40–60 $m^3 ha^{-1}$ in a single operation or between one-fourth and one-third of the trees each time. Long cycles are associated with slow-growing stands and short ones with more productive crops.

Type of Thinning

A certain intensity or weight of thinning can be achieved in many different ways regarding the kinds of trees that are removed. A useful indicator of the size of tree removed, and hence for describing the thinning type, is the ratio of the mean volume of thinnings (v) to the mean volume of the stand before thinning (V). The types of thinnings normally carried out may broadly be classified as follows:

1. Systematic methods

   line and strip thinnings – v/V ratio 1.0

2. Selective methods:

   low thinning – v/V ratio about 0.6

   intermediate thinning – v/V ratio about 0.8

   crown or high thinning – v/V ratio about 1.2

3. Combinations of 1 and 2

   e.g., Queensland selection thinning – v/V ratio variable.

Systematic or Neutral Methods

Systematic thinning entails the removal of trees in a predetermined way, regardless of their individual size or quality. Complete lines of trees are usually removed, though other systematic patterns are possible. Systematic methods are neutral in terms of the size of trees removed. On average they will be the same as the average in the stand as a whole, hence $v/V = 1$.

Systematic methods are now very commonly employed as first thinnings which, because of the small average tree size, usually yield little income. Neither brashing (low pruning) nor selective marking of trees is necessary so costs are low. Also, extraction routes for the first and subsequent thinnings are created.

The disadvantages are that defective trees are not deliberately removed, and the removal of a complete range of tree sizes, including some dominants, results in a small loss of total cumulative production. Even a single-line thinning can lead to the development, through larger branches, of some undesirable reaction wood on the exposed trees along the edges of lines. It may also expose a stand to serious risks of windthrow.

Selective Thinning Methods

Low thinning is a selective thinning that particularly favors the dominants by removing trees progressively from the lower to the upper canopy classes. The first trees to be marked for removal are suppressed trees, then subdominants ($v/V = 0.6$); in heavy, low thinnings some of the dominants may then have to be felled to achieve the desired volume. At the other extreme, crown thinning favors the most promising stems which are usually dominants (**Figure 4**). Most commonly, poorer quality dominants and codominants are removed and these have higher average volumes than in other types of thinning ($v/V =$ about 1.2).

Figure 4 Early thinning of ash (*Fraxinus excelsior*) and sycamore (*Acer pseudoplatanus*) to secure high-quality broadleaved woodland. © J. Evans, 2004.

The commonest type of selective thinning is intermediate between low and crown thinning ($v/V = 0.8$), but in all selective thinnings defective trees, especially defective dominants, are also removed.

Included among numerous variations to these methods is the early selection of final crop trees in broadleaved stands. The best trees are marked when they are young and favored in subsequent thinnings. Because some inevitably become damaged or do not grow as well as expected, it is necessary to mark, at the outset, two or three times the number that will actually form the final crop.

The effects of some of the various types and intensities of thinning on productivity have been illustrated in the context of a classic British trial, the Bowmont Thinning Experiment of *Picea abies* in Scotland. In it, four thinning intensities were applied, described as:

- B grade: mainly dead and dying trees were removed, an extreme form of low thinning.
- C grade: a moderate low thinning, intermediate between B and D.
- D grade: a heavy low thinning in which only the best trees, mainly dominants, were left and given space for full crown development. It was somewhat heavier than the marginal thinning intensity.
- LC grade: a moderate crown thinning, resembling D except that suppressed and subdominant trees were left to fill spaces between the best dominants. Defective dominants were removed.

The results (**Table 1**), 64 years after planting, confirm the expected trends of larger individual trees being found in the heavier thinning treatments, but with little overall difference in total production except in the largely unthinned treatment B.

Combinations of Systematic and Selective Thinning Methods

Where circumstances permit, there are attractions in combining some of the cost savings of purely systematic thinning with the ability to select for vigor and good growth form. The Queensland selection method is a combined method and was developed for treating hoop pine (*Araucaria cunninghamii*) plantations in Queensland and has a wider potential for use in tropical and temperate forests.

Table 2 An example of the selection of trees in Queensland high pruning

Selected	S				S	S	S				S	
Tree number	1	2	3	4	5	6	7	8	9	10	11	12

It involves selecting dominant trees along rows for retention and marking them in an obvious way, in Queensland by high pruning. The trees are selected by considering running groups of four trees (counting blanks as trees) on a row-by-row basis as, for example, in **Table 2**. Thus, the first group comprises tree numbers 1, 2, 3, and 4. Of these, 1 is the best stem and is selected (S) and pruned. The next group is tree numbers 2, 3, 4, and 5, and of these 5 is selected. In the next group, 3, 4, 5, and 6, tree 6 is better than 5 and therefore the best in the group and is selected. In the next group, 4, 5, 6, and 7, tree 6 remains the best of this new group, so no additional tree is selected, and so on.

Selection can be done quickly by unskilled workers and results in about 40% of the stems originally planted being selected, though the percentage can be varied by altering the size of the group. Thinning rules can be applied equally simply in relation to the selected trees. For example, all trees which are equal in height to or taller than the selected trees and adjacent to them may be removed in the first thinning.

Thinning and Wood Quality

The faster diameter growth in thinned stands can cause an increase in the size of the core of juvenile wood which is undesirable for many end uses. This is particularly so if the thinning is done early, before the lower branches have died naturally. In thinned stands, branches and hence knots are bigger and may be associated with more reaction wood. Among many conifers, a high wood density is desirable if strength is required. The faster growth following heavy thinnings results in lower density because the wide annual growth rings contain relatively wide bands of low-density earlywood. These alternate with narrow bands of higher-density latewood. The resulting uneven texture is also undesirable. Ideally timber should have as consistent a texture as possible, and this is produced by regular, moderate thinnings. Infrequent, very heavy thinnings lead to much more varied wood properties. Thinning also increases taper, and slightly reduces the amount of the log that can be used.

On the positive side, the removal of leaning and misshapen trees, and ones with crooked stems and basal sweep, reduces the amount of reaction wood and spiral grain remaining in the stand, and the trees left to grow on will have a higher percentage utilization. Also, because the remaining trees are encouraged to grow large, their sawlog and veneering potential is improved since more of the log is used.

Thinning Policy

The purpose of most commercial forestry has been described as ‘the production of neither the greatest volume, nor the largest sizes in a given time, but the production of material which will most suitably fit the demands of the market, yielding, at the same time, the greatest revenue.’

Unfortunately, this is much more easily said than done. Many forest owners have a general idea of what they are trying to achieve but no one can know precisely what market demands will be decades ahead.

The regimes that achieve the best results consequently differ widely, according to the economic and other conditions in a country and region, and often according to the particular circumstances of individual owners.

High Pruning

R James, Australian National University, Canberra, Australia

Introduction

Pruning is a technique usually employed with the aim of enhancing the quality of solidwood products derived from the butt log of trees in forest plantations. The aim of the technique is to remove knots from the outer wood of such logs but it may also result in loss of growth when living foliage is removed or may introduce rot into the wood, especially in hardwood species. While pruning has been known for many years it is not commonly applied except where trees grow fast enough to provide returns that satisfy economic criteria. It is most common in New Zealand where most stands of radiata pine (*Pinus radiata*) are pruned and where a price premium for pruned logs has been established.

Pruning Defined

Pruning can be defined in straightforward terms as the removal, close to the stem, of living or dead branches from standing trees. The process of pruning is closely allied to that of 'brashing' which refers to the removal, by beating, of branches on a tree stem from ground level to a height of about 2 m. In some countries (e.g., the UK) the term 'high pruning' may be used to refer to pruning above the height where branches have been removed by brashing.

The definition clearly refers to the deliberate action of removing branches using tools designed for the purpose. Sometimes this is called 'artificial pruning' to distinguish it from the practice of natural branch shed which occurs in many species, particularly within natural stands over an extended period of time. Pruning has been known to and used by foresters for some time. It was mentioned by John Evelyn in 1664, in his book *Sylva*, in which he referred to pruning as having been practiced by the 'ancients.' It has been applied as a scientifically based technique for many decades and examples appear in modern literature from at least 1935. Despite its history, pruning is not a general practice in all parts of the world and although statistics are poorly recorded it seems to be mainly carried out in plantations of countries in the southern hemisphere such as Argentina, Australia, Chile, the Republic of South Africa, New Zealand, and Uruguay. These countries can obtain the fast individual tree growth necessary to provide a yield of improved timber within an economic time frame. In New Zealand, where pruning has been a prominent feature of plantation silviculture since the 1970s, over 1 million ha or two-thirds of the area of radiata pine plantation forest has received pruning treatment. As a consequence, the technology associated with pruning pine has been well developed in that country and much of the information presented here has come from New Zealand sources, including recent research papers.

Rationale for Pruning

Doubts about the economics of pruning usually preclude its use in natural forests although it is a frequent practice in urban forests where the main objective is improved access, increased visibility, and enhanced appearance. In plantations, branches are usually removed to a height of about 6 m and pruning may be carried out in a number of stages or 'lifts' to a specified height or diameter up the stem. Except for brashing where a club may be used, branches are usually severed by shears or saws. Even in plantations pruning may not be regarded as an essential operation. Where it is applied as part of stand silviculture it may be carried out for a number of objectives such as: a precaution against the spread of fire into the upper crown, to provide stand access, to reduce timber degrade, and finally as a planned series of operations aimed at eliminating or reducing the effect of knots as a source of degrade in sawn and sliced or peeled wood. (Additional, minor, but locally important objectives may include the use of the branches themselves as stock food, fuelwood or to obtain essential oils. Other special products can include cricket bats made from pruned willow and matchsticks from veneer peeled from pruned poplar.) Eliminating degrade and provision of high-quality wood are similar but the impetus to carry out pruning to reduce degrade implies that some features of the stand or its silviculture will cause the wood to be degraded by exceptionally large knots should pruning not be applied. An example is the pruning of 'stand edge' trees in South Australian plantations of radiata pine where the extra growing space resulting from roads, fire-breaks or other clear space adjacent to the stand may result in branch sizes much larger than those within the stand which are controlled by normal silviculture.

Application of Pruning Techniques

Pruning as a method of preventing the spread of fires, to provide access within the stand or obtain fodder or fuel does not require strict timing. However when the provision of clear, knot-free timber is the aim, then the pruning should be carefully programmed and carried out at times in the life of the stand which will result in the maximum size of a clearwood zone outside the 'defect core' of knotty wood.

The process by which clear, knot-free timber is produced by pruning is illustrated in **Figure 1**. When trees are young and stem diameter is small, branches are removed and, after a process of occlusion (or covering of the branch stub by continuing growth), normal stem growth continues with the new wood being free of knot defect. Since trees taper, pruning is usually carried out in lifts (generally two to four) to avoid enlarged cores at the base of the tree. Pruning should be scheduled to minimize the size of the defect core within the pruned zone yet retain sufficient foliage to permit the tree to continue with adequate growth. Sawn timber or veneer recovery will also be enhanced if the maximum diameter of the defect core is the same for each lift. Since sawing and peeling are carried out effectively in straight lines, boards cut from the outside of the log will be knot-free until the saw encounters the limits of the defect core. Because sawn pieces are usually graded on the basis of the worst defect, the value of some boards would be reduced if they contained isolated defects caused by a diameter over pruned stubs which was larger than the others in the same pruning series. Thus an important component of efficient pruning technique is to time operations so that the maximum DOS is the same for all lifts. Models to predict maximum DOS have been developed and these are used for scheduling operations in plantations of radiata pine in New Zealand and Australia. These models are driven by the expected diameter of the tree at the base of each pruning lift or stage. This can be related to the tree or stand mean diameter at breast height, a parameter which is commonly measured or predicted during the course of forest management.

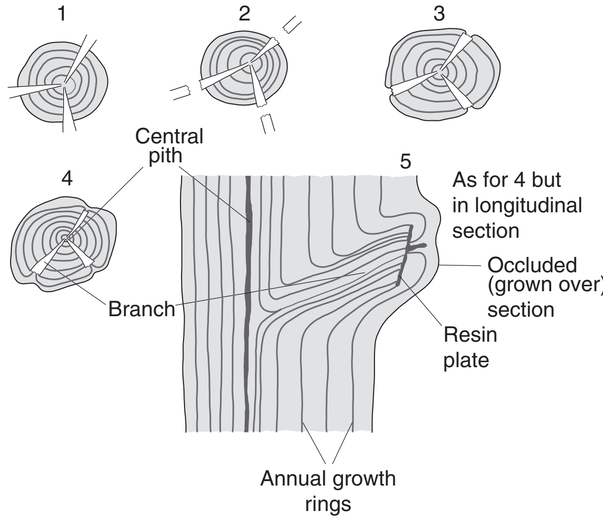

Figure 1 Production of knot-free 'clearwood' using pruning.

A pruning schedule which could be used for stands of radiata pine grown in eastern Australia is given in **Table 1**. The schedule is designed to result in a maximum diameter over pruned stubs of 18 cm for all three lifts. The stand is assumed to have been planted at 1000 stems ha^{-1} for a final crop of 200 stems ha^{-1}. Three thinnings are scheduled, two without yield and one, to 200 stems ha^{-1}, with yield in year 20.

The efficient production of knot-free wood can be achieved only if pruning is accompanied by rapid individual tree growth. This is achieved by thinning (or removing) all unpruned stems. As pruning is usually carried out when the trees are young and

Table 1 Schedule of silvicultural operations for radiata pine (*Pinus radiata*) in eastern Australia, featuring pruning to improve wood quality in the butt log

Age (years)	*Silvicultural operation*
0	Plant 1000 stems ha^{-1}
5.8	Prune 350 stems ha^{-1} to 2.2 m
5.8	Thin to 500 stems ha^{-1} residual stocking, without yield
6.7	Prune 275 stems ha^{-1} to 4.0 m
7.6	Prune 200 stems ha^{-1} to 5.8 m
7.6	Thin to 350 stems ha^{-1} residual stocking, without yield
20	Thin to 200 stems ha^{-1} residual stocking, with yield
30–35	Clearfell

DOS is small, the thinned trees may also be too small in diameter to provide a useful product and the thinning will be without yield (or 'to waste'). The example of a pruning regime given in **Table 1** has two such thinnings scheduled to occur at the same time as the first and third pruning lifts with the objective of reallocating stand growth to the pruned crop trees.

The total diameter of the defect core is however larger than just the DOS. It will be enlarged by any inclusion of resin or bark which is incorporated at time of occlusion and any exaggeration from stem crookedness. In the case of peeled veneer logs the defect core will also be exaggerated by noncentral pith. In conifers the presence of resin pockets within the clearwood zone may eliminate any improvement arising from pruning. Resin pockets (or streaks) are often typical of a particular location and may occur locally in excess; an effect seen in plantations of radiata pine and slash pine (*P. elliotii*). Pruning should not be applied on such sites.

The correct selection of crop trees, particularly of the straightness and most vigorous, and the combination of pruning with other silvicultural operations such as thinning so that growth is enhanced, is necessary to ensure that the benefits of pruning are maximized. When pruning is applied to improve wood quality, it should be applied over a complete commercial log length (with appropriate allowance for stump height and any applicable cutting allowance) to obtain full financial benefit. Pruning above the first or butt log is rare but has been carried out in countries where labor costs are low.

Effect of Pruning on Tree Health

In conifers the severed stub usually becomes coated with a layer of exuded resin which is generally sufficient to prevent fungal infection. This protective mechanism is not present in hardwoods and for some (e.g., the eucalypts, *Eucalyptus* spp.) the chance of rot occurring as a result of the pruning operation is quite high.

To avoid the formation of internal rot, it is necessary to adopt a quite different method of scheduling pruning of eucalypts. Eucalypts shed their branches under natural conditions and during the long rotations applied in extensively managed natural forests this is sufficient to provide defect-free timber. The process of natural branch shedding is well known. The branch dies and an abscission zone develops close to the trunk in which the xylem of the branch becomes blocked and subsequently brittle. With the growth of the stem, the branch becomes more horizontal in orientation and pressure from the continued growth of the trunk together with the weight of the dead branch eventually results in its ejection from the growing stem with a part of the branch occlusion zone remaining within the trunk. When pruning removes a dead branch there is no residual weight to ensure ejection and the short stub remaining outside the abscission point may be 'caught' by the enlarging stem wood and dragged outwards with continuing growth, leaving a kino-filled trace behind. This effect has been observed in both *Eucalyptus nitens*, a temperate eucalypt, and the tropical eucalypt *E. grandis*, although the rate of occurrence has not been established. While this effect negates the objective of pruning it can be counteracted by pruning only green (living) branches. When this is done the occlusion process is similar to that of conifers (**Figure 2**). The scheduling of pruning in eucalypts therefore involves 'chasing the green crown' or pruning before the natural death of branches occurs in the lower crown. Models of the change in height of the base of the green crown can be used to schedule pruning so that branches are pruned while they are alive.

However green pruning disrupts the natural protection from rot formation which, is afforded by the abscission zone in the natural branch shedding process. Research in both New Zealand and Australia has found decay associated with pruning especially the pruning of large (>2 cm) branches; although rot is mainly restricted to the defect core. Results from one study (in *E. nitens*) found that about half of the pruned trees will contain stem rot associated with at least one pruned branch. For some species pruning in the correct season may confer some protection from infection, e.g., *Prunus avium* is reported to suffer bacterial canker when pruned in winter or spring and should be pruned at other times. However results from surveys of eucalypts are conflicting on this aspect and a seasonal effect is yet to be established.

The effect of pruning on stability during windstorms is not clear. If there is an effect, it is probably

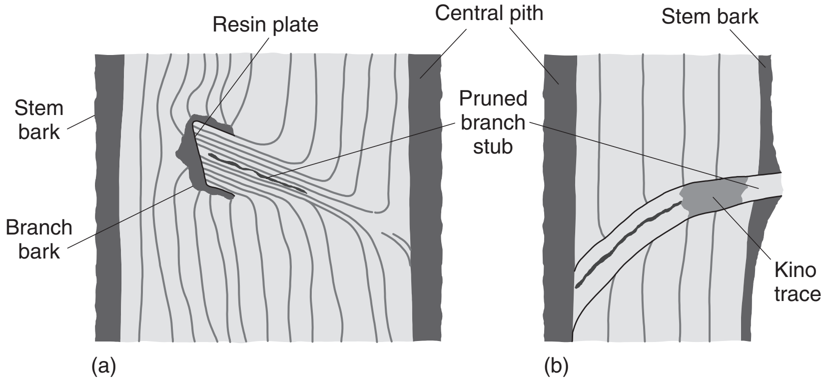

Figure 2 Detail of occlusion over pruned branch stubs in (a) *Pinus radiata*, (b) *Eucalyptus nitens*. (a) Shows normal conifer occlusion over a dead branch, (b) illustrates a frequent result when dead branches of a eucalypt are pruned. Redrawn with permission from Gerrand AW, Neilsen WA, and Medhurst JL (1997) Thinning and pruning eucalypt plantations for sawlog production in Tasmania. *Tasforests* 9: 15–34.

only found in young stands where the length of pruned stems represents at least one-quarter of total tree height. For older trees, especially where the lower branches of unpruned trees would be dead and leafless, there is probably no difference in susceptibility to storm damage between pruned and unpruned trees. In young trees pruning could:

- reduce the crown surface area and hence the area on which the wind could exert pressure
- allow greater air movement through the lower stand in the pruned zone
- lessen the energy-absorbing effect of tree to tree canopy contact
- elevate the center of gravity and center of bending moment and thus alter the natural sway of the tree.

The net effect of these theoretical possibilities is unclear as observers have found both greater and lesser damage amongst pruned trees within stands that have suffered damage from windstorms.

Pruning Tools and Methods

The tools used for pruning are mostly simple hand-operated tools such as shears or saws. The shears may be of the double-fulcrum type and either one or two cutting blades may be used. If saws are used they may be self-supporting blades with a short or long handle and commonly with back-raked teeth (which cut on the pull stroke). Alternatively they may be of the frame and tensioned blade type. Ladders are used to support the operator when branches are pruned above 2 m. This is more efficient than using saws mounted on poles (*see* **Operations**: Ergonomics). In the past a number of striking tools such as axes or modified slashers have been used. The use of these has largely been discontinued because of the damage caused to the stem, the irregular surface of the cut branch, and the danger to the operator.

There have been a number of attempts to mechanize the operation of pruning, but with little success. The necessity for repeat visits to carry out each lift, lack of easy access to trees under forest conditions, and the difficulty of building a power unit without the disadvantages of weight, noise, vibration, air pollution, and the danger inherent in motorized cutting tools have precluded mechanization on an operational scale. Although lightweight chainsaws are sometimes used for the first, ground-based, lift, especially where branches are large, the inherent danger of this operation and the restrictions imposed by safety regulations mean that it is not a widely applied method. Recent developments in electronics have led to one method of power-assisted pruning that is currently used in Argentina and Chile. Power is supplied by a set of lightweight (about 3 kg) rechargeable batteries which is carried on a waist-band and shoulder harness and which powers shears similar to those used by some types of hand shear. Studies carried out in Argentina have shown that while productivity increases are marginal, the workers are less fatigued and achieve target rates more easily, and the workforce need not be restricted to the 'fit young male' category. The forestry version of this tool is a modification of equipment developed in France for vineyard pruning and used for that purpose in many other countries.

Effect of Pruning on Tree Growth

When living branches are severed in pruning there will inevitably be a reduction in tree foliage. Although this lower foliage may be less photosynthetically active than that of the upper crown, there may be some loss of increment as a result. This effect has been well established for many species (both hardwoods and softwoods) throughout the world. Some experimental results suggest that almost any level of foliage removal will result in at least some reduction in tree growth. However other results suggest that removal of inefficient lower foliage may result in some increase in tree growth. The necessity of obtaining a small defect core will usually require that some of the 'green crown' (or living foliage) be removed even if this results in some growth loss. For pines, regimes are often designed to ensure that a 4-m length of green crown is left after pruning. For eucalypts, where the mechanism for scheduling is focused more on the height of the base of the living crown than diameter over pruned stubs, removal of 40–50% of the length of the green crown has been identified as an acceptable compromise. Physiological changes within the remaining foliage have been noted probably leading to increased photosynthetic efficiency in the residual crown. In any case, where reduction of growth has been observed, the effect has been temporary. Of more concern than this temporary reduction in growth is the permanent loss of tree stem dominance status. That is, when trees that were selected for pruning because of their dominance are left to compete with unpruned trees, they are liable to lose dominance because the loss of foliage has slowed their growth and reduced their ability to compete with the unpruned stand component.

Removal of living foliage may stimulate the growth of epicormic branches within the pruned zone. In pines these arise from stem-borne needle fascicles and in hardwoods from dormant buds beneath the bark. It is common practice to use a knife to remove needle fascicles from pine stems when pruning branches and for both pines and hardwoods to remove epicormic branches that have formed since the last pruning lift.

Growth is derived from the foliage of the crown, and crown length per hectare has been found to be correlated, on a stand basis, with growth for young stands of New Zealand grown radiata pine. Although the relationship is not a simple one it has been used as the basis for models which can be used to predict the early growth of stands and particularly the effect of early pruning and thinning on subsequent growth.

The Economics of Pruning

The decision whether or not to incorporate pruning into a silvicultural regime will depend on an assessment of the financial benefits, including the improvement in returns from pruned compared to unpruned logs. A study which investigated the effects of various parameters on estimates of pruning profitability (plantation grown radiata pine in New Zealand) using a silvicultural modeling system found that profitability was not particularly sensitive to total pruned height or diameter over pruned stubs but in both cases the volume yield of clear grades was sensitive to these effects. The lesser effect on financial estimates was probably a result of trade-offs between costs and production effects. Price assumptions and interest rate markedly affected estimated profitability.

As there are few firmly established premiums for pruned logs estimates of future prices are usually regarded as a matter of informed conjecture. Since pruning involves considerable investment and results will not be obtained for some years, the decision to prune involves some risk. One source of price information is the New Zealand Ministry of Agriculture and Forestry which publishes averaged prices received for New Zealand grown radiata pine, on a quarterly basis. Based on data as at June 2002, there was a premium of about \$US50 m^{-3} (Japanese Agricultural Scale, free on board) for pruned export logs and \$US36 $tonne^{-1}$ (mill door) for pruned domestic logs.

While premiums have been established for some markets, it is a matter of judgment whether they will be available more generally or whether they will be sufficient to compensate for the cost of the investment in pruning. Some utilization companies are using technology instead of pruning to improve the appearance of sawn wood. This can include cutting out knots and finger-jointing the shortened lengths into boards, covering boards with a plastic sheet on which has been printed a photographic image of knot-free wood and extruding defect-free components from wood pulp. Some would regard such solutions as less aesthetically pleasing than wood from pruned trees.

Even when margins for pruned logs have been established, pruned log quality must be determined before the margin is realized. This may be achieved from presentation of silvicultural records. The Pruned Log Certification Scheme which has been established in New Zealand is a record system that allows evaluation at time of sale. For the certification scheme, parameters that would indicate the quality of pruning (such as the average diameter over pruned branch stubs) are assessed immediately after pruning has taken place and records are held by authorities independent from the forest owner. Prospective purchasers can use these records and the size of the trees at time of felling to estimate the yields of high-quality timber. Assessment at time of sale varies from simple pragmatic rules-of-thumb, to sawing of samples, to detailed measurement of the internal and external properties of sample logs. An example of pragmatic assessment is the acceptance of pruned logs where growth since pruning has eliminated all appearance of nodal swelling, such logs being regarded as having increased their diameter sufficiently for knot-free timber to be recoverable. An example of detailed assessment is the Pruned Log Index used in New Zealand. This is derived from measurements of log size, log shape, and defect core size and relates directly to, but remains independent of, grade and value recovery by any sawmill. Application of this measure of pruned log quality resulted in mill door prices for pruned logs which ranged from \$NZ140–215 m^{-3} (approx. \$US75–115) during 2002.

Rotations

P Maclaren, Piers Maclaren & Associates, Rangiora, New Zealand

Introduction

When should a tree be harvested? At 'maturity'? Unlike animals, trees do not reach a maximum size and then stop growing, so the definition of 'maturity' is not clear. A tree can be harvested at any age that the owners consider desirable. The question of rotation age (also called rotation length) is very relevant for foresters and indeed has long been one of the main decisions that foresters are trained to make.

Because forests usually contain a mixture of species and age classes, they are more complicated than stands which can consist of even-aged trees growing from bare ground – like a crop of wheat. Starting with the simplest situation, a planted or naturally regenerated tree in an even-aged stand, there are several phases in the growth cycle.

Stages of Tree Growth

The first phase is site capture. Of the thousands, or tens of thousands, of seedlings per hectare, few trees can survive the initial years. The tree uses energy to put down roots, build up a green crown, and outcompete weeds. Access to water and nutrients is vital, but light is often not so limiting. Wood production is not of major survival benefit, and in any case the plant does not yet have the resources to generate high amounts of photosynthate. The tree expands until it encounters the influence of neighboring trees, at which point the rate of growth slows, for both the roots and crown. Weeds become suppressed and cease to be a major problem.

In phase 2, the tree can progress in only two ways: by competing with, and taking over the space of the neighbors, or by extending upwards. The tree's survival is guaranteed only if it can maintain access to light, water, nutrients, carbon dioxide, and space. For most species, light becomes critical, because a well-lit tree can acquire the energy to obtain the other resources. On the other hand, overtopping by neighbors will suppress and kill a tree. That is the main reason trees produce wood – survival advantage is ensured by gaining height and securing the light.

As the tree's height increases, the lower branches become shaded and die. A steady state is reached where growth at the top of the tree is matched by death at the bottom of the green crown. Nutrients are translocated upwards from branches as they become moribund. The important point for foresters is that trees in phase 2 require low inputs of minerals – most nutrients are used in the formation of the green crown, and little extra is required for either the maintenance of the crown, or for the production of wood. Wood is a carbohydrate, comprising overwhelmingly carbon, hydrogen, and oxygen and little else. Once the 'factory' has been constructed, good growth can be expected wherever there is adequate temperature, water, and sunlight.

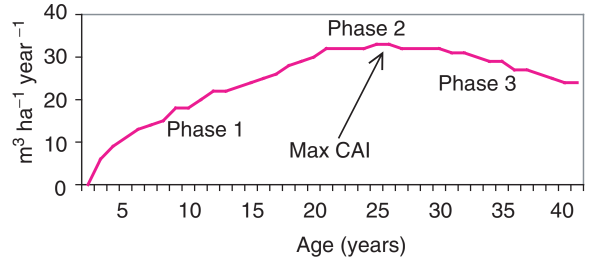

Figure 1 Annual stemwood growth (net current annual increment (CAI) and volume). Adapted from the New Zealand National Exotic Forest Description 1995. Although indicative of the weighted-average growth for radiata pine in New Zealand, the line has been smoothed for the sake of clarity.

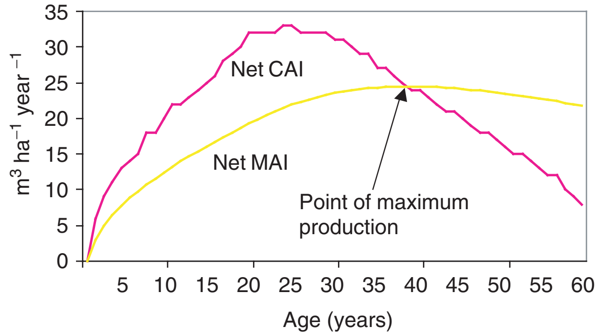

Figure 2 Rotation age to maximize production. CAI, current annual increment; MAI, mean annual increment. Adapted from New Zealand National Exotic Forest Description (1995). For the sake of clarity, the data have been smoothed and extrapolated past age 40.

But eventually the tree's increasing size and age come at an energy cost: water must be pumped from the root tips to the topmost foliage, and starch must be translocated the same distance in reverse. The tree's size makes it vulnerable to the effects of wind, and the wounds it has developed over its long life make it susceptible to attack by insects and disease. Its productivity drops off and it becomes senescent (phase 3). Thus there is a point in the life of an individual tree or stand where it is the most productive at growing stemwood (**Figure 1**).

Gross and Net Increment

The volume increment of the stand is measured per unit area (i.e., per hectare or per acre). Gross increment is the wood produced each year, and net increment is the same, less the quantity lost through death and decay. While individual trees may still be actively growing, other trees are dying, and the forester must consider the stand as a whole. The current annual increment (CAI) is the wood produced in the most recent year. The mean annual increment (MAI) at a given age is the CAI averaged up to that age. It is usually expressed in net terms, but can include the wood harvested from extraction thinnings. Such thinnings are a way of using, and preventing, loss from natural mortality.

Rotation Age for Maximum Volume

As the stand progresses from phase 1 to phase 2, and more resources are channeled into wood production, the CAI increases. As long as this is greater than the MAI, the MAI will continue to improve. At the point where the CAI has declined to equal the MAI, the MAI will have attained its maximum level (**Figure 2**). The point of maximum MAI is of great significance to foresters, because if all stands were harvested at this age then the forest would be producing the maximum sustainable volume.

For hundreds of years the main job of foresters in both Europe and China was to 'conserve the maturity' of the forest resource – to prevent trees being felled before they had reached their maximum potential. It is always tempting to overcut, i.e., cut more wood than the allowable volume that has been calculated by estimating the yield of a theoretical forest where the stands were harvested at their maximum MAI.

A healthy mixed-aged forest can sustain a certain level of production indefinitely, but assume that a greedy government or population cuts more wood than this figure. What effect does this have? The average harvest age is reduced, the productivity of the forest is diminished, and it will require greater and greater numbers of younger and younger trees to meet the same demand. If overcutting is allowed to continue, eventually trees only a few years old will be harvested. These will not provide nearly the same quality or quantity of wood as the original 'mature' forest.

At the other end of the spectrum, an overmature forest is also not productive. This means that it contains a high proportion of trees that are senescent or at risk from storm or insect damage. Overcutting this forest will, if done carefully, restore the forest's vigor, by returning the average rotation age to its peak value of MAI.

In practice it is difficult to calculate the age and amount of maximum MAI for any tree species. A huge database is needed, as growth rates vary with species, soils, climate, management regime, and genotype. Some of these are constantly changing. It is also difficult to quantify mortality. Some death and decay are inevitable, as a result of trees becoming more crowded. Trees naturally thin themselves out as they take up more space, and this can be predicted with a reasonable degree of accuracy. Such tree loss is called attritional mortality. Tree death also commonly occurs from storm events, from fire, drought, frost, and epidemics of disease and pests. If large numbers of trees die, this is called catastrophic mortality. The distinction between the two types is vague, and in any case the two types influence each other. The significance of the latter is that it is inherently unpredictable and cannot easily be built into models.

Even if the forester overcomes these difficulties, the job is not complete. It is not sufficient to determine the rotation age that will provide the greatest quantity of wood from a given area of forest in perpetuity. Wood quality must also be considered. Revenue at harvest is a combination of both quantity and quality.

Rotation Age for Maximum Harvest Revenue

Generally speaking, the older the tree, the better the quality of wood, unless the tree has started decaying. Wood density is an important attribute, being a determinant of strength, stiffness, and hardness. It increases with tree age: the outer growth rings are denser than the inner rings. The proportion of heartwood also increases with tree age. Heartwood is noteworthy because it imparts durability and color, depending on species. Heartwood can be yellow, brown, black, red, or combinations of these. This contrasts with sapwood, which is generally a bland white and is nondurable. In addition to these well-known qualities, a number of other characteristics, such as moisture content, spiral grain, and distortion in processing, become less problematic with maturity. Most importantly, the lower branches of very old trees die and fall off, with subsequent wood being knot-free (‘clearwood’).

Wood is sold in distinct grades, with log specifications that relate to straightness, number of growth rings, heartwood content, branch presence and size, and small-end diameter, among other considerations. Often there are substantial price differences between successive log grades, which may correspond to different end-uses. The stumpage revenue at clear-felling therefore does not increase smoothly with age: it may remain fairly flat over several years and then rise sharply when a critical threshold of wood quality is attained.

Near the time of harvest, the value and value increment of a stand need not be predicted from generalized silvicultural models – it can be obtained more directly from inventory models. Individual trees often display features that are inherently unpredictable, so generalized models have limited utility. For example, a tree may have a predictable height and diameter at breast height, with an excellent butt-log up to a certain height, but upper logs are downgraded by lack of straightness, woodpecker holes, or other stem damage. Average branch size may be predictable, but individual large branches or forking (possibly induced by a storm event affecting most trees in the stand at a certain height) are not so amenable to mathematical modeling. Good inventory models will optimize the value of individual trees when cut into logs. Although these models may amalgamate data to describe the whole stand, they will simulate future growth without losing the detail obtained from an inventory of individual, idiosyncratic trees.

The output of intensive measurement and modeling for mature stands is an accurate assessment of standing value, currently and for a decade into the future. While the volumes by log grade are predictable by this process, any projection of prices is fraught with difficulty. One can use current prices, or prices averaged over the last (say) 12 quarters, or prices obtained from a trendline, or prices estimated from anticipated market conditions.

Rotation Age for Maximum Profitability

An astute forester will take all these things into consideration when determining rotation age, but the task is still not complete. The combination of quantity and quality of wood provides the revenue at harvest for a range of ages, but it is necessary also to consider cost, risk, and the time interval between costs and returns.

Maintaining a forest is not usually free of costs. Imagine a forest where stands are harvested at 60 years of age. The forester calculates that the revenue will improve if stands are harvested at age 80. But to do this each stand has to undergo 20 years of extra fire protection, land taxes, and supervision. The investment carries an extra 20 years of risk: the older stands could be susceptible to disease or storm damage. Most critically of all, the revenue will need to be deferred for 20 years, and time is money. This difficult concept needs some explanation.

Faced with an offer of $1000 today or a promise of $1000 in 1 year’s time, most people would take the former. The money can be used right now for paying off debt, for investing in another project, or obtaining interest via somebody else’s investment. In the jargon, people have a time preference for early returns. A rational time preference can be calculated by examining the compound interest on alternative investments. This is called the cost of capital. In addition to the cost of capital, risk is sometimes included in the figure. For example, the $1000 today is certain, whereas the $1000 next year is only a promise. For all these reasons, future returns are heavily discounted, and the greater the investment interval, the higher the discount factor. It is important to understand that this is the major reason why rotation lengths in commercial forests are less than the point where revenue is maximized. The optimum rotation age financially is less than the optimum rotation age physically.

The Opportunity Cost of Capital

To illustrate this concept, let's consider the financial growth of a tree crop grown as an even-aged stand. As the crop grows, it becomes more valuable. The return on capital is the current value increment of the crop divided by its standing value. The current value increment increases, but eventually cannot keep pace with the gain in value of the stand. The ratio of increment to standing value increases to a maximum and then declines. The possibility of selling the asset and investing the money elsewhere becomes ever more tempting. This occurs well before the stand has reached its maximum MAI for value or even for volume. The complaint is often heard that a stand is being felled 'just when it is starting to show substantial annual gains in value,' and long before it has achieved its maximum average volume production. True, but is it gaining in value relative to the considerable – and increasing – value of the asset?

To reinforce this point, let's consider two mixed-age forests of the same species and growth potential. Forest A is grown on a rotation of 80 years, whereas forest B has a 40-year rotation. They are both managed sustainably, with a constant proportion harvested and replanted every year. Forest A has a greater proportion of older trees and has a standing value twice as high as forest B.

An accountant standing at the gates of the forests observes that daily inputs (i.e., costs) to each forest are the same, but the daily outputs are substantially different. The older forest is producing more wood every day, because the rotation age is closer to the peak of MAI.

Simple accounting would suggest that forest A is more profitable (revenue minus costs), but this is not necessarily the case. More capital is tied up in forest A. If this forest were liquidated (i.e., cut down and sold) it would sell at twice the price of forest B. It would be possible to use the money to buy two forests exactly like forest B. Thus it is not only important to maximize the output of the forest relative to daily costs, it is also important to minimize the capital tied up in the forest. The easiest way to do this is by maintaining a relatively low rotation age.

Foresters who calculate the internal rate of return (IRR) for a crop of trees at every rotation age often experience a sense of shock: the maximum IRR is found at very young ages – far lower than conventional wisdom would suggest. Rapid turnover of capital is of crucial importance in any calculation involving IRR: it is important to keep costs down, to delay costs, and to obtain revenue at the earliest opportunity.

An alternative approach is to use net present value (NPV), where the discount rate is specified. Discount rates used in forestry are commonly 6%, but can be 10% or more. The discount rate represents the real (i.e., inflation-adjusted) rate of return that foresters expect to get from alternative investments, plus a factor for risk. Rates of this magnitude may be reasonable for short-term investments, but the awesome exponential power of compound interest over the time spans implicated in forestry suggest that such rates are unreasonable for forestry and unsustainable for the general global economy. Be that as it may, the effect of using high discount rates is exactly the same as that of using IRR. It emphasizes the value of money upfront, and downplays the benefits of distant rewards.

Because many foresters throughout the world have used IRR or NPV at a high discount rate to determine their regimes, trees harvested from plantation forests are usually very young. This means they have a small diameter and are inferior for either structural or appearance uses. They are inferior in terms of strength, stiffness, and hardness because of their low wood density, among other characteristics. They are inferior for appearance purposes because they contain very little heartwood and very little knot-free wood (unless pruned). Short-rotation regimes can be justified as long as there is a good market for pulpwood and chip-and-saw grades, or as long as reconstituted wood can satisfactorily and cost-effectively substitute for the natural product, but it is conceivable that the predominance of short-rotation regimes could lower the price of this material and result in a premium for older and larger trees. It is also possible that there could be a swing away from the use of high discount rates in forestry.

Forests Versus Stands

One final point must be made regarding rotation age. A forest is more complicated than a stand, and the optimum solution for a forest may not coincide with the optimum solution for the stands within it. This is because there may be supply commitments, or there may be bottlenecks of labor or machinery. Even if there were no such restrictions, it makes sense to sell wood when the price is high and to minimize harvesting when the price is low. In other words, some stands may be felled long before their optimum rotation and others may be felled a lot later. A specialist branch of forestry is concerned with estate modeling, which varies the rotation length of individual stands to ensure both continuity of supply for the whole forest and responsiveness to market signals.

Consider a processing plant that handles large, old logs (perhaps it requires clearwood with a high proportion of heart). It pays a very high price for the wood, and is a dominant customer of the forest. It requires a regular, predictable supply of this type of wood.

The resource forester examines the inventory records of the whole forest and observes that there is an impending gap in the supply of this log grade, followed soon after by a glut. This is because no real forest exists where there is a perfectly balanced mixture of age classes. Disruptions such as planting booms, wars, depressions, storms, or fires always mean that there is a higher proportion of certain age classes, and gaps where there are no trees of optimum age. What to do? The answer may be to overcut the oldest age classes, followed by undercutting the next oldest. In other words, in order to satisfy the major customer and fill the gap in supply, some age classes will cut well before their optimum rotation age and others many years afterwards.

The forester's decision has long-lasting consequences. Not only does it greatly influence the asset value, the cash flow, and the profitability of the existing resource, but it also has a major bearing on the next generation of trees. This is because a planting boom immediately follows a harvesting boom, because land cannot be left idle for long without weed encroachment. The existing age class structure of the forest is creating headaches for planners, but it behoves them also to consider the effect of their actions on their successors.

Summary

The issue of rotation age is a good example of the complexity of forest science. To the uninitiated, forestry may seem like a simple business ('you plant a tree and you cut it down') but a deeper examination reveals the difficulties of determining and imposing rational solutions on long-lived biological systems. The measurements, calculations, and models in forestry can be highly complex but can never reach the degree of precision that could be attained in purely physical systems. Also, the payback periods envisaged by the forester are significantly longer than almost any other human endeavor. What factory, what engineering structure, what work of art, would take three decades or more to commission?

Multiple-use Silviculture in Temperate Plantation Forestry

W L Mason, Northern Research Station, Roslin, UK

Published by Elsevier Ltd., 2004

Introduction

Silviculture can be defined as the growing and tending of forest stands to meet management objectives. One of the characteristics of forests is that they can be managed to meet a wide range of objectives, from timber production to provision of recreation opportunities, from conservation of rare species to sheltering farm animals during harsh weather. In recent decades, a common tendency has been to try and zone forests into areas of 'dominant use' where a particular objective would take precedence over all the others. Thus recreation might be the most important objective close to a forest visitor center whereas the emphasis would be on timber production in areas with little public access and low visibility. Management for these contrasting objectives might foster stands that would vary appreciably between zones. Thus stands in the first zone might be very variable over a short distance with a range of tree species of different sizes, whereas the second would have much less spatial variation with more regular stand structures composed of one to two species. This approach may be termed 'single' or 'dominant use' silviculture where the aim is to maximize the yield of a particular output (visitor days or volumes of timber) subject to providing minimum levels of any other outputs. However, it is often possible and desirable to manage stands for several objectives at the same time, for instance by providing a habitat with an attractive landscape that accommodates game shooting and where regular harvests of timber provide income for the owners. This alternative strategy is called 'multiple-use' silviculture because managers explicitly seek to develop stands that will provide for a range of uses at the one time. The purpose of this short review is to explain some of the increasing interest in 'multiple-use' silviculture and outline some of the challenges to its wider adoption. The emphasis is upon experience in the British Isles, but the principles should be applicable in other countries and forest types.

Plantation Forests: An Example of Dominant Use Silviculture

A frequent legacy of national forestry policies during the nineteenth and twentieth centuries is extensive areas of conifer plantations that were established in many parts of the north temperate zone to provide a wood supply for local industries. Examples of such plantations can be found in Britain, Ireland, The Netherlands, Belgium, Germany, New Zealand, Chile, South Africa, and many other countries (**Figures 1** and **2**). The plantations created during this era of forest expansion have often developed into homogeneous stands of trees of similar ages ('even-aged') of one or two species. The main silvicultural system used in their management has been clear-felling. Under this system all the trees on a given area (coupe) are felled and removed from site when they have reached the desired size for processing. The average coupe size can vary from less than 1 ha to up to 50 ha or more, depending upon location and visibility. The felled area is generally reforested by planting young seedlings that have been raised elsewhere in a forest nursery. However, if the chosen tree species produces regular supplies of seed, and if the site is of low fertility so that weed competition is not serious, then reforestation may be achieved through natural regeneration. In either case, the aim is to ensure rapid growth of the young trees so that a full canopy cover is restored. Any competing vegetation or unwanted tree species are normally removed during the establishment phase. In a similar way, any trees of poorer quality of lesser vigor are gradually thinned out after canopy closure so that by the time of clear-felling, the stand is composed only of the better-quality stems. The age at which clear-felling occurs (rotation age) varies with species and site but in the north temperate zone is generally between 40 and 120 years.

Figure 1 Cawdor. An internal view of a 100-year-old Scots pine plantation in north-east Scotland managed under a group shelterwood system. The mixture of mature trees and clumps of regeneration of pine and other species provides a varied woodland which is both attractive to the local community for recreation and a source of valuable timber for the landowner. Courtesy of the Forestry Commission.

Recent changes in forest policy in many countries have given much greater emphasis to the sustainable management of existing forests for multiple benefits, including maintenance and enhancement of biodiversity, provision of recreational opportunities, and increased visual diversity, as well as timber production. There has been ongoing criticism that the limited number of tree species and the lack of structural diversity within the stands of plantation forests is not compatible with management for multiple objectives. A particular concern has been that the relatively short rotations employed have resulted in a lack of older stands and the rich habitats

Figure 2 Glenbranter. An 80-year-old Sitka spruce stand in western Scotland which is starting to develop some of the features of the later phases of stand development. Note the large trees, the regeneration in the background, the fallen deadwood, and the developing ground flora which all combine to provide some of the features aspired to in multiple use silviculture. associated with features such as large trees, abundant deadwood, and an open stand structure. Such criticisms have been particularly strong in countries where plantation forests are a major part of the forest area as in Great Britain and Ireland, or where the natural forest stands have been gradually simplified towards a structure similar to a planted forest (e.g., Scandinavia, parts of Central Europe). As a result, there has been a growing perception that conventional plantation silviculture based upon clear-felling may not be the most effective way of delivering multiple benefits, particularly in forests with high landscape, recreation, or conservation values. This has led to increasing interest in the use of a range of alternative silvicultural systems to clear-felling such as shelterwood and selection systems, all of which involve retaining some mature trees on the site during the regeneration phase. This approach has been given a variety of names such as 'continuous cover forestry,' 'close-to-nature forestry.' and 'ecological silviculture,' to name but a few.

Stand Dynamics and Multiple-Use Silviculture

A better understanding of these issues is gained by considering the development of a forest stand over time, otherwise termed stand dynamics. While this is a complex process with appreciable variation between both forest types and regions of the world, a comparatively simple conceptual model in widespread use separates the development into four distinct phases. These are generally known as stand initiation, stem exclusion, understory reinitiation, and old-growth with the first being the youngest and the last the oldest stage in the process. It is not inevitable that a stand has to develop through all four phases since damage caused by a major disturbance (e.g., the wind storms of 1987 in southern England and of 1999 in France and Germany) will destroy so much of the overstory that a stand reverts back to the initiation phase.

Table 1 gives more details of these phases using a Scottish Scots pine (*Pinus sylvestris*) stand as an example. A point to notice is that a forest will generally contain stands at different stages of this development process, depending upon the history of harvesting or natural disturbance due to fire, wind, snow, or disease. The frequency of such disturbances can affect the relative area of stands in the different phases. Thus an area with frequent severe disturbances from wind or fire will have comparatively few stands in the old-growth phase and more in the younger phases than would be the case where such events are less frequent.

The traditional practice in timber management of harvesting a stand at or close to the age of maximum mean annual volume increment tends to occur towards the end of the stem exclusion phase. Management would also seek to maximize the return on investment by reducing the length of the stand initiation phase. The impact of this silvicultural approach can be examined by looking at the way a range of timber and other benefits change with different stand development phases (**Figure 3**).

In this figure, the variation of an illustrative range of market and nonmarket benefits is presented in relation to these four phases for Sitka spruce (*Picea sitchensis*) plantation forests in northern Britain. The benefits are not quantified, but the relative values are supported by findings from studies on public preference and biodiversity carried out in Great Britain and elsewhere in the last decade. For example, timber value peaks in the stem exclusion and early understory reinitiation phases but declines towards old-growth. By contrast public preference is lowest in the

Table 1 An outline of the four phases of stand development using a Scots pine (*Pinus sylvestris*) stand in northern Scotland as an example. Phase	*Approximate tree age (years)*	*Approximate height of dominant trees (m)*	*Comments*
Stand initiation	0–20 (40)	0–5	The period during which the trees are becoming established on the site, but a closed canopy has not yet been formed. The longer period refers to what happens when natural regeneration is being used and/or the trees are being affected by browsing.
Stem exclusion	20–80	5–20	The trees form a closed canopy over the site. No shrub or tree understory is present. Tree death will occur as a result of competition unless this is reduced by thinning.
Understory reinitiation	80–150	20–25	Gaps start to occur in the canopy as a result of disease or disturbance. Regeneration of pine and other tree species can occur. Height growth has slowed down but diameter growth continues.
Old growth	150–350 (or more)	25 or more	The survivors of the original trees begin to die out. The stand becomes a mosaic of groups of trees each of different ages. Comparatively low stocking compared to the previous two phases. Increasing abundance of standing and fallen deadwood.

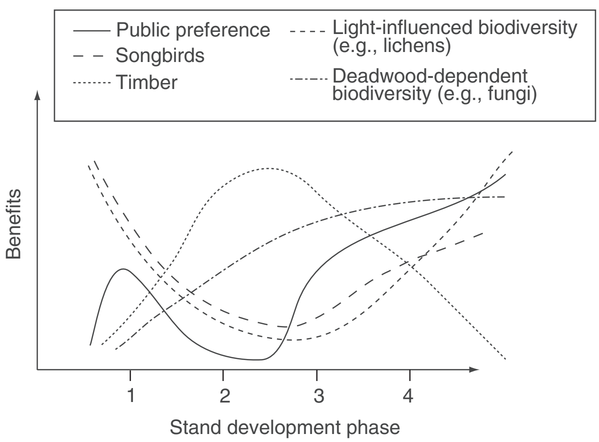

Figure 3 The changes in relative magnitude of selected benefits with different stand development phases in Sitka spruce (Picea sitchensis) plantations in Scotland. Phase 1, stand initiation; 2, stem exclusion; 3, understory reinitiation; 4, old growth. See text for further details.

stem exclusion phase and highest in the stand initiation and old-growth phases. Deadwood-dependent biodiversity is highest in the old-growth phase.

These relationships also suggest that management regimes that produce forests dominated by stands of a particular phase will not produce as wide a range of benefits as could be achieved if all the development phases were represented. This has particular implications when alternative silvicultural systems to clear-felling are being evaluated for possible use in forest management.

Silvicultural Systems and Multiple-Use Silviculture

As noted earlier, there is a range of silvicultural systems that can be used to manipulate stand structure to meet objectives. For the purpose of this discussion, three main systems can be distinguished although there are many local and regional variants, and one type can often intergrade into another. These are:

1. The clear-felling system where a particular area of a forest is cleared in a single operation and is generally followed by replanting.
2. The shelterwood systems where again a particular area of forest is cleared, but in this case the process involves a number of regeneration fellings designed to promote natural regeneration.
3. The selection systems where selective felling of trees is being carried out and natural regeneration is being fostered over the whole forest area.

In general terms, these systems provide different proportions of the various stand phases and therefore different flows of benefits. Thus, a clear-felling system provides a forest with stands that are predominantly moving from the stand initiation to the stem exclusion phase and back again. Stands in the later phases can be provided if stands are retained beyond normal rotation age, but once they are felled they return to the stand initiation phase. By contrast, a shelterwood system, with regeneration occurring either under the canopy of the mature trees or in gaps adjacent to these trees, provides some characteristics of the understory reinitiation phase. Once the regeneration is established, the overstory trees are generally removed so that the stand reverts to a stem exclusion phase. Depending upon the extent of the regeneration fellings and the amount of the overstory that is retained, the area in the stand initiation phase can be appreciably reduced compared to that found under a clear-felling regime. A selection system differs again since one essential aim is to foster and develop regeneration in small gaps so that the whole stand is predominantly in the understory reinitiation phase. Finally, in a broadleaved plantation, one also has the option of introducing a coppice system where the combination of mature trees and different sizes of underwood can provide features of all stand development phases except old growth.

Therefore, if one is seeking to introduce multiple-use silviculture to a forest previously managed for timber production using a clear-felling system, introduction of one of the alternative systems on a percentage of the area will change the proportion of the various stand phases in that forest. This is generally likely to increase the range and spread of benefits being obtained. For example, the recent colonization of many plantation forests in upland Britain by the goshawk (*Accipter gentilis*) is associated with the retention of more stands into the early understory reinitiation phase. By contrast, uncritical adoption of an alternative system can imperil species dependent upon particular habitats. In pine forests in lowland Britain, populations of the rare wood lark (*Lullula arborea*) require the bare ground conditions associated with stand initiation following clear-felling. Greater use of shelterwood or selection systems would limit the amount of such open habitat and could reduce the population.

The various silvicultural systems produce stand structures which show different horizontal and vertical distributions of features such as foliage, branches, open space, and stand microclimate. All of these can influence factors like the growth of a tree, the habitat available for a given organism, or the spiritual enjoyment of the forest. The clear-felling system will produce stands that are more homogeneous than those produced by the other main systems. Thus, in a 50-year-old Sitka spruce plantation nearing felling age which has been managed for timber production with regular thinning, the spacing between trees will be uniform, and there will be relatively little variation in tree height or diameter. The tree crowns will intercept about 90% of incident light so that there is little vegetation growth on the forest floor and there will be no other tree species present in the canopy. By contrast, in a stand of the same species being managed on a selection system to produce large dimension timber (i.e., 60 cm diameter at breast height), there will be a wider range of diameters and heights associated with trees of different ages, and the light climate may vary considerably where overstory trees have been harvested and regeneration is developing.

A point that emerges from this discussion is that none of the systems as traditionally formulated is designed to provide the old-growth phase and associated deadwood habitat which is increasingly recognized as lacking in many forests that have been intensively managed for timber production. This is not to say that the systems cannot be adapted for this purpose, but rather that one needs to understand the range of stand structures that can be produced by each system and that mix of structures which is appropriate to provide a sustained flow of market and nonmarket benefits.

Site Classification, Mixtures, Native Species, and Multiple-Use Silviculture

Since the interest in adopting multiple-use silviculture often occurs in response to reactions against plantation forest management for timber production, this is often accompanied by attempts to increase the species diversity of such forests. A common aspiration is to convert single-species stands into mixtures and to increase the percentage of native species in such forests.

However, the success of such aspirations is critically influenced by the availability of a site classification methodology that adequately reflects the ecological factors affecting tree growth in different regions and on varying soils. Without such knowledge, it is difficult to decide which species can be appropriate for use in mixture and at which stage in a stand development life cycle it is most effective to introduce them. For example, in northern Britain there has been increasing interest in the potential of introducing birches (both *Betula pendula* and *B. pubescens*) into Sitka spruce plantations to increase visual amenity and species diversity. These species are broadly compatible with Sitka spruce in terms of site fertility but are less tolerant of wind exposure. Both birches can be found colonizing clear-felled sites in the stand reinitiation phase and can persist into the early stem exclusion phase in areas that have been replanted with Sitka spruce. However, examination of height growth curves for these species shows that they are unlikely to compete with Sitka spruce in the long term and that intimately mixed species stands of birch and spruce are unsustainable in the stem exclusion phase. Therefore, it appears that a strategy for increasing the percentage of birch in spruce forests would need to be based around the creation of pure stands of birch within a spruce matrix. Such stands would need to be large enough to provide for the development of mature trees to ensure a seed source whenever nearby harvesting or wind disturbance created an area for potential regeneration.

An understanding of the limiting factors on a site is essential if species diversification is to be successful as part of multiple-use silviculture. An example can again be drawn from the birch–Sitka spruce case in northern Britain. There have been a number of instances where spruce plantations were established on exposed sites with difficult access and the prospects for commercial timber production have proved limited. In such circumstances, conversion of the spruce plantation to a native birch forest should provide a better flow of benefits over time. However, clear-felling of the spruce and replanting with birch has been problematic, largely because the removal of the spruce has resulted in a loss of stand microclimate and the birches have suffered from the wind exposure. Site assessments indicate that a more certain, if longer-term approach would be to establish birch within gaps developed within the spruce plantation and progressively remove the conifer matrix, possibly over 10–20 years.

A further point that is raised by these examples is that the introduction of multiple-use silviculture into plantation forests requires an ability to consider what the 'future-natural' state of the stands is likely to be, particularly if it is anticipated that such forests will continue to be managed with timber production as one of the objectives. In countries where the plantations are dominated by nonnative species and/or little natural forest remains, then it may not be obvious what are the appropriate species to introduce into the plantations, let alone what pattern of mixture or silvicultural system should be employed. In such situations, a site classification which can provide objective guidance on species suitability will prove an invaluable aid.

Challenges to Greater Use of Multiple-Use Silviculture

As outlined in the previous sections, successful adoption of multiple-use silviculture requires a grasp of the stand dynamics of the particular forest type(s), an appreciation of how different benefits are affected by silvicultural system and stand development phase, and an understanding of how silvicultural options are limited by site conditions. However, even where these prerequisites have been achieved, there are still a number of serious challenges to be considered. These are:

1. The need to relate the desired structures at a stand level to the wider pattern that is appropriate for a whole forest or catchment. As shown in **Figure 1**, the various phases of stand development each provide a different mix of benefits and it is generally unrealistic to expect a single stand or small forest area to provide the whole range of potential benefits. Therefore, some thought has to be given to the various benefits that are to be provided at a whole landscape level and how the flow of benefits is to be sustained over time. Such an approach can be difficult enough when the landscape unit is managed by a single landowner, but it becomes very complex when there are a number of owners with contrasting objectives.
2. An assumption underpinning the link between the landscape and stand levels is that it is possible to agree what should be an acceptable mix of stands in the different phases and how these might be distributed over a forested landscape. Reference is often made to using natural disturbance regimes for a given region (e.g., the return periods for damaging winds) as a means of calculating the proportion of stands in different phases. Unfortunately, this approach requires good knowledge on disturbance history which is often lacking or can be an artifact of past forest management. Examples of the latter include a reduction in fire frequency because of fire suppression policies or an increase in wind damage because of delayed thinning.
3. Forest management in the last century tended to simplify stand structures in many forest types in the interests of increased timber production as has been shown by numerous studies in Scandinavia and North America. Therefore a major silvicultural challenge is to identify and foster stands that can eventually provide the structures characteristic of the understory reinitiation and old-growth phases. In particular, there is a lack of guidance on the potential structural and spatial features of old-growth stands in areas where plantation forests have been created. It is unclear whether the development of such features can be accelerated through stand manipulation practices such as thinning to produce a variable spatial distribution of trees (variable density thinning). The best location for and the appropriate size of such stands in a forested area also requires to be considered.
4. Successful application of multiple-use silviculture will require better understanding of the way key outputs from the forest are influenced by silvicultural practices. For example, adoption of continuous cover forestry systems may seem desirable to avoid the visual impacts associated with clear-felling, but dense natural regeneration within such stands might produce a closed and less attractive internal forestscape for walkers. The complex

interactions between stand structures and desired outputs mean that managers will need to be certain which are the key species, values, and products which their forests are to provide. They can then propose how such outputs will be affected by changes in stand structure achieved through silviculture, decide which mix of interventions is most appropriate, carry these out, and monitor the results after a suitable time interval. The silvicultural prescriptions may then be changed as a result of the information provided by the monitoring.

5. This highlights the need for decision support tools that are capable of simulating the development of stands under contrasting management regimes and that can be linked via a geographic information system (GIS) to show the flow of benefits over space and time from particular strategies. For instance, widespread adoption of a selection system might produce stands that were very heterogeneous at a small scale, but a landscape that was monotonous and where species dependent upon the stand initiation phase were underrepresented. Better understanding of how different benefits are influenced by stand structure is important here since silvicultural interventions seek to provide those structures that are thought to fulfill management objectives. Criteria for success in even-aged plantation management are well researched and described for many forest types in the world, but equivalent aids for multiple-use silviculture are rare.

In the last analysis, successful implementation of multiple-use silviculture requires the development of a shared future vision for a forest that can be used to inspire the public, employees, and various stakeholders. In areas such as the British Isles where the area of native woodland is small and fragmented, it is unrealistic to expect the native woods to provide the social and environmental benefits while the considerably more extensive area of plantation forests is managed largely as a wood factory. Instead, the plantation forests have to be diversified through multiple-use silviculture to provide the mix of benefits required by commitments to sustainable forest management. The challenge for foresters in such situations is not whether to adopt multiple-use silviculture, but rather how to do it and where best to begin the process.

Sustainability of Forest Plantations

J Evans, Imperial College London, Ascot, UK

Introduction

Plantation Forests

The present extent of planted forests worldwide probably exceeds 180 million ha. New planting in both tropical and temperate regions is leading to a significant net increase of forest plantation each year. It is predicted that in time a greater proportion of industrial wood will be sourced from plantations than from exploiting natural forests, and that this trend towards increasing reliance on planted forest for wood production will continue. Thus forest plantations appear set to become a major, even dominant, form of forest development. But as a way of growing trees, is it sustainable?

Sustainability

The concept of sustainability in plantation forestry may be considered to have two components. There are the general or broad issues of sustainability – so clearly articulated and placed on the international agenda in the 1980s by the Brundtland commission – of whether, in the case of tree plantations, using land and devoting resources to them is a sustainable activity from the economic, from the environmental, or from the social sense. Is such development unsustainable because it is economically questionable, or environmentally damaging, or a threat rather than a help to people's livelihoods and way of life and lead to alienation? The same questions may be increasingly asked about sustainable agriculture. Each of these, and related issues, are important in their own right and fundamentally depend on national policies governing plantation development, understanding their impacts, and ensuring full public participation in the process. They concern the concept of 'sustainable livelihoods' as a crucial dimension of the grand aim to eliminate world poverty by 2030.

An example in the case of plantations and sustainable environmental impacts is that it is generally accepted that plantations should not be established on land obtained simply by clearing natural forest formations. There is plenty of already degraded land resulting from past clearance or poor farming practices and which is of no importance for conservation, but will grow trees well: indeed, plantations can help restore degraded land. Thus plantations should not conflict with natural forest but be complementary to them. These and other issues relate to what can be labeled 'broad-sense' sustainability.

The second issue to do with sustainability concerns the practice of plantation silviculture itself. Is growing trees in plantations a technology that can work in the long term? Is such silviculture ecologically sound or are there inherent flaws which will eventually lead to declining growth rates as plantation crop succeeds plantation crop? This is what is meant by 'narrow-sense' sustainability and is the subject of this article.

'Narrow-Sense' Sustainability

The question raised is: can tree plantations be grown indefinitely for rotation after rotation on the same site without serious risk to their health and rate of growth? More specifically, can their long-term productivity be assured, or will it eventually decline over time? Are some sites or forest crops more at risk than others and is this influenced by how they are managed? These questions are pertinent, owing to the increasing reliance on planted forests, but are also scientifically challenging since in previous centuries trees and woodlands were seen as soil improvers and not impoverishers. Are today's silvicultural and management practices more damaging because of greater intensity, such as clonal plantations, optimizing stocking levels, and harvesting on short rotations, which lead to high timber yields typically two to five times that of natural forest increment? Furthermore, are the use of tree-breeding programs, refined fertilizer treatment, more sophisticated manipulation of stand density and so on likely to lead to even more productive forest crops with time, or could they mask evidence of genuine site degrade or increasing risk of damaging pests and diseases?

Figure 1 Litter raking beneath *Pinus caribaea* in southern China. This regular removal of needles, twigs, and branches intempts the nutrient cycle.

Understanding sustainability also applies to nonindustrial uses. Sustaining the numerous benefits people derive from plantations should be a top priority and arise out of good management. Does the perpetual gathering and removal of leaves, twigs, and litter from beneath tree stands, so widespread in India and China, for example (**Figure 1**), simply loot the site of nutrients? And what of the flow of nontimber products, often of more value than wood, and perhaps less directly damaging to sites when harvested? These are relevant to plantation forestry, even if it is not always possible to answer such questions adequately.

Evidence of Productivity Change

Productivity Change in Successive Forest Rotations

Problems with data For forest stands (crops) firm evidence of productivity change over successive rotations is meager with few reliable data. Compared with agriculture, the long cycles in forestry make data collection difficult. Records have rarely been maintained from one rotation to the next or have simply been lost; funding for such long-term monitoring is often a low research priority; measurement conventions and even practices change which confound ready comparison; detection of small changes is difficult; and often the exact location of sample plots is inadequately recorded. In addition, because few forest plantations are second-rotation, and even fewer third- or later-rotation, even the opportunity to collect data has been limited. Unfortunately without data it is difficult to demonstrate whether plantation silviculture is robust and so refute (or otherwise) claims that successive rotations of fast-growing trees inevitably lead, for example, to soil deterioration.

Review of Evidence Comparing Yields in Successive Rotations

Over the last 100 years there have been six main reports that have thrown into question the sustainability of plantations over successive rotations. They are grouped here by region.

Spruce in Saxony and other European evidence In the 1920s reports began to emerge suggesting that significant areas of second- and third-rotation spruce (*Picea abies*) in lower Saxony (Germany) were growing poorly and showed symptoms of ill-health. There was a fall of two quality classes in second- and third-rotation stands, but this was only recorded over 8% of the plantation area. This became a much researched decline and was attributed to insect defoliation, air pollution, the effects of monoculture, drought, and simply the intensive forms of forestry practiced. It is now clear that much of the problem arose from planting spruce on sites to which it was ill-suited, to litter raking that depleted soil of nutrients, and planting on degraded agricultural land. Later studies, that included other sites, showed that growth of spruce was unchanged from rotation to rotation or even increased. Today young stands of pure spruce in Saxony and Thuringia appear to be growing more vigorously than equivalent stands 50 or 100 years ago.

Elsewhere in Europe reports of productivity comparing first and second rotation are limited. In Denmark no great change has been observed for Norway spruce crops but for beech (*Fagus sylvatica*) second-rotation productivity is reported as significantly better. In the Netherlands growth of second-rotation forest is generally 30% faster than the first where it has been assessed. Similarly, in Sweden second-rotation Norway spruce shows superior growth. In France some decline was reported from successive rotations of *Pinus pinaster* in the Landes, though this is not attributed to site deterioration. In the UK most second-rotation crops are equal to or better than the previous rotation and, in the case of restocking of Sitka spruce (*Picea sitchensis*), there is no requirement to reapply phosphate fertilizer which had been essential for establishing the original crop.

***Pinus radiata* in Australia and New Zealand** Reports of significant yield decline in second-rotation *Pinus radiata* emerged in South Australia in the early 1960s and by the end of that decade fall-off in productivity of about 30% affected most pine plantations in the state. These reports were alarming and generated a great deal of research into possible causes. By 1990 it had become clear for South Australia that harvesting and site preparation practices which failed to conserve organic matter, and an influx of weeds in the second rotation, especially massive growth of grasses, were the main culprits. With more sensitive treatment of a site, conservation of organic matter, and good weed control the decline problem was eliminated. With the additional use of genetically superior stock, growth of second- and third-rotation pine became substantially superior to the first crop, a situation which now prevails throughout the state. Indeed, a substantial proportion of the second and third rotation has been upgraded from low site qualities (mean annual increments (MAIs) 13–18 $m^3 ha^{-1} year^{-1}$) to high (MAIs 25–33 $m^3 ha^{-1} year^{-1}$).

In the state of Victoria the yield of second-rotation *P. radiata* is equal or superior to that of the first rotation and in New South Wales basal area and volume per hectare increases of 13 and 18% respectively are reported in the second rotation. In Queensland a careful study of first- and second-rotation *P. elliottii* of the same seed origin shows no evidence of yield decline, but a 17% increase in volume per hectare at 9 years where organic matter was left undisturbed.

In parts of New Zealand, on a few impoverished ridge sites in the Nelson area, there were signs in the 1960s and 1970s, albeit transitory, of yield decline. Today, as with plantations in Australia, holistic management and genetic improvement lead to yield gains from one rotation to the next.

Pines in Swaziland and South Africa Long-term productivity research by the writer in the extensive industrial pine plantations of the Usutu forest, Swaziland, began in 1968 as a direct consequence of the reports from South Australia about second-rotation decline. For 35 years measurements have been made over four successive rotations of *P. patula*, grown for pulpwood, from a forest-wide network of long-term productivity plots (**Figure 2**). Plots have not received favored treatment, but subject to normal forest operations, and tree growth simply measured and recorded during each successive crop.

Over most of the forest, where granite-derived soils occur, third-rotation height growth is significantly superior to second and volume per hectare almost so. There had been little difference between the first and second rotations. On a small part of the forest (about 13% of area), on phosphate-poor soils derived from very slow-weathering gabbro, a significant decline had occurred between first and second rotation, but this has not continued into the third rotation, where there is no significant difference between rotations. Fourth-rotation measurements are currently ongoing and initial results suggest it is growing better than all previous rotations: there is certainly no evidence of decline.

The importance of the Swaziland data, apart from the long-term nature of the research, is that no fertilizer addition or other ameliorative treatment has been applied to any long-term productivity plot from one rotation to the next. Although some third-rotation *P. patula* is probably genetically superior to the second rotation, this effect is small and more than compensated for by the severe drought in the period 1989–1992 which will have adversely impacted third-rotation growth. These data are also of interest because plantation silviculture practiced in the Usutu forest over some 72 000 ha is intensive, with pine grown in monoculture at stockings of 1100–1500 stems per hectare, never thinned, and on a rotation of 15–17 years, which is close to the age of maximum MAI. The limited genetic improvement of some of the third rotation could have disguised a small decline, but evidence is weak since breeding generally improves net primary productivity (NPP), which cannot be realized if one or more nutrients is deficient. Also, it can be strongly argued that without the severe and abnormal drought, growth would have been even better than it is. The current indications of improved fourth-rotation growth probably reflect the impact of genetic improvement. Overall, the Swaziland evidence suggests no serious concern over narrow-sense sustainability.

Figure 2 Signs of three rotations in the Usutu forest, Swaziland, photographed in 1986. Old first-rotation stump (indicated), second-rotation stump cut 6 years ago, and third-rotation stand in background. This site now supports a fourth-rotation stand of pine which is growing better than the three previous rotations.

In South Africa there is no evidence of productivity decline over successive rotations other than localized small-scale examples arising from compacted soil. Excessive accumulation of undecomposed litter in some high-altitude stands of *P. patula* does give rise to concern over increasing soil acidity and nutrient immobilization. In wattle (*Acacia mearnsii*) crops grown intensively for their bark for tannin production, there is no evidence of yield decline with successive rotations.

Chinese fir in subtropical China About 6 million hectares of plantations of Chinese fir (*Cunninghamia lanceolata*) have been established in subtropical China. Most are monocultures and are worked on short rotations to produce small poles. Foliage, bark, and sometimes roots are all harvested for local use. Reports of significant yield decline have a long history. Typically there is a drop in productivity between first and second rotation of about 10% and between second and third rotation of up to a further 40%. Chinese forest scientists attach much importance to the problem and pursue research into monoculture, allelopathy, and detailed study of soil changes. However, it is clear that the widespread practices of whole-tree harvesting, total removal of all organic matter from a site, and intensive soil cultivation that favors bamboo and grass invasion all contribute substantially to the problem.

Teak in India and Java In the 1930s some evidence suggested that replanted teak (*Tectona grandis*) crops (second rotation) were not growing well in India and Java. Although significant soil erosion is widespread under teak and organic matter is frequently lost as leaves are burnt, research into the 'pure teak problem,' as it was called, did not generally confirm a second-rotation problem. Site deterioration under teak does often occur with yields from plantations not coming up to expectation but causes are mainly management-related, namely poor supervision of plantation establishment, overintensive taungya (intercropping) cultivation, delayed planting, and poor aftercare. There are few data from successive rotations – the ideal way of evaluating changes in productivity – since teak rotations are long, typically 50–80 years.

Southern pines in the USA Plantations of slash (*P. elliottii*) and loblolly (*P. taeda*) pines are extensive in the southern states. Significant planting began in the mid-1930s as natural stands were logged out .With rotations usually about 30 years, restocking first began in the 1970s. The growth of this second rotation appears variable, with reports of both better and poorer growth. Changes between rotation are attributed to differences in site preparation and to competition from understory shrubs and weeds. Where weeds are well controlled and appropriate site preparation used, such as a bedding plough, growth is often superior. Genetically improved stock and use of fertilizers are expected to bring further increases.

Within-Rotation Yield Class/Site Quality Drift

The recently observed phenomenon of yield class or site quality change with time has two aspects – change between predicted and actual yield over time, and correlation of site quality (yield class) with date of planting rather than just site fertility.

Inaccuracy in predicted yield For long-rotation (>20 years) crops it is usual to estimate yield potential from an interim assessment of growth rate early in life and then to allocate a stand to a site quality or yield class. This is a good way of forecasting likely yields overall, though imprecise for estimating actual final timber outturn from individual stands. A change from predicted to final yield can readily occur where a crop has suffered check or other damage in establishment that delays its development and thus distorts early estimates of site potential based on growth-to-age relationships. Similarly, fertilizer application which corrects a specific deficiency may also have this impact. However, there is some evidence for very-long-rotation (>40 years) crops in temperate countries that initial prediction of yield or quality class underestimates final outturn, i.e., the crops grow better in later life than expected. Either the models derived from data of 40 or more years ago were wrong, or they are now inappropriate to present conditions, or growing conditions are improving in the sense of favoring tree growth. Across Europe, research by the European Forest Institute shows this to be happening and it is attributed to rises in atmospheric CO_2 and nitrogen input in rainfall, better planting stock, and cessation of harmful practices such as litter raking.

However, as noted earlier, the opposite may occur with teak. High initial site quality estimates do not yield the expected outturn and figures are revised downward as the crops get older. Plantation teak does suffer soil erosion in established stands, development of understories is rare, and burning of debris, especially the large dry leaves, is commonplace. Like litter raking, these practices may contribute to loss of nutrients from a site.

Relation of quality (yield) class with time of planting Closely related to the phenomenon of changing yield potential as a crop grows is the observation that date of planting is often positively related to productivity, i.e., more recent crops are more productive than older ones, regardless of inherent site fertility. This shift is measurable and can be dramatic and is well seen for *P. radiata* in Australia and New Zealand, where the more recent the planting, the more productive the stand. And in the UK, attempts to model productivity on the basis of site factors have often been forced to include planting date as a variable. Maximum mean annual growth of Sitka spruce increases by about $1\,m^3\,ha^{-1}\,year^{-1}$ for each succeeding decade up to the present. This phenomenon seems common and suggests that some process favors present growing conditions for trees over those in the past, such as the impact of genetic and silvicultural improvements – and cessation of harmful ones – and possibly the 'signature' of atmospheric changes.

Interventions to Sustain Yield

Genetic Improvement

Change in species, seed origin, use of new clones, use of genetically improved seed and, in the future, genetically modified trees all offer the prospect of better yields in later rotations.

Species change There are surprisingly few examples of wholesale species change from one rotation to the next, which suggests that in most cases foresters have been good silviculturists, drawing on trials and long experience with a species before commencing large-scale plantations. It is also worth noting that, where a successful exotic species is replaced by a native one in the second rotation for reasons of conservation or public preference, productivity may diminish.

Better seed origins, provenances, and land races The impact of these genetic improvements are well known and reported elsewhere (*see* **Tree Breeding, Practices**: Genetics and Improvement of Wood Properties). It is important to cover the range of site conditions where a species is believed to have potential owing to site – genotype interaction. The best seed origin in one location may not be the best in another. This refinement in understanding offers the prospect of further yield improvement.

Clonal plantations Some of the world's most productive tree plantations, including both eucalypts and poplars, use clonal material. Both the potential productivity and uniformity of product make this form of silviculture attractive and it is likely to expand in the future. Although clonal forestry has a narrow genetic base, careful management of clone numbers and the way they are interplanted can minimize pest and disease problems. Use of 30–40 unrelated clones per stand is usually considered to provide security against catastrophic failure in most circumstances.

Tree breeding Genetic tree improvement offers by far the greatest assurance of sustained and improved yields from plantations in the medium and long term. Improvements of 20–50% are reportedly relatively easy to achieve. A compilation of estimated percentage gains from genetic and silvicultural interventions in plantation forestry is now incorporated into the Food and Agricultural Organization's global fiber supply model.

Genetically modified trees There are presently no significant plantations of genetically modified trees, except possibly in China. The expectation is that genetic engineering may be used to develop disease resistance, modified wood properties, or cold or drought tolerance. Research in progress includes modified lignin content of eucalypts and poplars and insertion of disease-resistant genes in elms (*Ulmus* spp.).

Subject to their public acceptance, these powerful genetic tools will become increasingly cheap and hence accessible to forestry use and offer an important aid to intensification of production.

Role of Different Silvicultures

Silvicultural knowledge continues to increase through research and field trials, often focused by greater understanding of tree and stand physiology. While large yield improvements appear unlikely, several incremental gains can be expected. Examples include the following:

1. Manipulation of stocking levels to increase output of total fiber or a particular product such as high-quality sawlogs. The object will be fuller site occupancy, less mortality, and greater control of individual tree growth.
2. Matching rotation length to optimize yield – the rotation of maximum mean annual increment – offers worthwhile yield gain in many cases. Of course, other factors frequently prevail, leading to rotation lengths other than this one.
3. In some localities, such as the British Isles, prolonging the life of a stand of trees subject to windthrow will increase yield over time, since most threatened stands are felled or windblown long before maturity. Research to predict damaging storm impacts and silvicultural research which increases crop stability and stem strength assist increase in yield.
4. Use of mixed crops may help in tree stability, may possibly lower pest and disease threats, but is unlikely to offer a yield gain over growing the most productive tree species the site can support.
5. Moves to silvicultural systems that maintain forest cover at all times – continuous-cover forestry practices – such as shelterwood and selection systems are likely to be neutral to slightly negative in production terms while yielding gains in tree quality, aesthetics, and probably biodiversity value.
6. Crop rotation, as practiced in farming, appears unlikely as a feature in plantation forestry, although there are examples of tree plantations benefiting from a previous crop of nitrogen-fixing legumes such as *Acacia mearnsii*. Industry is likely to require a similar, not widely differing, species when replanting.

Traditionally, use of exotics carefully matched to site has often offered a yield gain over native species, even where suitable native species are available, owing to relative freedom from pest and diseases. This advantage cannot be expected to last indefinitely and there are already examples of increasing susceptibility of exotics to local pests and diseases.

Fertilizing

Regular and automatic application of mineral fertilizer as in much of farming practice is not presently a feature of plantation forestry, with the exception of some tropical eucalypt plantations. Most forest use of fertilizer is to correct known deficiencies, e.g., micronutrients such as boron in much of the tropics and zinc in Australia, macronutrients such as phosphorus on impoverished sites in many parts of the world, and nitrogen in some locations such as the Pacific Northwest of the USA. In most instances, fertilizer addition has only been required once in a rotation to obtain satisfactory establishment and growth.

Spectacular yields have been achieved on some sites by frequent or even annual fertilizer addition as part of intensive management that includes full weed control and optimal spacing. Examples include the British Forest Research experiment Wareham 156, the trials by Torsten Ingestad in Sweden, and the biology of forest growth experiment carried out by the Commonwealth Scientific and Industrial Research Organization (CSIRO) in Australia. These trials are experimental and serve more to elucidate principles of stand physiology, applied nutrition, and maximum growth potential rather than to offer practical and economically worthwhile operational prescriptions, since wood is a low-value product. In some situations irrigation offers similarly dramatic increases in growth.

Monitoring of nutrient levels in foliar analysis or fertilizer trials has a role mainly as an aid to good overall silviculture, although increasingly foliar analysis is used in intensively managed plantations as a diagnostic growth promotion tool to inform fertilizer prescriptions. Fertilizing is likely to be the principal means of compensating for nutrient losses on those sites where plantation forestry practice does cause net nutrient export to the detriment of plant growth.

Site Preparation Establishment Practices

Ground preparation to establish the first plantation crop will normally have introduced sufficient site modification for good tree growth. Cultivation loosens soil, improves rooting, encourages drainage, limits initial weed growth, improves water percolation, may reduce frost risk and, perhaps importantly for the long-term health of the forest, brings relatively unweathered soil minerals nearer to the surface and into the main feeding zone of tree roots. Substantial new investment in site manipulation is unlikely in second and subsequent crops owing to the cost of handling stumps and the implied failure first time round. Exceptions are alleviation of soil compaction after harvesting, and measures to reduce infections and pest problems. For example, in the UK destumping and windrowing of debris on some alkaline sites helps avoid fomes infection (*Heterobasidion annosum*).

Weed control strategies may change from one rotation to the next, owing to differing weed spectrum and whether weeds are more or less competitive to planted trees. The issue is crucial to sustainability since all the main examples of yield decline problems cited earlier reflect worsening weed environments, especially worsening competition from monocotyledons such as grasses and bamboos.

Changes between rotations in treatment of felling debris and organic matter may occur, such as cessation of burning, use of windrowing, or removal from site in whole-tree harvesting. It is clear that the felling, harvesting, and reestablishment phase is crucial to sustainable practice and needs to be viewed as a whole to minimize impacts from compaction along extraction routes, from loss of organic matter, and from soil erosion.

Organic Matter Conservation

Treatment of organic matter both over the rotation and during felling and replanting is as critical to sustainability as coping with the weed environment. While avoidance of whole-tree harvesting is probably desirable on nutrition grounds, both prevention of systematic litter gathering during the rotation and careful handling of accumulated organic matter at harvesting are essential to minimize disturbance and help aeration of soil and accelerate decomposition. Many authors attribute poor tree growth of the past and evidence of increasing yields in many plantations today to better conservation and handling of organic matter.

Holistic Management

Where all the above silvicultural features are brought together, a rising trend in productivity can be expected. If any one is neglected, it is likely that the whole will suffer disproportionally. For example, operations should not exclusively minimize harvesting costs, but rather those of harvesting, reestablishment and initial weeding should be taken as holistic activity, and without impairing tree vigor.

Holistic management also embraces active monitoring of pest and disease levels, and researching pest and disease biology and impacts will aid appropriate responses such as altering practices, e.g., delayed replanting to allow weevil numbers to fall. Careful reuse of extraction routes to minimize compaction and erosion is a further example.

Conclusions

Three main conclusions may be drawn from this review of yield assessments made over long periods, and often more than one rotation, and the summary of interventions to sustain yields.

1. Measurements of yield in successive rotations of trees suggest that there is no significant or widespread evidence that plantation forestry is unsustainable in the narrow sense. Where yield decline has been reported, poor silvicultural practices and operations appear to be largely responsible.
2. Evidence in several countries suggests that current rates of tree growth, including in forest plantations, exceed those of 50 or 100 years ago owing to changes in the environment, especially atmospheric composition, and improvements in silviculture.
3. There are several interventions in plantation silviculture which point to increasing productivity in the future, providing management is holistic and good standards are maintained. Genetic improvement in particular offers the prospect of substantial and long-term gains in yield over several rotations.

Short Rotation Forestry for Biomass Production

M G R Cannell, Centre for Ecology and Hydrology, Penicuik, Scotland, UK

Introduction

Some hardwood species have very rapid juvenile growth and also coppice readily. They are often natural pioneers. High yields can be sustained over many coppice rotations as short as 3–15 years. These properties can be exploited to produce large quantities of woody biomass, which can be used for pulp or to produce energy.

Recent ideas on short-rotation forestry developed during the 1960s with discussions on silage sycamore in the USA. The initial attraction was the prospect of obtaining both high yields and early returns on investment. There was also the added advantage of producing a uniform product by using clones and of rapidly selecting and deploying improved genetic material.

The notion of growing species such as willows, poplars, and eucalypts over short coppice rotations gained momentum as agricultural surpluses in Europe and North America offered the possibility of large areas of fertile land becoming available. At the same time, there was increased interest in biomass as a renewable energy source, while, in the tropics, short rotations enabled exceptionally high yields of wood pulp to be produced, with high financial returns.

This article outlines the extent to which short-rotation forestry is being practiced, the yields being obtained, some aspects of the silviculture, pest and disease problems, the utilization of short-rotation biomass, and environmental impacts.

Short-Rotation Forestry Around the World

Globally, *Eucalyptus* is probably the most widely planted genus. About 10 million ha have been planted worldwide, notably in China, India, Brazil, South Africa, Chile, and Portugal. Much of this area is managed on short rotations, virtually all for pulp. Over recent decades there has been a large increase in international trade in pulp from *Eucalyptus* and other fast-growing plantations.

Aracruz Celulose began growing *Eucalyptus* in Brazil in 1967. It is now one of the world's leading suppliers of bleached eucalypt pulp. Most of the pulp is exported. The plant produces about 1 million tonnes of pulp per year and is supplied by plantations covering about 150 000 ha. Aracruz has not only been commercially successful; it has also pioneered the development of new genetic stock, nursery methods, and clonal propagation.

Elsewhere in the tropics and subtropics, a wide range of species is grown on 10–15-year rotations for pulp and other products, including *Terminalia* spp., *Acacia* spp., *Casuarina* spp., *Virola koschnyi*, *Jacaranda copaia*, and many other species. Mention should also be made of the many woody species used in tropical agroforestry systems, yielding fuelwood, wood products, and green manure. Species such as *Sesbania sesban* have rapid juvenile growth, coppice rapidly, and fix nitrogen.

In North America, there are not many examples of short-rotation forestry being practiced commercially, but there are vigorous research and development programs. In Canada, attention has focused on poplars in Ontario province, grown on rotations of about 10 years, harvested with feller/bunchers. In the USA, the Short Rotation Woody Crops Program and the Biofuels Feedstock Development Program have examined the potential of growing fast-growing hardwoods on suitable agricultural land. Extensive trials involving about 150 species have been conducted since 1978. Databases exist on species yields in different regions, effects of varying spacings, fertilizer responses, pesticide prescriptions, and harvesting methods. The most productive species, besides *Eucalyptus* in Florida and Hawaii, have been *Populus* clones, *Liquidambar styraciflua*, *Acer saccarum*, *Platanus occidentalis*, and *Robinia pseudoacacia*.

In Europe, extensive short-rotation *Eucalyptus* plantations are grown for pulp along the Atlantic seaboard in Portugal and Spain. Elsewhere, Sweden pioneered the growth of willow and poplar as biofuels in the Swedish Energy Forestry Project, launched in 1976. Currently, 15% of Sweden's energy is supplied from biomass. Commonly, willow is grown over 6-year rotations on abandoned farmland, yielding biomass for small combined heat and power plants. New clones have been selected, cultural prescriptions defined, and harvesting machinery developed. Elsewhere in Europe, short-rotation forestry is practiced in most countries, but on a relatively small scale. However, the ambition of the European Commission to meet 12% of the European Union's primary energy demand from renewable sources by 2010 might require up to 10 million ha of energy crops, much of which would be short-rotation coppice.

Considerable research on short-rotation biomass plantations has been coordinated by the International Energy Agency (Bioenergy) since 1974, particularly within the task group Short Rotation Crops for Bioenergy Systems. The country partners are Sweden, Norway, Netherlands, Denmark, UK, Croatia, USA, Canada, Australia, and New Zealand.

Biomass Yields

Yields of *Eucalyptus* at Aracruz reach 40–50 $m^3\,ha^{-1}\,year^{-1}$, in excess of 30 $t\,ha^{-1}\,year^{-1}$ dry matter, over 7-year rotations. Similar extraordinarily high yields can be achieved over 4–8-year rotations by *Eucalyptus* in New Zealand and *Leucaena leucocephala* in Florida and other subtropical regions. Record yields approach 100 $m^3\,ha^{-1}\,year^{-1}$.

During the 1970s, some exaggerated claims were made for the potential yields of poplar and willow in temperate regions. Claims were based on yields in small plots, with large edge effects, which can give yields four to seven times greater than those in extensive commercial plantations. Also, breeding is unlikely to increase biomass yields as much as has occurred in agricultural crops, where yield has been increased largely by increasing the fraction harvested (the harvest ratio) rather than total biomass.

In Sweden, dry biomass yields of coppice willow from well-designed trials average about 8–9 t ha^{-1} $year^{-1}$ in the north-east, 9–10 t ha^{-1} $year^{-1}$ in the east, 11–12 t ha^{-1} $year^{-1}$ in the far south, and peak at 16–17 t ha^{-1} $year^{-1}$ along the west coast. In England, dense plantings of the erect willow clone 'Jorunn' have produced 11–12 t ha^{-1} $year^{-1}$ on 3-year rotations, while hybrid poplar clones have produced 12–14 t ha^{-1} $year^{-1}$ on 4-year rotations on wet sites. Overall, biomass yields of well-tended short-rotation poplar and willow growing on fertile sites in central and northern Europe are likely to be 8–12 t ha^{-1} $year^{-1}$. However, when in extensive cultivation on less-than-ideal sites, yields are lower, often in the range 4–8 t ha^{-1} $year^{-1}$.

Clones of willow, poplar, and other species differ severalfold in yield. Analyses suggest that these yield differences are mainly due to differences in the amount of light intercepted during the growing season, because clones differ in times of leaf emergence, leaf-fall and canopy structure. Early spring foliation is particularly important. Clones differ less in the amount of biomass produced per unit of light intercepted, commonly around 0.8–1.5 g MJ^{-1}, similar to agricultural crops with the same photosynthetic mechanism.

Profitability

Short-rotation pulp production using *Eucalyptus* in tropical and subtropical regions is clearly highly profitable in some locations and has attracted substantial venture capital. The same is true for the short-rotation pulp plantations in countries like Chile, China, India, and Portugal.

The uptake of short-rotation forestry in North America and most of Europe has been more constrained. In England, the only significant power plant to be fueled by willow coppice (ARBRE in Yorkshire) has ceased operation. The obstacles to short-rotation forestry are primarily: (1) the relatively low cost of electricity generated from fossil fuels; (2) the high cost of agricultural land, often inflated by agricultural subsidies; and (3) the lack of an industry infrastructure for handing biomass. The technologies for cultivation, harvesting, and conversion do not seem to be the main constraints, although advances can be made.

Research in many countries has quantified the costs of cultivation, storage, transport, and conversion to electrical energy. Profitability is normally very sensitive to energy prices and coppice yields, provided transport distances do not exceed about 100 km. However, there appears to be a 'catch-22' of investors reluctant to finance tree planting without guaranteed markets or conversion plants without guaranteed feedstock supplies. Some market intervention is required to develop both a level playing field with other land uses and energy sources and to establish industries with a critical mass.

Silviculture

Species and Breeding

As indicated above, a variety of species are used for short-rotation biomass production, the only condition being that they have rapid juvenile growth and coppice readily. The same selection strategies are used as in conventional tree-breeding programs, except the vegetative propagation is normally much easier, so that clones and multiclone mixtures can be selected. Most countries have lists of approved and recommended clones, based on screening for yield and pest and disease resistance.

In Europe and many other regions, *Eucalyptus globulus* is the preferred eucalypt species for short-rotation pulp production.

Poplars are the most universally grown species in temperate regions, being hugely diverse and tolerant of a wide range of conditions. Poplars of the *Aigeiros* and *Tacamahaca* sections respond to nutrient-rich, well-watered conditions and are easily propagated by cuttings, whereas species of aspen belonging to the *Leuce* section root less easily but are tolerant of a wide range of site conditions.

The *Salix* genus is hugely variable and is characterized, like poplar, by hybridization and the selection of clones, several hundred of which have been screened for their potential to produce biomass.

Site Conditions

The idea of short-rotation forestry is to obtain high yields over short periods of time, capitalizing on rapid juvenile growth. That rapid growth will only occur on fertile soils, rich in nutrients and with adequate water. A ready supply of both nutrients and water is required for rapid canopy development and photosynthesis. Former agricultural land, able to sustain arable crops, is ideal, but less fertile grassland can be used with fertilization. The rootable depth should be at least 1 m and, to allow mechanization, there should not be more than 6% side-slope and 10% in-row slope.

Forests, including coppices, use more water than short vegetation because they intercept 10–30% of rainfall, which evaporates from leaf surfaces without reaching the ground. Thus, short-rotation forests have similar effects on local hydrology to high forests, potentially decreasing groundwater and river flows. In Sweden, it has been estimated that the evaporation of intercepted rain accounts for 11% of total annual evaporation. Also, rapid photosynthesis by fast-growing species is always accompanied by high transpiration of water. Poplar and willow coppice transpire about 1 kg water for every 3.5 g of stem-wood produced, so $10\,\mathrm{t\,ha^{-1}\,year^{-1}}$ is equivalent to 286 mm rainfall — allowing for no groundwater recharge. Thus, an adequate water supply is crucial, and areas with summer droughts, or where groundwater supplies need to be sustained, may not be suitable.

Cultivation

The International Energy Agency (Bioenergy) has produced a Production Systems Handbook for Seven European countries and the USA. It provides a decision support system on species, spacing, cultivation, harvesting, and production costs.

It is normally assumed that sites need to be deep-ploughed. As mentioned, the sites need to be fertile enough to support fast-growing broad-leaved species. Willow and poplar grow best on mildly acidic soils with pH 6.0–7.0. Fertilizers are generally required to make good the nutrient losses from harvesting. High nutrition speeds canopy development, maintains a high leaf area index, a low root-to-shoot ratio and high light conversion efficiency. Herbicides are normally needed to suppress ground vegetation and temporary fencing may be needed to protect trees from browsing.

Spacing has little effect on biomass yield, provided a full canopy cover is established rapidly, but it obviously has a large effect on average stem size. A rule-of-thumb is that the optimum spacing is that required to reach the point of self-thinning by the end of the rotation. However, the market determines the type of biomass required and hence the spacing and harvest machinery. For poplar and willow grown for bioenergy in Europe, planting 5000–10 000 cuttings per hectare is recommended, with a rotation of 4–6 years. Rotations of 6–10 years are favored in parts of the USA, with 1000–2500 cuttings per hectare. Very short rotations of 1–3 years are rarely economic because of high establishment costs, weakened stools, and difficulty in handling small stems.

Harvesting

Mechanization is essential and is part of the attraction of short-rotation forestry. Commercial short-rotation forestry harvesting machines are available using single pass cut and chip and whole stem systems. The latter are used to harvest larger stems produced over longer rotations. Harvesting accounts for over half the costs of production, so considerable research has been done to produce dedicated machines. Clearly, harvesters can compact the soil when wet and harvesting is best done in winter when the ground is frozen.

Pests and Diseases

Warnings that clonal plantations of fast-growing species would be vulnerable to outbreaks of pests and diseases have proved to be justified. Pests and diseases have become serious issues in most places where large areas of poplars and willows have been grown in trial plantations. There are around 130 known pest species on poplar and willow and many fungal pathogens. It is uneconomic to apply pesticides or fungicides. However, there are resistant types. For instance, poplar susceptibility to defoliation is roughly in the order *Populus nigra* < *P. trichocarpa* < *P. deltoides* × *nigra* < *P. trichocarpa* × *deltoides* and resistant clones can be found.

In Sweden, gall midge (*Rhabdophaga terminalis*) became a serious pest on *Salix alba*, with the result that this species was rejected from the bioenergy program.

In the UK, willow beetle (*Phratora vulgatissima*) affected over half of the willow bioenergy trials, with very heavy infestations on young trees. Research has identified volatile organic production by the leaves as being related to beetle resistance and semiresistant clones have been selected. Also, it has been shown that mixtures of five or more clones, including resistant clones, slow the build-up of beetle populations.

Fungal pathogens are also a serious problem. Rust (*Melampsora epitea*) is probably the most important factor limiting willow yields in the UK. It is also a serious pathogen on poplar. The fungus expresses great variation in virulence types and specificity to clones, and alternates (spends half its life cycle) on *Larix* (also *Ribes*, *Allium*, and *Saxifraga*). It is therefore wise to locate willow or poplar plantations distant from these alternate hosts. Again, mixed clonal stands delay the onset and progress of the disease and can provide an effective means of control.

Coppicing exposes the stools to infection and particular care has to be taken to treat stumps to inhibit rot fungi.

Utilization

At present, short-rotation forestry can compete, in some instances, with traditional forestry in the production of pulp, especially in the tropics and warm temperate countries. There are also limited markets for poles and stakes, and in the future there may be demand for biomass as a chemical feedstock.

As mentioned, the economics of growing biomass for energy (other than traditional fuelwood in the tropics) is currently uncertain. In most regions, biomass energy is competitive at current fuel prices only if: (1) yields are high; (2) plantations are close to conversion plants; (3) residues and waste materials are used as well as newly grown biomass; and (4) there are, preferably, saleable products from the biomass plantations in addition to bioenergy. It is, of course, possible to establish short-rotation forestry enterprises that produce pulp in the first instance and then make the transition to supply energy at a later date.

Nevertheless, concerns about carbon emissions and future energy security have stimulated considerable research on the potential to produce renewable energy from biomass. The energy content of dry woody biomass is about 18.5 MJ kg^{-1}, regardless of species. Clearly, energy is used to cultivate, harvest, dry, and transport biomass to electricity-generating plants, but this is commonly only about one-twentieth of the energy contained in the biomass delivered to the plant. One tonne of dry biomass contains about 0.5 t of carbon and has about the same amount of chemical energy as 0.5 t of coal (which is carbonized biomass) or 0.44 t of oil or 0.28 t of methane gas. Globally, if 200–400 million hectares of high-quality land were used to grow biomass (14–28% of the current cropland area), with an average yield of 10 t ha^{-1} year^{-1}, it could, theoretically, generate 37–74 EJ year^{-1} (9–18% of current global energy production from fossil fuels), offsetting 15–30% of global carbon emissions. A more conservative estimate of the likely contribution of biomass to global energy supplies by 2050–2100 is 9–37 EJ year^{-1}, requiring 50–200 million hectares. As mentioned, European renewable energy ambitions might require 10 million ha of biomass energy crops by 2010, and there is the potential to increase this 10-fold during this century.

Environmental Impacts

When compared with natural forests, short-rotation biomass plantations are at odds with the paradigm of an environmentally desirable land use. They are even-aged, regularly clear-felled, have no large dead trees and woody debris, and have little recreational value and a limited range of habitats for wildlife.

However, when compared with agricultural land, short-rotation forests offer some benefits and few disadvantages. Increased litter fall can improve soil conditions after some years. Land in the USA, which lost 18 t ha^{-1} year^{-1} of soil by erosion under arable cropping, lost only 2 t ha^{-1} year^{-1} when converted to short-rotation forestry. Compared with arable agriculture, nitrogen leaching to groundwater may be decreased, with less nitrous oxide emission. Short-rotation forests can, in fact, be used for sewage sludge disposal, and as wastewater filters to purify municipal wastewater, landfill leachate, and sewage. In Sweden, wastewater with 160–190 kg N ha^{-1} year^{-1} has been applied to fast-growing willow coppice without substantial nitrate leaching and, in some instances, the trees have taken up heavy metals, reducing levels in soils.

Short-rotation forests can sustain levels of biodiversity that are equal to, although different from, those on farmland. Arthropods are abundant on willows and poplars (sometimes as pests), which support a high bird population. The bird populations in hybrid poplar plantations in the USA are higher than those in crop fields. Short-rotation forests can also be used as cover for game.

Fiber Resources

P J Ince, USDA Forest Service, Madison, WI, USA

Published by Elsevier Ltd., 2004

Introduction

In economics, primary inputs or factors of production define the term 'resources.' Resources include land resources (plants, animals, and minerals), labor, capital, and entrepreneurship. Almost all pulp and paper fiber resources are plant materials obtained from trees or agricultural crops. These resources encompass plant materials harvested directly from the land (wood, straw, bamboo, etc.), plant material byproducts or residuals from other manufacturing processes (wood chips from sawmills, bagasse fiber from sugarcane processing, cotton linter, etc.), and fibers recovered from recycled paper or paperboard.

Some relatively expensive nonplant fibers derived from mineral resources are also used in papermaking (e.g., synthetic plastic fibers) but very small quantities and only in some specialized paper or paperboard products.

Resources derive value from their utility in producing goods or services, but utility varies among different fiber resources and utility varies as technology and product demands shift over time. Different plant fibers have different physical properties that influence their utility in pulping and papermaking. Utility of industrial resources also depends on profitability, or availability of resources at competitive market prices. Market demands for fiber products and supplies of fiber resources vary over time, and thus the market value and utility of fiber resources are variable over time. Some resources have competing multiple uses and alternative values in society. Forest resources have value in producing a range of different wood products, not just pulp and paper products. Forest resources also have alternative values in society because they produce other important services such as recreational, spiritual, environmental, or aesthetic services.

For example, selected species of trees grown in monoculture (single-species) plantations may have high intrinsic value in pulping or papermaking because of uniformity in fiber quality or desirable fiber characteristics, but cultivating trees in plantations can be more expensive than relying on natural regeneration of trees in a forest. The typically more heterogeneous mixture of tree species found in a naturally regenerated forest may have less intrinsic value in pulping or papermaking because of less uniformity or less desirable fiber characteristics, but may have utility in any case because of lower cost. However, a natural forest will likely have high value to society in terms of ecological or aesthetic amenities. Also, advances in plantation systems or biotechnology can yield faster-growing trees or more desirable trees for pulping, which can affect the market value of fiber resources. The actual market values of wood and fiber resources are determined by shifting patterns of resource abundance and overall demand. This article describes various categories of fiber resources used for pulp and paper products, factors influencing their utility and relative market values, and trends in fiber resource supply and demand.

Pulping Processes

Understanding the utility and value of pulp and paper fiber resources begins with an understanding of how fiber resources are converted into products of value to society through modern pulping and papermaking processes. Pulping generally refers to various industrial processes used to convert raw plant materials or recycled paper into a fibrous raw material known as pulp, which is used primarily to make paper or paperboard products (and, to a smaller extent, other products derived from cellulose such as synthetic rayon). Plant materials such as wood, straw, or bamboo generally contain cellulose fibers together with lignin, a natural binding material that holds together cellulose fibers in wood or in the stalks of plants.

Although pulping and papermaking are ancient technologies, commercial pulping and papermaking processes have advanced significantly since the eighteenth century, toward more capital-intensive and increasingly large-scale automated production processes, with continued emphasis on improvement in product uniformity and quality as well as production efficiency. Modern society places considerable value on uniformity of quality and efficiency in production of pulp, paper, and paperboard products. At the present time, most pulp produced worldwide is wood pulp (pulp made from wood that is either harvested from trees or obtained as wood residues or byproducts from other wood-manufacturing processes).

Wood pulps are categorized by pulping process, with two major categories known as chemical and mechanical. Actually both types of processes typically use a combination of chemical and mechanical means to reduce wood into pulp. Chemical pulping relies mainly on chemical reactants and heat energy to soften and dissolve lignin in wood chips, followed by mechanical refining to separate the fibers. Mechanical pulping often involves some pretreatment of wood with steam heat and/or weak chemical solution, but relies primarily on mechanical equipment to reduce wood into fibrous material by abrasive refining or grinding.

The chemical pulping processes involve reaction or 'cooking' of wood chips with a solution of chemicals in a heated digester vessel for an extended period (up to several hours or more) followed by mechanical refining. Principal chemical pulping processes include the alkaline sulfate (or kraft) pulping process, acid sulfite, and semichemical pulping. Mechanical pulping processes include thermomechanical pulping (TMP), chemimechanical (CMP), chemithermomechancial pulping (CTMP), and groundwood pulping. The TMP, CMP, and CTMP processes involve reduction of wood chips into pulp in mechanical disk refiners, usually after pretreatment of chips with steam and/or weak chemical solutions. The older groundwood process involves grinding of wood bolts (small logs) into pulp against a grindstone.

Mechanical and semichemical pulps typically have much higher yield than kraft or sulfite pulps, as measured by weight of pulp produced per weight of wood input (over 90% yield for mechanical pulps and over 80% for semichemical pulp, versus 50% or less for kraft or sulfite pulps). However, kraft and sulfite pulps usually have higher market value because they have higher costs of production and because their fiber quality is usually better and more uniform, with generally less lignin or other wood constituents and proportionately more cellulose fiber and more intact fibers. Kraft and sulfite pulps can be more readily bleached to yield high brightness or whiteness that is desirable in many paper products, and kraft pulp typically produces a stronger sheet of paper or paperboard.

After wood pulp, the second largest and growing share of pulp produced worldwide is pulp made from recycled paper or paperboard. In the recycling process, recycled paper or paperboard is rewetted and reduced to pulp principally by mechanical means, followed by separation and removal of inks, adhesives, and other contaminants, through chemical deinking and mechanical means. Because the fibers in recycled paper and paperboard have been fully dried and then rewetted, they generally have different physical properties than virgin wood pulp fibers (for example, microfibrils on the surface of recycled fibers tend to be collapsed), and a portion of the fibers tends to be broken or damaged because of recycling. Without further processing, these differences in fiber properties would contribute to lower product quality (e.g., weaker interfiber bonding and hence lower strength in recycled paper or paperboard products), while contaminants contribute to lower and less uniform product quality (lower brightness, sheet defects, etc.).

To a large extent modern processing technology can compensate for inherent disadvantages of recycled fiber, but additional processing results in additional costs. Modern mechanical refining is used, for example, to resurrect surface fibrils, and modern papermaking machines and coatings can enhance sheet strength and surface properties, while the efficiency of contaminant removal has been improved by modern deinking systems. The market value of recycled fiber is influenced by intrinsic challenges associated with producing uniform product quality (contaminant removal and differences in fiber surface properties), challenges that can be overcome, but at a cost.

A smaller but still substantial volume of pulp is made from non-wood plant fibers, including agricultural fibers such as straw and other plant fibers such as bamboo, bagasse (residual of sugarcane refining), and annual fiber crops such as kenaf. In general, non-wood plant fibers are more costly to collect and process than wood fiber in regions of the world where wood supplies are adequate, and thus pulp is produced almost exclusively from wood fiber in most regions of the world. However, substantial quantities of non-wood pulp are produced in regions of Asia and Africa where wood fiber is relatively less abundant and non-wood fibers are available. **Table 1** summarizes estimated global pulp production in the year 1999 by principal category, and by major region.

The estimated 1999 worldwide total pulp production was 304 million metric tons (including pulp from recycled fiber). This compares to worldwide paper and paperboard output of 315 million metric tons in 1999. There is a difference between the output tonnages because many paper products contain the added weight of coatings, additives, or fillers, such as clay coatings on coated printing papers. In addition, there are some minor losses of pulp in conversion into paper or paperboard, and also a small fraction of pulp production (around 1%) goes to products other than paper or paperboard

Table 1 Global pulp production by category and region, 1999, in million metric tonnes

Region	*Chemical wood pulp*[a]	*Mechanical wood pulp*[b]	*Recycled pulp*[c]	*Nonwood pulp*[d]	*Totals*
Europe[e]	28.3	14.6	36.3	0.5	79.7
North America	66.1	16.3	35.7	0.2	118.3
Asia[e]	17.8	2.3	44.9	15.2	80.2
Australia and New Zealand	1.0	1.2	1.7	0.0	3.9
Latin America	9.9	0.4	6.9	1.1	18.3
Africa	1.7	0.3	1.3	0.7	4.0
World totals	124.8	35.1	126.9	17.7	304.4

[a] Chemical pulp includes sulfate (kraft), sulfite, and semichemical pulp.
[b] Mechanical includes thermomechanical, chemithermomechanical, and groundwood pulp.
[c] Recycled inferred from paper consumed for recycling, adjusted for yield estimate (~88%).
[d] Nonwood includes pulp from straw, bamboo, and various agricultural plant fibers.
[e] Data for Europe include all of Russia; data for Asia include all of Turkey.

(such as dissolving pulp used to produce rayon or other cellulose synthetics).

Papermaking

The utility and value to society of paper or paperboard products depend on their physical properties, such as the strength of paperboard used in corrugated containers, the softness and absorbency of tissue paper, or the smoothness and printability of paper used for printing or writing. Papermaking, the process of making paper or paperboard products from pulp, has been described classically as a felting process, in which a mat of randomly distributed pulp fibers is formed and then pressed into a sheet and dried. Variation in modern methods of sheet forming, intensity of pressure and energy applied in sheet pressing, and other process variables strongly influence physical properties of the finished sheet, which can range from the soft and absorbent properties of modern facial tissue to the rigid strength properties of modern containerboard.

Products of a felting process derive strength, integrity, and other physical properties differently than other common fiber-based products, such as woven products (e.g., textiles) where intertwining of fibers into threads and weaving of threads into fabric provide strength and integrity, or composite fiber products (e.g., fiberglass) where an adhesive or bonding agent combines with fibers to provide strength and integrity. The strength and integrity of finished paper or paperboard products depend on random interlacing and weak (nonchemical) bonding among fibers, and this is influenced by the papermaking process and by the inherent properties of individual pulp fibers, such as fiber length, flexibility, and fiber surface properties. Other paper properties such as sheet smoothness and printability are also influenced by fiber properties, such as the length and stiffness of individual fibers.

There is substantial variation in fiber properties among different plant species, and different types of pulp fibers have distinctly different physical characteristics, which influence the quality and utility of fiber resources in papermaking. For example, wood fibers from softwood (coniferous) trees are generally longer and more flexible while wood fibers from hardwood (deciduous) trees are generally shorter and more rigid, properties that tend to give quality advantages of sheet tensile strength to softwood fibers but sheet smoothness and printability to hardwood fibers. Chemical pulps generally afford stronger and more uniform sheet properties than mechanical pulps, and chemical pulps are more easily bleached to a high degree of whiteness or brightness, but chemical pulps generally have lower yield and are more costly to produce. Pulps made from recycled paper are generally associated with some degradation of fiber properties or more fiber breakage relative to virgin fibers, and use of recycled materials also introduces contaminants (inks, adhesives, etc.). Variations in quality and characteristics of fiber resources can thus substantially influence the market value of various fiber resources.

Paper and paperboard products serve several primary categories of end uses, each of which subtends a fairly unique range of functions and product requirements. Primary end uses for paper and paperboard include: (1) printing and communication, with requirements for sheet smoothness, brightness, and printability; (2) packaging and wrapping, with requirements for strength and protection at the most affordable cost; and (3) sanitary products with requirements for absorbency, bulk, and softness. Although these product characteristics depend directly on properties of individual fibers and the source of fiber raw material, they also depend on characteristics of the papermaking process.

The physical properties and hence the utility and value of paper or paperboard products can be greatly enhanced or influenced by the papermaking process, or by subsequent processes of sheet coating or finishing. In some cases this can partially or wholly overcome inherent limitations of certain fiber resources or pulp categories. The techniques used in sheet forming, pressing, and drying can influence properties such as sheet strength and smoothness. For example, softwood fiber was historically preferred in products where sheet strength was highly valued, such as in linerboard (paperboard used in corrugated boxes) because the longer and more flexible softwood fibers inherently provided more interfiber bonding and sheet strength. However, advances in sheet pressing and drying technology (higher-intensity pressing, extended presses, and multilayer forming) have significantly improved interfiber bonding and thus advanced the strength properties of linerboard made from recycled fiber and even hardwood fiber.

Other advances in sheet forming, pressing, and drying have enhanced physical properties such as softness and absorbency in tissue paper products, while the smoothness of printing paper has been improved by additional press finishing or supercalendering. Likewise, applications of coatings, pigments, and fillers have enhanced the quality and economy of printing, publishing, and packaging paper products. With advances in papermaking technology, improvements in product quality and uniformity have been achieved while expanding the use of lower-valued fiber resources.

Fiber Markets

Demands for pulp and paper fiber resources are derived from society's dependence on paper, paperboard, and related products for human welfare and prosperity. Society has come to depend on paper and paperboard products for many purposes integral to human welfare and prosperity, including education, information storage, and product advertising (in pages of books, magazines, catalogs, newspapers, and countless other forms of printed media or written communication), protection, transportation and security of goods in transit and in storage (in corrugated boxes and shipping containers, food packaging, and an enormous variety of other packaging and industrial applications), and protection of human health and sanitation (via tissue and sanitary paper products).

Although there is a direct correspondence between demands for pulp and paper fiber resources and the demands for paper and paperboard, there is not such a direct correspondence between trends in value or prices of fiber resources and trends in paper or paperboard commodity prices. **Figure 1** illustrates, for example, historical trends in the US average real price indexes for pulpwood, recovered paper (wastepaper recovered for recycling), and paper and paperboard commodities.

As shown in **Figure 1**, the real price index for paperboard commodities increased in the 20-year period from 1982 to 2002, ending the period up by about 25%. Likewise, the real price index for paper commodities increased over the same period, ending the period up by about 10%. The real price index for recovered paper (wastepaper recovered for recycling) was much more volatile (plotted against the right axis in **Figure 1**), although trends in the price index for recovered paper generally followed the trends for paper and paperboard over the same period, and also ended the period up by more than 40%. The real price index for pulpwood exhibited considerably different behavior over the same period, and by the end of the period had declined by more than 40%. The variation in price behavior among these different indexes reflects the role of different market forces influencing market prices.

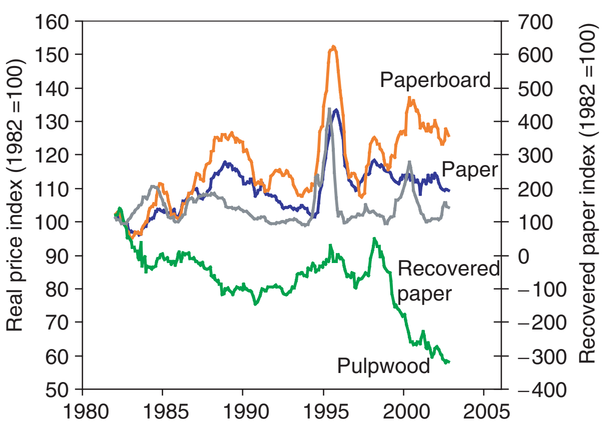

Figure 1 US real price indexes for pulpwood, paper, and paperboard, 1982–2002. Paper, paperboard, and pulpwood indexes plotted on left axis, recovered paper index plotted on right axis.

The variable price history of paper and paperboard commodities is primarily a function of variation in product demands in relation to available production capacity (the output capacity of paper and paperboard mills). To some extent there is a reflection of trends in fiber resource prices in the trends of paper and paperboard prices (**Figure 1**), but the variation in paper and paperboard prices is more strongly influenced by variation in demands for paper and paperboard commodities and by capacity utilization. Paper and paperboard commodities are used widely throughout society in virtually all sectors of the economy – domestic, institutional, commercial and industrial. Thus the trend in overall demand for paper and paperboard tends to be correlated with cyclical trends in broad indicators of economic activity, such as overall industrial production and per capita gross domestic product (GDP). The production capacity of mills that produce pulp, paper, and paperboard commodities establishes the short-run supply potential, with actual production varying in response to market demand. The ratio of actual production to available capacity (capacity utilization ratio) is a key determinant of product prices, with prices tending to be high when capacity utilization is high and low when capacity utilization is low.

The market value or price of fiber resources also tends to be influenced by the demand and price situation for paper and paperboard, and this has been particularly true for recovered paper prices (**Figure 1**). However, there are other important market forces that influence the supply of fiber resources, and thus the trends in market value for fiber resource do not precisely follow the trends in paper and paperboard prices. Indeed, for pulpwood in the USA (and in some other regions) the price trend has been opposite to the trend for paper and paperboard prices (i.e., downward as opposed to upward, as shown in **Figure 1**). Fiber resource supply tends to influence the market value of fiber resources as much as fiber resource demand, and fiber resource supply varies over time depending on such factors as the periodic volume of timber growth and availability for harvest, the area of forests or plantations managed for pulpwood production, and trends in recovery of wastepaper for recycling.

In the USA, for example, in the period between 1982 and 2002 there was a significant increase in the recovery of wastepaper for recycling, particularly during the period from the late 1980s to the early 1990s, reflected in a period of relatively depressed real prices for recovered paper (**Figure 1**). By the mid-1990s, however, the utilization of recovered paper had increased substantially, both in domestic paper and paperboard mills and in foreign mills that were increasingly importing recovered paper from the USA. Thus, in the mid-1990s the increased demands for recovered paper (domestic and export) helped to stimulate a significant spike in recovered paper prices. However, with the rapid escalation in US recovered paper prices, export demands subsided and prices rapidly declined. The mid-1990s' price spike in recovered paper markets also coincided with a price spike for paper and paperboard commodities, induced in part by speculative purchasing of market pulp and by relatively strong demands for paper and paperboard during the mid-1990s. Pulpwood prices also showed some firmness in the early to mid-1990s, but pulpwood prices in the USA were eventually dominated by expanding supplies of timber with expansion and maturation of pulpwood plantations, particularly pine plantations in the South USA, where millions of additional hectares of pine plantations were established in the 1980s and 1990s. In addition, the increased use of recycled fiber (which more than doubled in the USA during that period) also tended to offset growth in pulpwood demand and dampened the trend in real pulpwood prices.

Trends in Fiber Resource Supply and Sustainability

Although global demands for pulp and paper fiber resources have been increasing and are expected to continue increasing in the future, the available supply of fiber resources has likewise been increasing, and both supply and demand appear increasingly sustainable into the foreseeable future. In part this is because consumption of paper and paperboard products is not rising exponentially in developed countries such as the USA, but rather consumption is decelerating (continuing to grow but at a slower pace over time) with declining consumption per unit of GDP. Also, there remains vast potential to increase output from fiber plantations worldwide, and there is potential to increase paper and paperboard recovery for recycling. Indeed, in recent years (since the mid-1990s) pulpwood and recovered paper prices have been subsiding globally.

In the USA, which produces and consumes more pulpwood by far than any other country, wood pulp production declined by 12% while consumption of pulpwood at wood pulp mills declined by approximately 15% from the mid-1990s to 2001. Real prices of softwood pulpwood in the USA also declined in recent years, with prices in the South USA (the principal production region) declining to the lowest recorded levels in modern history (several decades over which pulpwood prices have been surveyed and reported). Pine plantations in the South have the potential to supply significantly greater volumes of fiber in the future, although expansion of supply may be inhibited by low prices and limited growth in demand.

Although paper and paperboard production and demands for fiber resources are going up in other developing regions of the world, such as in Asia and Latin America, global development of fiber resources is keeping pace with capacity expansion. China, for example, is experiencing fairly rapid economic growth, with expanding production capacity in modern papermaking facilities, but mills in China are able to rely in the near term on expanded wood pulp production in East Asia (in countries such as Indonesia) as well as global supplies of market pulp and recovered paper. For the future China can also rely on indigenous sources of fiber supply, having established a larger area of tree plantations than any other country.

Globally, wood fiber supply has expanded with the expansion of fast-growing plantations of species such as pines, eucalyptus, and acacia. Although plantations have in some areas displaced native forests, managed plantations account for only a small fraction of forested land area (e.g., only 6% in the USA, for example). Plantations generally have a potential to supply a much greater volume of wood fiber per unit of land area than unmanaged or native forests, and thus the use of a small fraction of land area for plantations can offset the harvest of pulpwood on large areas of forest. Environmental certification of forests and forest plantations has expanded globally over the past decade and is now common in many areas of the world, with increased emphasis on preventing illegal logging and encouraging sustainable forestry practices. Managed plantations are an integral part of ensuring the sustainability of forest resources in the future. Globally, plantations are expected to increase their share of total wood production from around 20% to upwards of 50% by 2050.

The recovery and use of paper for recycling have been on the increase, as the proportion of fiber obtained by recycling has been increasing. Globally, recycled fiber accounts for well over 40% of pulp fiber (**Table 1**), and some countries have achieved much higher rates (over 50% in Japan and around 60% in Germany). Although product needs and capacity growth may constrain the use of recycled fiber in some cases, there is still the potential to expand its recovery and use in the future.

Chip Preparation

W S Fuller, FRM Consulting, Federal Way, WA, USA

Introduction

Wood chips used in pulp mills are small, engineered pieces of wood cut from logs and wood pieces left over from the manufacture of solidwood products such as lumber and plywood. The target dimensions of a chip are usually 4–6 mm thick, 15–20 mm in length and width (**Figure 1**). This is the size range that will allow most batch and continuous chemical and mechanical pulping systems to reduce the wood uniformly to individual fibers and fiber bundles. There is no 'perfect chip' since wood variability does not allow consistently making the same chip over and over. There is an ideal chip size distribution that matches the needs of the mill's digester(s). This article will describe the process of making chips that meets the specifications of pulp mills. The basic chip production processes are:

Figure 1 Typical pulp chips sampled after going through the chip screen system.

- debarking of logs increases pulp yield and cleanliness
- chipping of logs and wood products residuals makes small particles (called chips) in as uniform size distribution as possible
- chip screening removes fines and oversize chips to improve pulping uniformity
- prevention of contamination of chip flows with metal, rocks and especially, plastic
- chip transportation and storage systems receive, store, convey, and meter chips without damaging them
- quality control programs monitor chip production and deliveries.

Mill Layout

The area in the mill that logs and chips are received, stored and processed is called the woodyard. The building or structure that contains debarking, chipping, and screening equipment is the woodroom. In cold climates, almost all the functions are contained in heated buildings to prevent freezing of equipment and people. In more temperate zones, only a sheltering roof is used to protect the chipper and screen from rain.

The goals of the woodyard and woodroom organizations are to:

- produce chips that are not only the right size for the mill's digesters, but also have very low short-term variability (i.e., hourly and daily)
- deliver chips to the pulp mill that have little or no contamination and a bark content that is below the mill's tolerance level
- manage the inventory of logs and chips at target levels that do not create a loss in chip value from deterioration in storage
- monitor the quality of chips received at the mill, made in the wood room and delivered to the digester with sampling and testing frequency consistent with the use of the data for decision-making.

Debarking

Bark is essential for a tree's growth and health. It is a protective layer around the wood that resists drying, attack by molds, wood staining and rotting fungi,

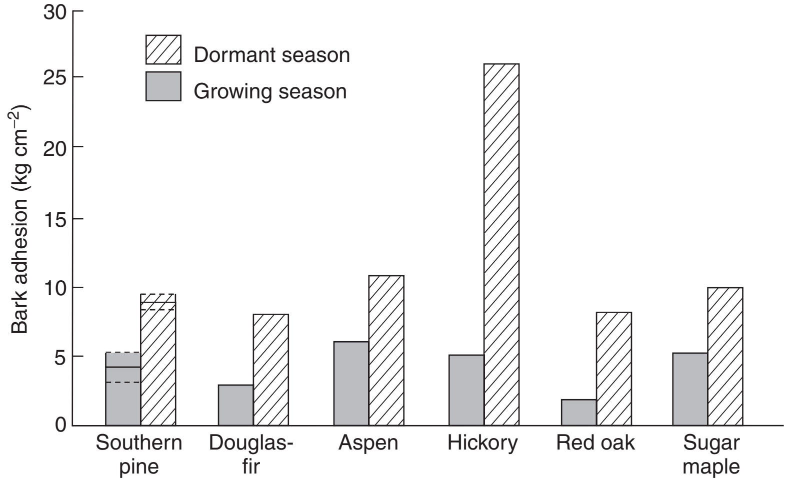

Figure 2 Comparison of bark adhesion for several common North American pulpwoods showing the difference between the tensile force required to remove the bark in dormant and growing seasons.

and most insects. Between the wood and the bark there is a single growth layer called cambium. This single cell layer is where tree growth occurs. Bark is formed toward the outside of the tree and wood to the inside. During the growing season, this layer breaks easily and bark is removed with little force. However, during the dormant, winter season, the bark and the wood are tightly bonded together by the inactive cambium layer and more force is needed.

The mechanism of bark removal is applying enough force to break the bond between the bark and the wood. The amount of force has been quantified for the most common North American wood species for both dormant and growing season conditions. **Figure 2** shows that bark adhesion approximately doubles in the winter for most wood species. In the industry, it is well known that debarking hickory (*Carya* spp.) is almost impossible in the winter and the data shows its high bark adhesion. At the other extreme, the bark of some hardwoods, like poplar (*Populus* spp.), is so loosely attached in the spring that it easily falls off in big sheets that are difficult to convey and process into wood waste fuel.

Other factors also influence the ability to remove bark. Thick bark absorbs energy and requires more time or force to remove it. Logs dry out after long storage times and the bark bonds to the wood more tightly.

There are two primary types of equipment to apply the force needed to remove bark from logs. In sawmills and plywood plants, mechanical ring debarkers are most common. **Figure 3** shows how debarking tools surround and rotate around each log. The tools are sharp and press against the log. The bark is peeled off the log and drops down to a

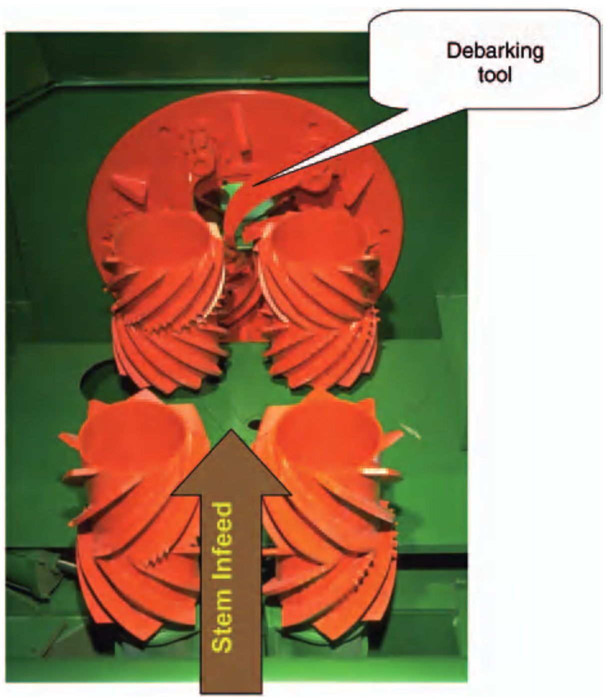

Figure 3 Mechanical 'ring' debarker. The debarking tool pressure on the log surface is adjusted for the diameter, storage time, and season.

refuse conveyor going to the wood waste fuel or bark products processing systems. While the linear speeds of the debarkers now reach 150 or more meters min^{-1}, this type of debarker can economically prepare logs for sawing or peeling.

In pulp mill woodyards, large drum debarkers ranging from 4 to 8 m in diameter and over 60 m long can debark up to 100 to 250 cm^3 of logs h^{-1} (**Figure 4**). Wood comes to pulp mills in two forms, shortwood and longwood. Shortwood tumbles

Figure 4 Long-log drum debarkers in an area with cold climate where equipment must be enclosed for winter operation.

randomly and longwood rolls in parallel against each other as the drum turns. The drums rotate at 6–10 rev min^{-1}, adjustable in more modern installations. Logs are fed into the open infeed end of the drum and the level is optimally about 50% full. Since the drum outlet is about 1 to 2 degrees lower than the infeed, the logs move down the drum. An adjustable vertical, horizontal, or elliptical discharge gate controls the rate of debarking. Operators control the residence time in the drum by adjusting the feed rate and the gate position. The tightness of the bark determines how long the wood must stay in the drum to keep the bark levels below the mill's tolerance levels. During the spring and early summer, it typically takes half an hour or less to reduce bark levels to well below 1%, depending on log size and species. In autumn and winter, the residence time may need to be as long as 1 hour to achieve the same low bark levels. However, long residence times will cause excessive wood loss as the logs hit each other and the walls of the drum. A balance must be achieved so that wood loss is controlled and bark levels are near the tolerance limit. The bark tolerance level varies between mills depending on the wood species, bleach sequences used, and customer demands for clean pulp and paper. In a survey of North American mills, a bark tolerance level in the range of 0.5–2% was typical. High debarking efficiency with low wood loss will achieve one of the primary objectives of the woodyard in reducing the bark content below the tolerance limit of the mill.

Chipping

Pulp mill chips are produced either in a pulp mill woodroom at a wood products mill, and most commonly, at both. The basic chipping mechanism is the same for each, but the difference in the wood sizes and shapes requires different sizes and types of chipper systems. Sawmill waste chipping is more challenging since the infeed material varies widely in size and shape (**Figure 5**). In general, woodroom chippers will be larger in diameter (1.8–3.1 m) than sawmill chippers (1.2–1.8 m). The life expectancy of a woodroom chipper is 30 years or more, while sawmill chippers are lighter duty construction and have a 10–15-year life.

Figure 5 Sawmill chipper infeed. Vibratory conveyors are commonly used to convey sawmill waste to chippers. The size and shape of sawmill by-products varies widely. Some flows are relatively uniform (a) while others contain long slabs, trim blocks, and chip screen oversize (b). uniform sawmill chipper feed material produces more uniform chips.

The basic chipping mechanism is a sharp knife passing through the wood, cutting across the grain (**Figure 6**). There is first a cutting action and as the knife continues to move into the wood a shearing action that pops off chips. This continues until the knife has cut completely through the log or piece of wood when the next knife begins its cut. Chippers have multiple knives mounted on a disk or a drum. The disk chipper is the most common (**Figure 7**). A slot is cut radially through the disk so that the chips will exit from the back of the disk after being cut. The knives are mounted at each of these slots with a clamp mounting or a face mounting (**Figure 8**).

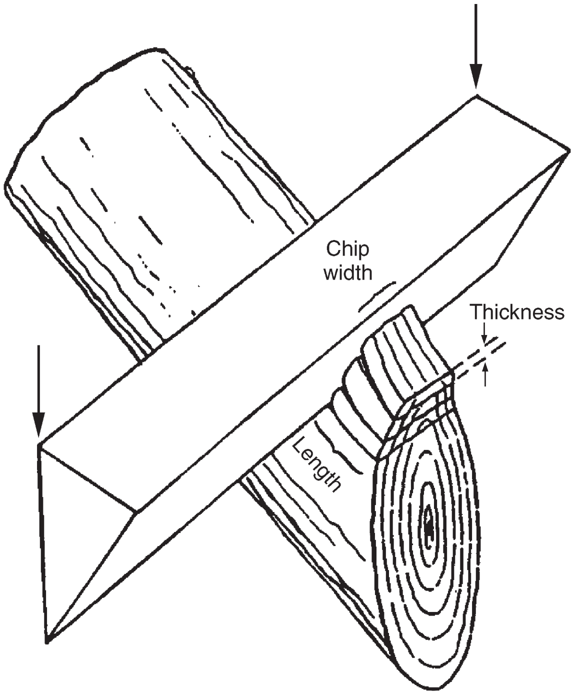

Figure 6 Chip cutting action. Only the chipper knife and log are shown in this drawing of how chips are formed as the knife passes through a log. The knife cuts the wood off at the desired length. As the knife continues into the log, it creates shear forces that pop off a chip at the designed thickness. As chip length increases, chip thickness also increases.

A woodroom chipper infeed system has these basic parts: (1) an infeed conveyor moves the logs from debarking to the chipper; it is usually a heavy link chain, heavy-duty rubber belt conveyors or a combination of the two; (2) the infeed chute guides the wood from the conveyor to (3) the chipper spout at the disk face. The chute is commonly at a 38-degree angle to the disk. The chute can be oriented to feed the wood by gravity or pulled in horizontally by the knives (**Figure 9**).

A disk chipper has 4–12 clamp-mounted knives positioned radially along slots that pass through the chipper disk. The chips will go through the disk after the knife cuts them off the log. Mounted on the back of the chipper disk are fanlike blades that catch the chips and blow them out of the top of the chipper hood. Without these blades, the chips fall onto a conveyor below the chipper. This is a bottom discharge compared to the overhead or blown discharge. The blades often have protrusions that break up the ribbon or card of chips that pass through the disk.

The layout of sawmill residual chippers is quite similar to a woodroom except that the material chipped is much smaller and has a wide variety of sizes (**Figure 5**). Sawmill chipper infeeds can be at either a right angle to the chipper shaft or as in some newer sawmill systems, the disk is tilted over the infeed chute, exerting more pull-in and hold-down forces on sawmill residuals or small logs.

Chipper maintenance is critical in producing an optimum chip size distribution. Maintaining the designed wood to knife interface requires daily, weekly, monthly, and yearly inspections and replacement of parts when the wear limits are exceeded. Most wear points can be checked during knife changes. Chipper knives can wear quickly depending on the tonnage being chipped, the wood species, the moisture content of the wood, and the amount of rock and metal contaminants that reach the chipper. Simple wear only requires grinding, but grinding done carefully so that correct knife angles are restored and metallurgy not altered by overheating. Other key wear areas are the anvils, bed knives, and face plates. Deciding the timing for knife changes depends on the rate of wear, the chip quality needs, and the times the mill making chips or the woodroom is down for enough time to change knives and inspect the chipper without losing production time. Shift changes and meal breaks are such times. The best way to decide when knife changes are needed is by tracking the chip quality. There is a gradual increase in pin chips and fines after a knife change. Depending on the mill tolerance for small particles and screen capacity, a tonnage or time for knife changes is decided based on chip quality and normal downtime schedules.

A 'disposable chipper knife' has become popular in the last 10 years. These knives have two chipping edges, are in segments about 40–60 cm long and are turned around and relocated on the disk in a pattern that takes advantage of the fact that some zones get more chipping action than others. **Figure 10** shows a cross-section of a disposable knife, knife holder and method of mounting the knife.

Chip Screening and Cleaning

Each pulping system operates best with a specific chip size distribution. Finding that distribution is

Figure 7 (a) Horizontal feed disk chipper and approx. 50 cm diameter fiber log; (b) gravity feed disk chipper and 15–20 cm diameter shortwood; (c) horizontal feed disk chipper and approximately 30 cm diameter fiber logs; (d) drive side view of a horizontal feed disk chipper; note the straight line design from the drum to the feed that eliminates log transfers and plug-ups; (e) chipper operator changing chipper knives; required safety equipment is being worn and a holding device has been made to reduce the risk of cuts while handling the newly sharpened knife; (f) the back side of a chipper with card breakers during a knife change; note that the chipper slots have been lined with a wear plate to prevent disk damage over time.

done with well-planned mill trials, pilot scale trials at a screen manufacturer's facility, applying information reported at a conference, literature searches or simply by observing how the day-to-day operations fluctuate as chip quality changes. These are listed in the order of likely success. Given an optimum size distribution, a chip screening system can be designed that meets the mill's needs. The size fractions most commonly removed from a chip flow are over length, over thick, pin chips, and fines (as defined by a Chipclass classifier in **Figure 11**). A well-designed screen system will remove a target size at high efficiency with low loss of good fiber.

The goal of a pulping system is to make pulp at the highest yield possible, with low variability the pulp properties that meet the customer needs. One of the most important contributions a woodroom can make to pulp mill operations is narrowing the chip size distribution after everything has been done to make optimum chips in the woodroom, sawmills, satellite chip mills, and plywood plants. Pulp chip screening equipment is designed specifically to remove and often reprocess the extremely large and small chip sizes.

There are several classes of chip screening equipment:

1. Rotary or gyratory screens. Although the first type of chip screens to be used in woodrooms, these screens are still used alone in sawmills or in combination with some of the more recent screening concepts in woodrooms (**Figure 12**). This type of screen segregates chips on the basis of length or width using flat punched steel plate or woven wire mesh stacked up to three or more decks. The circular or elliptical motion of the screen is in the horizontal plane of the plates. The top deck has the largest square, circular, oval, or rectangular openings 40–60 mm in diameter, length, or diagonally. Oversize chips are rechipped in a small drum or disc chipper. To remove the smaller fractions, plates or steel mesh with 4–6 mm round or square openings are placed in the bottom deck of the screen. The screening efficiency of this type of screen is relatively low. Typically, the small fraction removal efficiency is

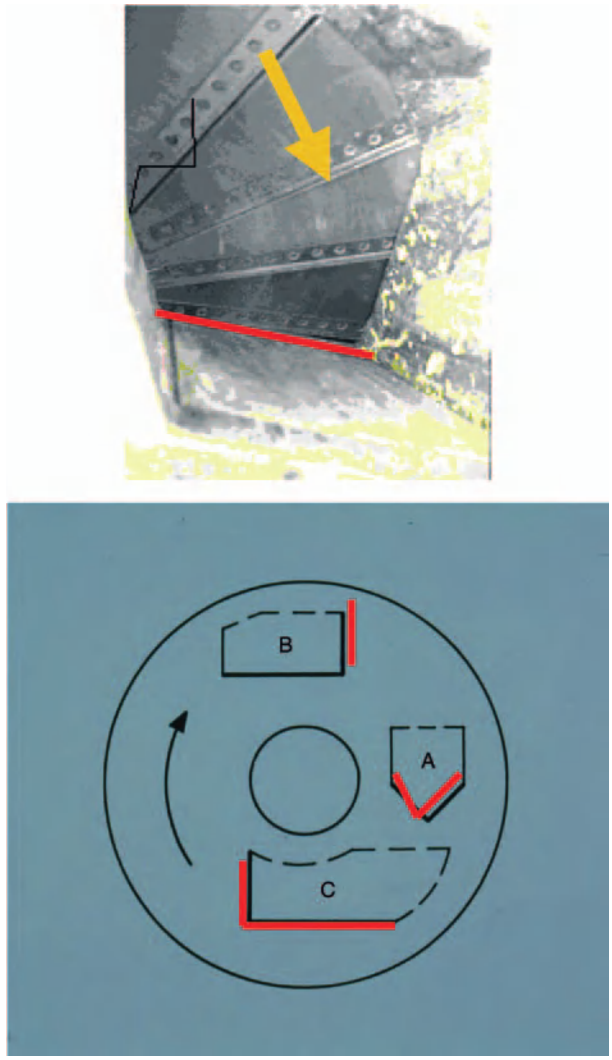

Figure 9 Spout location is a key part of chipper design. The picture shows a chipper spout with the direction of rotation marked with an arrow. The anvil location is marked with a red line. This design keeps wood in the lower right corner for uniform chipping. The sketch shows typical anvil locations of other designs: (A) a gravity feed with anvils at both of the bottom edges, (B) a horizontal spout overshaft with a vertical anvil, and (C) a spout undershaft horizontal feed with bottom and side anvils. Design (B) is not recommended for roundwood applications since the wood is lifted up against the force of gravity and wood (logs or sawmill residuals) do not remain stable.

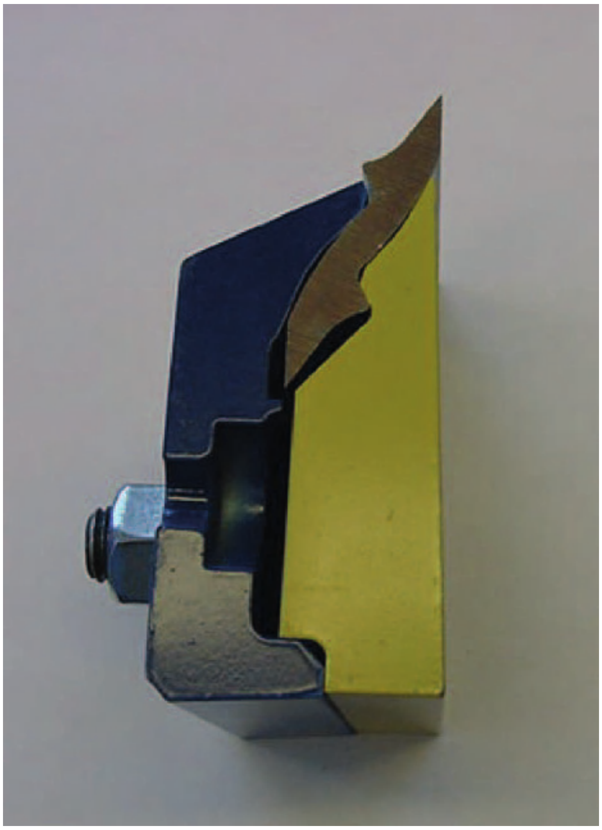

Figure 10 A cut-away section of a disposable chipper knife clamped into a knife holder that is then bolted into the knife pocket. Note the two chipping surfaces that allow the knife to be turned over when one side becomes dull.

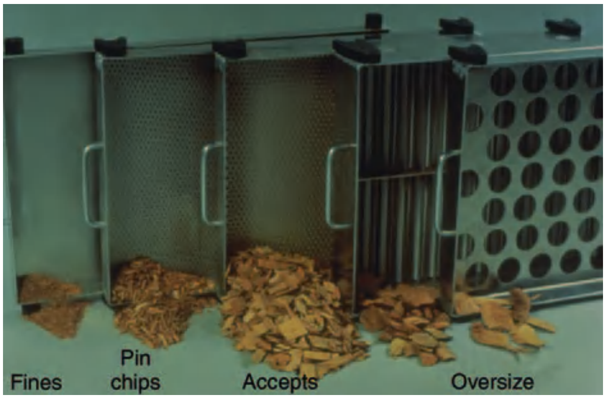

Figure 11 Chip classifier tray series that relates to pulping and chip handling operations. Oversize undercook, causing high dirt levels due to uncooked wood in the center. Feeders and chip chutes can plug due to long oversize. Pin chips can impede digester liquor circulation in high or highly variable amounts. Fines contain fibers that are too small to make good paper and contain high amounts of dirt and bark contaminants.

no more than 50–65%. A rotary/gyratory screen is usually a component of a multiscreen woodroom screen house and due to its simplicity, is used in sawmill and veneer plants.

Figure 12 A typical gyratory screen. Note that the round holes are larger in the feed end of the screen and smaller at the discharge end. This has been used to increase screen capacity, but actually reduces removal efficiency.

2. Disk screens. In the 1970s the industry became increasingly aware that chip thickness was as or more important than chip length. The disk screen is designed to remove over thick chips. A series of parallel shafts at a 90 degree angle to the chip flow have thin disks spaced uniformly and rotate in the same direction. The disks alternate and overlap so that the interface opening between opposing disks is in the range of 6 to 10 mm (**Figure 13**). Unscreened chips are evenly fed across the first rows of disks and the rotating motion moves a mat of chips down the screen with the help of undulations or serrations on the disk edges. The thinner, acceptable chips and small particles fall between the disks while the over thick and over length ones drop off the end of the screen. High screening efficiency always translates to some near-size acceptable chips staying with the rejects. During the process of treating the rejected oversize and carry-over of unacceptable chips, some of the fiber loss will be recovered. Disk wear is a significant issue for disk screens. Periodically, the interface openings should be checked with calipers and chip samples taken to determine the overall system efficiency. In areas where sand contaminants are found, the interface opening is increased in as little as 18–24 months. Some early attempts to screen out small particles with disk screens were commercially unsuccessful due to plugging, sensitivity to chip moisture content, and wear.
3. Roll screens. The development of roll screens to segregate both large and small particles has provided greater flexibility in screen system design and operation. The rolls are arranged with their shaft at a right angle to the chip flow. The roll surface is machined to form a pattern of diamond

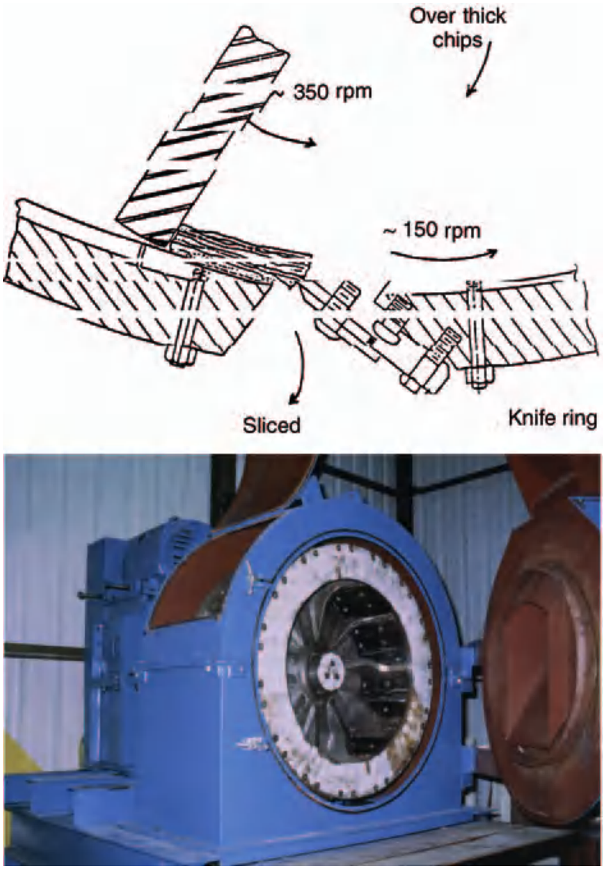

Figure 13 Chip slicing. The two rings in the slicer rotate in the same direction, but the inside ring brings the chips to the knife at a faster speed than the knife ring is rotating.

shaped peaks and valleys (**Figure 14**). The inter-roll opening is adjustable from 1.5 to 8 mm. Thickness screening is possible using the inter-roll opening to reject over thick and over length chips. The application of roll screens to fines screening and pin chip recovery provides the ability to tune the system by adjusting both the roll speed and the spacing. This is particularly important in responding to the higher pin chip and fines content produced by chippers in the winter months. Over time, the mix of sawmill chip supplying a mill will change and with it the average size distribution. The adjustability of roll screens provides the unique opportunity to respond to change without the high cost of system rebuild.

4. Bar and blade screens. Another way to provide an interface opening through which oversize chips cannot pass is the arrangement of segments of bars or thin blades that oscillate the length of the screen to move the chips down the screen and separate the over length and over thick chips. Wear is much slower in the bar screen than any other.

Over length, over thick, and accept chips rejected by thickness screens need treatment before they can be put back into the chip stream. The composition of the over length and over thick chips is dominated by wood knots and the distorted wood around branches. A few wood and pulping experts contend that the wood in these oversize categories is very high in compression wood and therefore should be diverted into the mill fuel system. Very few mills have analyzed this option and most mills continue to reprocess the oversize material to make it pulpable. The options available for rechipping and oversize treatment include:

1. Rechippers. Both disk and drum versions of rechippers are available. Disk rechippers are 1–1.5 m in diameter. Both horizontal and gravity feed are common. Tests have shown that it may take as many as three to five passes before a rechipper will reduce some oversize pieces to a size that will be accepted in rescreening. Fines production is increased by rechipping from random cutting and repeated recycling. The inadequacies of a rechipper has encouraged the development of better options, particularly since thickness screening implementation began in the 1970s.
2. Chip slicer. A machine that normally makes flakes for the production of flakeboard has been adapted to slice over length and over thick chips to a thickness that will pulp more easily (**Figure 13**). Oversize and carried-over accept chips are fed into the center of a drum surrounded by two concentric rings. Slicer knives are mounted on the inside of the outer (knife) ring that turns at about 150 rpm and in the same direction as the inner or anvil ring. At about 350 rpm, the inner ring anvils sweep the oversize material into the slower moving knives. A slice is taken at the target chip thickness (6–8 mm). As long as a rock or metal contaminant does not damage the knives, slicers have operated for 6 to 8 weeks before a knife change was needed. Four weeks is about average.
3. Chip crackers or conditioners. The poor pulpability of oversize material is due to the inability of pulping liquor to penetrate the chip. In laboratory studies, it has been observed that large chips that have partially separated during chipping will pulp almost as well as accept chips. It follows that if fissures can be created in oversize chips, liquor penetration should be sufficient to achieve pulping. This has been commercialized in chip crushers or conditioners (**Figure 14**). The oversize chips drop through the nip between two large rolls turning toward each other. There is pressure applied to prevent the nip from opening

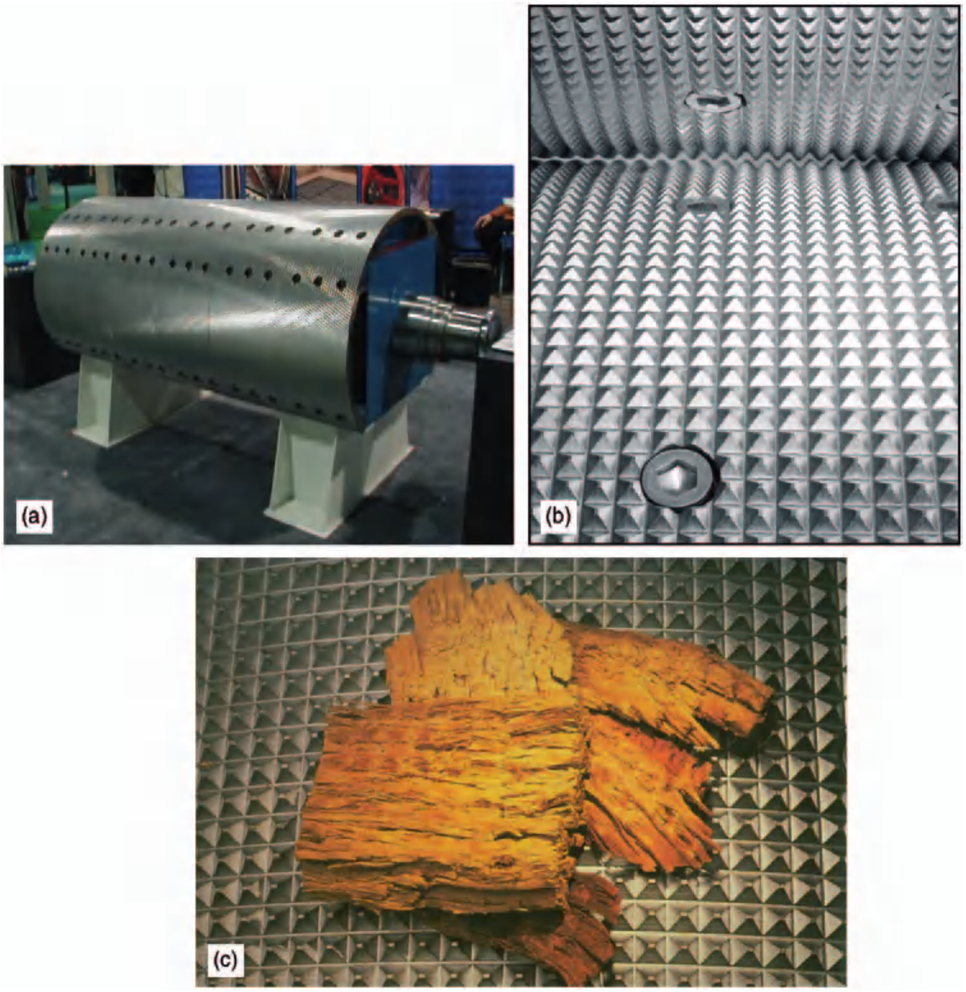

Figure 14 Chip cracker or chip conditioner. (a) One of the pair of rolls in the system; (b) close-up of the inter-roll opening; (c) examples of oversize after going through the roll opening. Note how the large chips are fissured by the crushing force and the roll surface.

when several chips go through at the same time. There is less maintenance since there are no knives to sharpen. The roll surface metallurgy resists abrasion and the occasional wrench. As with chippers and slicers, there needs to be protection from the occasional tramp metal and rocks that find their way into chip supplies.

Wear and equipment damage is a major problem in rechipping, slicing, and crushing oversize chips. Rocks and metal debris are particularly troublesome. Since both of these materials sink in water, running the oversize through a chip washer or settling basin will eliminate this problem. Sand and grit can be removed in a chip washer in much the same way as rocks. Mechanical pulping systems almost always have chip washers to reduce wear in the primary refiners.

In regions where freezing conditions preclude the use of water as a separation medium, air density separators have been highly successful. The oversize chips are fed into a vertical pipe that contains upward flowing air from a blower system. By adjusting the air flow, denser rock and metal debris will fall out of the oversize chip flow onto a conveyor belt below while the less dense wood will rise and be caught in a cyclone feeding a slicer, chip conditioner, or cracker.

There are other types of contaminants that must be controlled in the mill area to prevent paper downgrade due to spots and holes in the pulp sheet. Grease, oil, char, paint, rubber, and plastic are some of the most common contaminants. The most difficult of these is plastic contamination. Once plastic is in the pulp, there are very few methods of removing it economically. Plastic is introduced into chip flows primarily by people who do not understand the consequences of disposing of things like a sandwich bag, ear plugs, a candy wrapper, and other debris into a chip truck or onto a conveyor. After

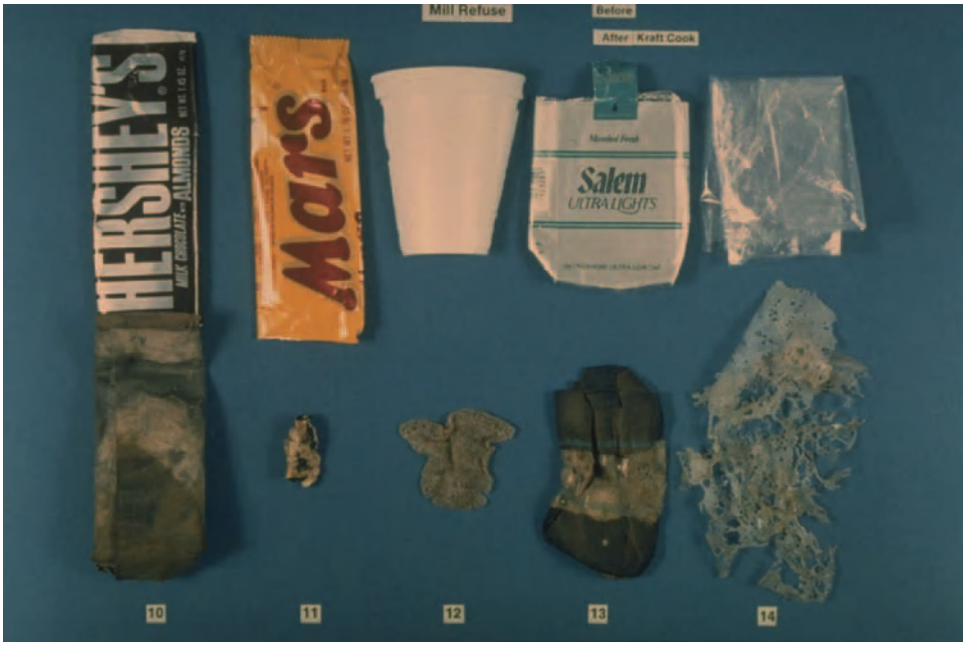

Figure 15 Common plastic items shown before and after kraft pulping. The wrapper on the far left is made of paper and will become part of the fiber furnish. The plastic bag at the far right has become a brittle lattice that will break easily in pulp handling and contaminate several hundred tons of pulp.

spare parts have been installed, the plastic packaging is often left to blow onto chip piles. It is commonly dropped onto the conveyor that is near something being repaired. **Figure 15** shows the results of a laboratory pulping study to determine how plastic reacts in pulping. Plastic will not dissolve in the kraft pulping process. Rather, the heat causes it to shrink, become filamentous, or form a hard tacky glob. The most reliable method of controlling plastic contamination is education of everyone from the point of chip production to the digester. The education must be continuous and effective.

Several types of screen combinations are available to design a screen room system. Sawmills and plywood plants install systems that are simple to operate and have relatively low capital cost. **Figure 16** shows this type of system and the more complex systems used in pulp mill woodrooms. Pulp mills can justify more complex systems based on the improvements a narrower size distribution and reduced oversize and fines can bring to mill operations. For example, the oversize chips in **Figure 17** have been pulped with no slicing or crushing treatment. Kraft pulping liquor could not penetrate more than 2 mm into the over thick chip. The distorted grain of surrounding a wood knot also shows a lack of penetration. One of the first observations a pulp mill makes after a screen room start-up is the dramatic drop in these partially pulped chips and fewer shives, small undercooked slivers of wood that break off of partially cooked chips.

Chip Storage and Handling

Chip storage would not be needed if on-site chipping and chip deliveries from off-site chip sources were precisely timed with the digester(s) demand for chips. A few mills are able to achieve as little as 3 days of inventory. This is the exception. If a mill buys chips from several sawmills, their delivery rate varies widely due to such things as shift scheduling, market conditions, equipment breakdowns, and availability of trucks. Chip mill production varies primarily with availability of logs, weather, soil conditions, and log availability. The amount of chips a mill stores depends on the level of risk the chip buyer and the pulp mill manager are willing to share. If a mill manager wants to have no risk of running out of chips, the chip buyer will maintain a large inventory taking into account the reliability of chip suppliers to fulfill the contracted deliveries. An impending wood products market decline would cause the chip buyer to increase inventory just in case the market slump lasted longer than expected. If the decline does not happen or is shorter than expected, the mill has an even larger inventory. It would seem logical to curtail deliveries, but sawmills and chip mills have no or limited chip storage capacity. This is an expensive approach to inventory management. The money invested in chips could be earning a return in other investments; the high inventory will deteriorate faster than normal and the properties of the chips going to the digester will be more variable. A better strategy is

Figure 16 The sawmill or satellite woodyard screen system (a) with only a gyratory screen is much less complex than a thickness screening system installed in most woodyards (b). Note the aerodynamic separator up-draft tubes can be seen on the closest side of the system.

to agree on a level of inventory that the pile should never go below (called a critical level). An estimate of the reliability of sources to deliver is made. Also, how quickly inventory could be replaced if a large supplier(s) could not deliver at all (after a fire, for example). This would establish a target chip inventory and a lower inventory level that if reached would trigger purchase options to be sure the inventory stayed above the critical level. A mill that routinely stored about 175 000 tonnes could comfortably operate at an inventory around 45 000 tonnes. **Figure 18** shows modern circular and linear chip storage systems.

Excessive inventory, long storage times, and physical damage when moving chips around result in two types of losses: physical loss and biochemical loss.

The physical deterioration is primarily fines generation. This occurs in blowlines as the chips impact the walls of the blowline at repeated bends and sharp corners. Fines are also created when chip dozers move chips from unloading systems onto the pile and later, back to the reclaim pit (**Figure 19**). Because chip dozers are so heavy, breakage extends down into

Figure 17 Oversize chips after kraft pulping. (1) Overthick chip with partial impregnation and a woody center; (2) overlength and over thick chip with only the first few millimeters on the outside that are pulped; (3) the distorted grain and compression wood near a branch created an oversize that has only surface pulping; (4) an over thick chip with a woody center; (5) knotwood creates a badly formed chip that only pulps on the surface.

Figure 18 State-of-the-art chip storage systems. Automated outstocking and reclaim is used to maintain a first-in/first-out pile rotation. The arrangement is either circular (a) or linear (b).

the pile half a meter or so. In all cases, acceptable chips break into pin chips and fines. Several studies have measured pin chips and fines generation in full-scale, commercial piles. **Table 1** reports data for a blow line test only. An adequate rule of thumb is that a doubling of fines and a 50% increase in pin chips can be attributed to the combination of tractor activity and pneumatic handling.

Biochemical deterioration is caused by a series of biological events that can heat the pile to a temperature that begins destructive chemical reactions.

Figure 19 Sources of fines generation. (a) Blowlines allow chips to be conveyed around existing equipment but the number and severe angles will break chips up; (b) wear plate or flat-backs should be replaced when worn rather than mended; (c) rubber-tired chip dozers cause less damage per pass than tracked dozers (d). However, high traffic in an area will degrade chip sizes for either type.

Table 1 Southern pine roundwood and residual chips transported through a 250-m blowline with six turns (sum of angles = 280 degrees)

Sample point	*Chip size classes*				
	+45 mm rh over length (%)	*+8 mm bar over thick (%)*	*+7 mm rh accepts (%)*	*+3 mm rh pin chips (%)*	*Passes 3 mm rh fines (%)*

rh, round hole (the shape of the classifier tray openings).

Hardwoods deteriorate at least twice as fast as softwoods. This text refers to softwood chips only. Internal pile temperatures are hard to measure without laying wires in the pile as it is built. This is not feasible in normal mill operations, but useful in smaller-scale study piles. A dial thermometer with an extended stem (up to 75 cm) will allow grids of surface temperature to be established and monitored periodically. More simply, an experienced dozer operator knows when areas are heating up faster than normal and can take temperature readings. From studies, the internal temperature is 15–20°C hotter than the surface readings. Following the heating curves in **Figure 20**, the initial heating to about 40–50°C in the first 2 weeks is caused by the growth of bacteria, mold, and the respiration of living sapwood cells in the fresh chips. Further heating is determined by the pile height and the degree of compaction. If the pile height remains at about 15 m and tractor activity is kept to a minimum, the pile temperatures remain at or below 50°C. At 50°C, few molds, wood staining, and wood rotting fungi can survive. However, at this temperature, the acetyl group on cellulose molecules is cleaved off, freeing acetic and formic acid and heat. If the heat cannot escape because the pile is being compacted by dozer activity or more chips being added to the pile, pile temperature will move higher. The higher temperature and acid conditions make the acid forming reactions go faster. If the pile height is increased to 45–50 m and compaction increases with more spreading of new chips on the pile, the temperatures will reach 60–70°C. Further height and consequent compaction increases will bring the temperature to 70–80°C. As cellulose and lignin begin to acid hydrolyze, an autoxidation cycle is begun. At this point, further heating will be determined by the amount of compaction. If heat cannot escape due to the combined actions of tractor activity and increased pile height, the pile will be out of control. There is a high risk that an internal fire will be ignited as temperatures rise above 80°C.

Chips that have been degraded in pile storage by heat have lower pulp yield and strength. The degree of loss depends on the length of time the chips were exposed to temperatures over 65°C. Since mills rarely, if ever, track temperatures in enough detail to develop a time–temperature relationship, the results of samples taken as a degraded pile was dismantled might be useful. The first pulp property that falls off is tear: 10% loss of tear is common in piles stored for 4–6 months at 65–70°C. In those same conditions, burst and breaking length losses will be 1–3%. Pulp yield loss is from 1 to 5 percentage points (e.g., going from 54% to 49%). Badly deteriorated chips with a pH below 3 and a buffering capacity over 100 ml g^{-1} produce pulps at a 30–35% yield and with at least 50% strength loss.

Chip pile measurements Attempting to get the book and physical chip inventory values to agree is very difficult, if not impossible. The values that go into the equation vary quite a lot:

$$\text{Book inventory} = \text{physical inventory} + \text{physical losses} + \text{biochemical losses}$$

Below are the ranges of error in data that go into the equation from a number of studies and mill practice:

- Belt scale weights: 0.5–1% (with good design and maintenance)
- Truck scale weights: 1–2% (in the USA, there is a requirement for calibration and periodic, unannounced, spot checks to confirm accuracy)
- Surveyed pile volume (ground or aerial): 1–3%
- Bulk density (kg of wood per cubic meter of pile volume): as high as 25%
- Moisture content (sample and dry): 2–7%
- Moisture content (meter): 1–2%
- Losses (mechanical and biochemical): 25–50%.

Only a few of the measurements have low error ranges. The best numbers are the green weights from truck scales, moisture content, and the pile volumes from aerial or ground surveys. The errors are cumulative and usually result in unreliable estimates. Using these data results in periodic corrections when a pile is completely reclaimed. The adjustments can be positive or negative.

Better estimates of inventory can be obtained by investing in belt scales before and after chip pile storage.

Chip Quality Control

An important principle in establishing a quality control program is that if the data are not going to be used to make meaningful decisions, there is no reason to do the test at all. A corollary to this is: a testing program will produce meaningless data if samples are taken at the wrong location using incorrect methods.

Sampling tools need to be more than just a shovel gathering a bucket of chips anywhere you can easily get to the flow. The scoop should be large enough to allow oversize chips to be caught. The size of the sample should be only enough chips to do the testing required. This avoids the need to split the sample, a

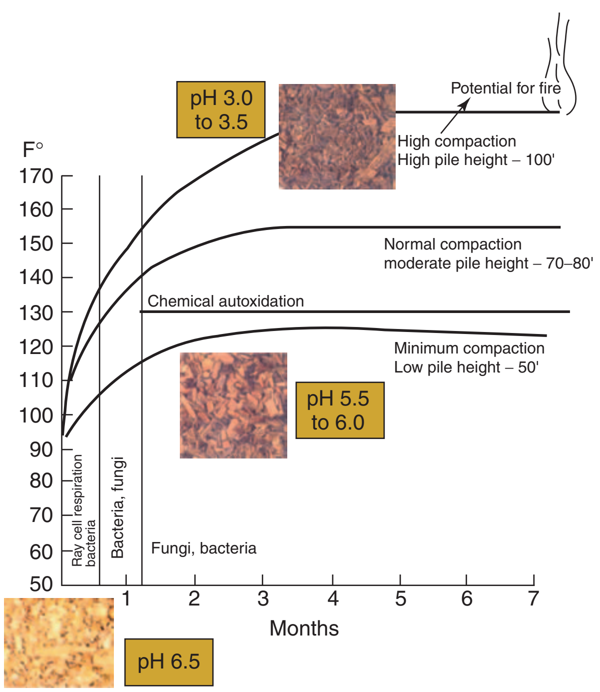

Figure 20 Conifer chip pile temperature profile. The rate of heating and the maximum temperature are primarily determined by pile height and compaction after the first 1–2 months. Initial heating is the result of rapid bacteria growth and respiration of the remaining living cells in the wood. Note the change in pH and color as the chips degrade from exposure to high temperature. The chips in the top photo easily break up into small particles.

process that introduces as much or more error as incorrect sampling. If special testing will require more than the normal scoop full, it is better to collect two scoop fulls and composite them for testing. If a barrel of chips is needed to send to a research laboratory, it should be gathered over a full day to avoid the risk of getting chips from one supplier or type of chip that is only a part of the total chip consumption.

After deciding what chip flows need to be sampled, sampling points must be located where they are safe to access, easy to get to, and allow a sample scoop to be inserted and so that chips can be gathered that represent the entire cross-section of the flow. Belt conveyor transfer points are an ideal place to do this. In most cases, there is access to the entire flow as it falls from one conveyor to the next. If not, a door can be cut in the hood. Access is preferable with the flow of chip coming toward the sampling point. The scoop is inserted upside-down, pushed all the way through the flow, turned over and quickly drawn out to take the sample from the entire depth of chip flow. A permanently mounted tube sampler replicates this sampling process. **Figure 21** shows several standard and tube sampling applications. There are other types of samplers that allow representative sampling of truck deliveries. Since installing samplers is almost always an add-on to existing systems, there are few that are alike. There are commercial samplers available that can be adapted to many situations.

A sample taken from the top of a moving belt or the top of a delivery truck or rail car will always contain fewer fines than a representative sample. As soon as chips are moved along a belt, in a rail car or truck bed, fines immediately begin to percolate downward. Similarly, a sample removed from the lower part of a rail car or chip trailer will be biased with more fines that have moved down the chip bed. Sometimes, a sample taken correctly at a transfer point is not representative. The likely cause is several types of chip flows joining together and one of them being loaded toward one side of the conveyor. The addition of cracked or conditioned oversize back into the accept flow often comes down a chute, depositing to one side of the belt.

The most widely used test methods to track woodroom and supplier quality performance are:

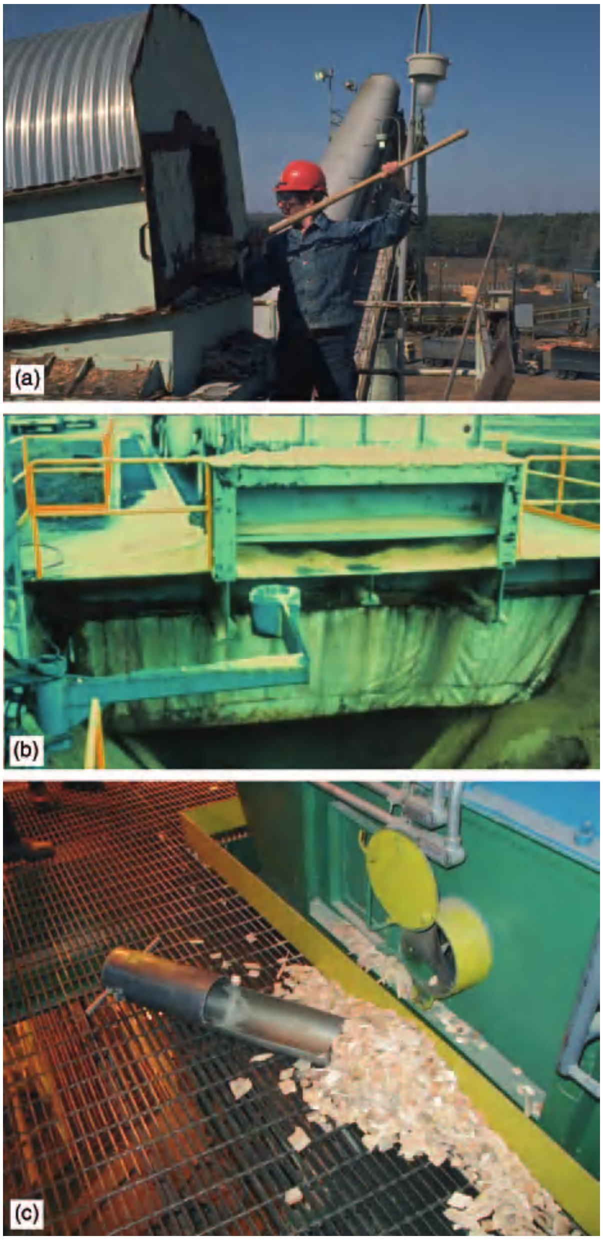

Figure 21 Options for chip sampling. (a) Manual sampling at a belt transfer point using a scoop sized to collect enough chips for the tests being done; (b) an automatic sampler using a bucket mounted on a swinging arm for truck dump sampling; (c) a tube sampler and sample port at a chip screen system to remove chips after screening.

1. Moisture content or %OD (percentage of oven-dry solids) solids. This is used to convert the green weight of chip deliveries to a dry weight. Moisture contents of sawmill and plywood plant residuals, woodroom production, and wood chipped thinnings can differ by as much as 15–20% points. Depending on the mix of wood being used, a pulp mill may be buying a lot of water at chip prices. Factors that influence the reliability of this test were listed earlier.
2. Bark content. The test is a tedious separation of all bark and wood. Optical methods of testing bark have not been successful. To speed the test up, some mills only measure bark in the accepts fraction. This underestimates the actual bark content since up to half of the bark breaks down into small pieces. The need for precise estimates is

diminishing as pulp bleaching technology has made headway in controlling pulp dirt associated with bark that was not removed in sawmill or woodroom debarking. A survey of mills confirmed that the specification for bark has been increasing in recent years from less than 0.5% to 1–2%.

3. Size distribution. There is no agreement on which testing machine and method should be used to describe the size variation in chips. There are two systems that are the most popular. One is currently sold under the trade name Chip Class. It was conceived as part of the Swedish pulping work that demonstrated the importance of thickness in kraft pulping. As shown in **Figure 22**, a series of trays are stacked on a table with linear motion. Each of the fractions has a different importance to the pulping process:

- Over length (retained on a 45 mm hole)
- Over thick (retained on bars spaced 8 mm apart)
- Accepts (retained on a 7 mm round hole)
- Pin chips (retained on a 3 mm round hole)
- Pan (passed through the 3 mm round hole)

An automated version of the Chip Class mounts the classifier trays in a hexagonal drum. The small fractions come out first and weights are accumulated and delivered in a final report by the system PC.

The Rader CC2000 classifier is based on thickness with the ability to separate pin chips and fines (**Figure 23**). Chips are fed into a rotating drum of movable bars. At the beginning of the test, the bars are 2 mm apart and thin chips are extracted. Automated balances weigh the amount of material leaving the drum as the space between the bars is increased in 2 mm increments up to 12 mm. A PC controls the cycles and calculates the percentage in each size classification. Several companies have adopted one or the other as standard size classification methods for their mills.

Figure 22 Chip Class classifier. The classifier next to the Chip Class is the Williams Classifier. It is the earliest classifier that the industry adopted as a standard. It is based on round holes only.

The most critical element of a chip quality control program is the technical staff. Training in test methods should go back to the written method rather than word-of-mouth training. In addition to doing the tests correctly, there must be training to recognize visually what chips should look like, and also to be able to see a problem before the test values are available. It is better to have this person out of the normal progression ladder because experience is vital to the success of a long-term testing program. The testing facilities should be designed specifically for chip testing with good light, heating control, office area for meetings and paperwork, room for all equipment, open area to lay out samples on the floor in sorting and displaying them, and located near the

Figure 23 Rader CC2000 classifier. (a) Two systems allow much more productivity from the chip testing laboratory; (b) like all instruments, it must be periodically cleaned and carefully calibrated.

Figure 24 Chip quality education tool. A display of chip quality definitions, impact on the mill, and real examples of each material type will help suppliers, truck drivers, and others who work with chips to understand the importance of chip quality. Customers of the pulp and paper products will appreciate this example of making chip quality a high priority. The one category missing in this display is emphasis on the requirement to eliminate contamination of chips with metal, plastic, dirt, and rocks.

woodroom. The chip testing position should never be near entry level and the lead tester should be part of the woodroom operating team.

A chip quality report should be more than a stack of computer printouts. In order to be able to see trends and changes, key data should be presented in graphs that are easily interpreted. The graphical reports should be made visible to everyone working in the woodyard and woodroom and discussed with suppliers. With the available spreadsheet graphics programs available, graphing of data should be standard practice. Visual displays focusing on aspects of quality should be developed so that those who deliver chips can know what they should look like, too (**Figure 24**).

Woodyard and Woodroom Safety

Woodyard safety is a critical function for every woodyard employee. Whenever in the operating area, personal protective equipment must be consistently used to reduce the risk of injury. The noise levels around operating debarking, chipping, and screening systems is well above the level that causes permanent hearing loss. Safety glasses with side shields are always needed to prevent wood dust and debris and flying objects from damaging eyes. Hard hats prevent injury from falling objects or head injury in areas with low headroom. When cleaning up dusty areas, respiratory masks will prevent inhalation of small wood particles that can accumulate in the lungs and cause long-term health problems. Some people are sensitive to the molds that grow in enclosed and damp areas such as conveyor tunnels. These people should not be assigned work in the contaminated areas. Equipment that is subject to high stress and impact loads need to be examined periodically. A logjam in the chipper infeed must be cleared to resume production. It is essential that no person place himself or herself at risk of falling into an operating chipper infeed at any time and particularly in this situation. Mechanical systems such as the one shown in **Figure 25** are invaluable in this instance. The rams are pushed in and out to dislodge the jammed logs. If no such device is installed on a chipper, the chipper must be stopped with the use of a disk brake and locked out and tagged out to prevent starting when workers are clearing the chute. Only then should woodroom operators get near the logs in the infeed to attach grapples attached to overhead winches. Log tongs should be attached with both a shackle and a restraining chain in the event the shackle breaks. Normal required lock-out and tag-out procedures are followed to return the chipper to service. Chipper knives are very sharp and should be handled with steel reinforced gloves.

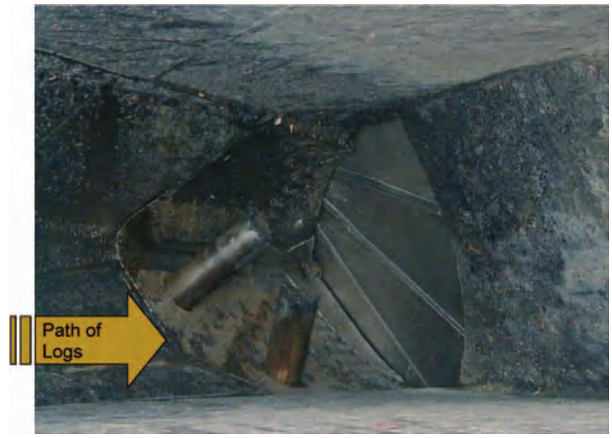

Figure 25 Rams that can be pushed into the chipper infeed to dislodge logs that sometimes frequently plug the spout. This is much safer than trying to break up the jam with pike poles or log tongs and takes less time.

Large mobile equipment and trucks used to transport, store, and reclaim logs and chips have limited visibility and even less in bad weather and at dawn and dusk. If two-way radio communication is possible in the mill, it is good to carry one while working in such hazardous areas. Sign-in and sign-out log sheets are also used to keep track of visitors and workers from other parts of the mill. A short, 10 to 15 minute, safety meeting of woodyard and woodroom operators at the beginning of the work period allows everyone on the crew to hear about special situations, like digging of a large ditch across a woodyard road, and identify and remedy hazards that were observed the day before. With everyone participating, prevention is a lot easier than the consequences of a serious accident.

Mechanical Pulping

J H Cameron, Western Michigan University, Kalamazoo, MI, USA

Introduction

When mechanical action is the principal means for separating fibers from wood, the pulping processes are known as mechanical pulping, and the resulting pulps are mechanical pulps. This section contains descriptions of mechanical pulping processes, products, applications, limitations, and future prospects for mechanical pulps.

Mechanical pulping includes a large number of processes involving mechanical action or a combination of mechanical action and chemical pretreatments that separate fibers from the wood matrix. The main difference between mechanical pulping and chemical pulping is that, in mechanical pulping, the fibers are separated without removing the lignin, whereas in chemical pulping, the lignin is dissolved from the wood using chemicals. Mechanical pulps are characterized by high yield, high lignin content, and relatively stiff fibers that can be bleached to high brightness levels but that will photoyellow (darken) on exposure to light. The yield from the mechanical pulping processes ranges from as high as 98% for some groundwood pulps to about 85% for some of the chemimechanical pulps. In refiner mechanical pulping, the woodchips may be pretreated with chemicals either to reduce refiner energy usage or to help separate the fibers. Compared to chemical processes, the chemimechanical pulping processes remove only a small amount of the lignin in the wood. Since mechanical fibers are stiff and contain large amounts of lignin, these fibers form poor fiber-to-fiber bonds, which decreases sheet strength, but increases sheet opacity and bulk. Because of their high yield and low chemical consumption, these pulps are less expensive to produce and have less impact on the environment than do chemical pulps. The production of mechanical pulps worldwide is about 30% of the total virgin pulp production and is increasing because of its higher yield, lower cost, and less complex environmental concerns. On a per-country basis, the percentage of mechanical pulps ranges from 9.2% of virgin pulp in the USA to 45% in Canada and 62% in Germany.

Usage

The major use of mechanical pulps is in nonpermanent (grades that do not require permanent lightfastness) printing grades. Mechanical pulps are historically used in the following grades: newsprint (newspapers, paperbacked books, magazines), supercalendered magazine (catalogs), and coated mechanical and coated fine paper (commercial printing grades). Depending on the strength properties of the mechanical pulp, newsprint usually contains from 80% to 100% mechanical pulp, with the remainder being chemical pulp added to increase sheet strength. In addition to the nonpermanent printing grades, mechanical pulps are also used in a wide variety of other paper products, including board and tissue/towels. A short description of the major applications for mechanical pulp is presented here.

Newsprint

The quality parameters for newsprint are runnability (low frequency of breaks during printing) and printability (smoothness, opacity, brightness, ink pickup, and strikethrough). Traditionally, newsprint furnishes consist of 80–85% stone groundwood with the remaining fiber being lightly bleached kraft. The groundwood provides high bulk, high opacity, and good ink receptivity, while the kraft provides resistance to cross-machine tear.

Supercalendered Magazine

This grade is usually manufactured with mechanical pulp (typically 70% of the fiber), chemical pulp (30% of the fiber), and a high level of filler, typically 20–30%. These papers are printed using gravure and offset printing processes, which require good smoothness, ink receptivity, and high opacity, all provided by the mechanical pulp. The high level of filler reduces sheet strength, requiring a relatively high level of long fibers, usually softwood kraft.

Coated Papers

One of the most important coated grades is lightweight coated (LWC), used in gravure and offset printing. This grade normally contains 50–70% mechanical pulp with the remaining fiber being chemical pulp and up to 17% filler. These papers have low basis weights (less than $40\,g\,m^{-2}$ for the base sheet), which require a relatively high level of chemical pulp.

Other Products

Fine printing and writing papers are normally classified as wood-free (free of mechanical pulp), but will tolerate as much as 10% mechanical pulp. The mechanical pulp increases opacity, bulk, and printability. Since mechanical pulps are stiff, they are added to the middle layers of multiple-layer board grades. Because of their high bulk, resiliency, and low cost, mechanical pulps are also added to tissue and towel furnishes.

Historical Background

Before 1800, books were printed on handmade paper produced from many different fibers, principally flax before the invention of the cotton gin. With the invention of the cotton gin by Eli Whitney in 1793, cotton gradually replaced flax as the principal papermaking fiber. The first successful use of wood fiber as a paper stock was groundwood in the early 1840s. Fredrich Keller of Hainchen, Saxony and Charles Fenerty of Springfield, Nova Scotia are independently credited with the invention of groundwood pulping. Fredrich Keller, a bookbinder, apparently started experimenting with pressing wood against a grinding wheel with running water after reading about the shortage of rag fibers. By the mid-1840s, he had developed his groundwood process such that newspapers were printed using groundwood. In 1846, Keller sold his invention to JM Voith of Heidenheim, Germany and the first commercial grinders were installed in a mill in 1852. Fenerty, the credited co-inventor, operated a sawmill in Nova Scotia, and pursued groundwood experiments by pressing wood against a grinding wheel. However, after writing to the Halifax newspaper describing his invention, Fenerty did not further pursue the concept.

Mechanical Pulping Processes

From the starting point of pressing wood against a grinding stone with running water, a large number of mechanical pulping processes have been developed. The more important of these are listed here:

- Groundwood (GW): produced by pressing wood against a wet grinding surface.
- Pressurized groundwood (PGW): similar to groundwood but at a temperature of 100°C, which generates steam pressure.
- Refiner mechanical pulp (RMP): plate refining of wood at atmospheric pressure and no chemical treatment.
- Thermorefiner mechanical pulp (TRMP): the wood chips are heated with steam before refining at atmospheric pressure.
- Thermomechanical pulp (TMP): the wood chips are presteamed and fiberized at temperatures above 100°C. After fiberizing at high temperature, the fibers are often further treated by refining at atmospheric pressure.
- Pressure thermomechanical pulp (PTMP): like TMP, but with both refining stages being pressurized.
- Chemical mechanical pulping (CMP): the chips are treated with chemicals before refining at atmospheric pressure.
- Chemithermomechanical pulp (CTMP): chemicals are added prior to fiberizing at temperatures above 100°C.

Mechanical Pulp Properties

Mechanical pulps are produced from many different tree species using several different mechanical pulping processes. These pulps are incorporated into a large number of furnishes for use in a variety of paper products. The characteristics of the pulps depend on the tree species, the mechanical separation process, and the treatment steps following mechanical pulping. The papermaker incorporates specific mechanical pulps into paper furnishes to produce the desired characteristics. In general, mechanical pulps provide good sheet formation, increase sheet bulk, increase sheet absorption, increase sheet opacity, and increase sheet resiliency, but reduce sheet strength. Many of these properties, such as resiliency and bulk, are important for the impact printing processes. The lower strength results from the high lignin content of these pulps, which reduces the surface area available for bonding and reduces the fiber flexibility, thus decreasing the relative bonded area. A major reason why mechanical pulps are not used in permanent grades is that they photoyellow (darken) on exposure to light. One needs to recognize that mechanical pulps differ greatly in their characteristics, and they must be used with knowledge of how the various types will affect the furnish and product properties.

General Process Objectives

Groundwood and Pressurized Groundwood

GW is produced by pressing bolts (debarked short-logs) against large rotating grindstones. Today, the grindstones are artificial stones made from silicon carbide or aluminum oxide abrasives with a fused bonding agent. They are typically 1.5 m in diameter and driven by 2000–4000-kW motors. The grit on the stone surface rapidly becomes rounded and the fibers are separated through a series of compression–decompression pressure pulses. **Figure 1** illustrates a representative grinder and shows the key grinder elements. The bolts are fed in a pressurized magazine to the grinding stone. Since the stone gradually wears, an online lathe is periodically used to sharpen the stone. The separated fibers are washed from the stone into the pit with grates controlling the size of the fiber bundles allowed to pass out of the wood magazine.

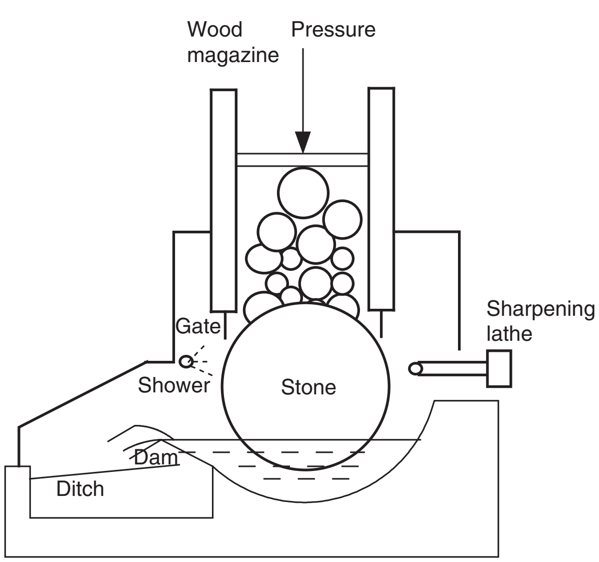

Figure 1 Representative grinder for groundwood production.

Low-density woods, because of their thin fiber wall and relatively large lumens, are good candidates for GW processes. These low-density species tend to be northern species because of the greater predominance of springwood with its thinner fiber walls. The flexing of the fiber walls allows the wood to absorb the compression–decompression, which results in fiber separation. With high-density woods, such as southern pines, the compression–decompression forces are not absorbed by the flexing of the fiber walls, and the fibers are cut rather then separated, resulting in poor pulp quality. Water washes the pulp from the grindstone and keeps the grindstone clean.

Having low density and relatively white color, spruce and fir are commonly used for pulp in newsprint, and in nonpermanent printing grades, while aspen is used in the base sheet of coated mechanical grades. Since these species are found at northern latitudes, Canada produces a high percentage of the GW pulps.

In PGW, the pressure is controlled using compressed air, enabling temperatures as high as 140°C to be reached. This increased temperature softens the lignin between the individual fibers, resulting in better fiber separation and improved strength properties. At high temperatures (typically above 160°C), there is a risk that lignin will become fluid and coat the fibers, which reduces fiber bonding and sheet strength.

Refiner Mechanical Pulp, Thermomechanical Pulp, Pressure Thermomechanical Pulp Processes

Refiner pulping uses two disks marked with bars radiating outward: usually one disk rotates (rotator) and one remains stationary (stator). Before refining, the wood is debarked and chipped. The wood chips enter at the center of the disk and are forced toward the perimeter of the refiner. The disk rotates at high speeds, typically 1500–2000 rpm, exposing the wood chips to a series of compression and decompression stages as the chips are forced from the center to the perimeter of the disks. Normally two refining stages are employed. The first stage operates at a consistency of about 30% and separates the fibers from the wood (fiberizing); the second stage operates at a consistency of about 10% and improves the paper-making properties of the fibers (refining).

TRMP and TMP are modifications of RMP, with TMP being the dominant RMP process. With thermorefiner pulping, the wood chips are heated with steam but are refined at atmospheric pressure. With TMP, the chips are presteamed at atmospheric pressure and then screw-fed to pressurized refiners. Both refining stages are usually pressurized and operate at pressures from 3 to 5 bars and temperatures from 140 to 160°C. The higher temperatures provide easier fiber separation and result in an increase of about 50% in paper strength at the same freeness and same total refiner energy relative to RMP.

RMP processes offer several advantages over GW and PGW processes. These include the ability to refine wood residues, including sawdust, less staffing requirements, and the ability to use lower-quality woods.

Chemical Mechanical Pulping and Chemithermomechanical Pulping

In these processes, the wood chips are treated with chemicals before the fibers are mechanically separated in the refiner. Compared to chemical pulping, the chemical treatment in these processes is very light, and the yield typically ranges from 80% to 95% compared to the yield of 45–50% in the chemical pulping processes. The objective of the chemical pretreatment is not to remove the lignin, as would be the case in chemical pulping, but to aid in the mechanical separation of the fibers in the refiner. Among the benefits of the chemical pretreatment are improved fiber properties, whose properties are between those of RMP and chemical pulping, and reduced refiner energy. Although the major reason for the chemical pretreatment is improved fiber properties, it is common to treat the wood chips simply to reduce the required refiner energy.

CMP consists of treating the wood chips with sodium sulfite (2–4% on oven-dried wood basis) in the case of softwoods and sodium sulfite (0–4%) plus sodium hydroxide (1–7%) in the case of hardwoods. Few hardwoods, the exceptions being aspen and popular, can be mechanically refined without the addition of chemicals. Sodium peroxide, which bleaches the pulp and allows higher hydroxide levels to be used, can be added in combination with the sodium hydroxide and sodium sulfite. The cold process, used for some of the denser hardwoods, employs sodium hydroxide without sodium sulfite. The wood chips are refined at atmospheric pressure, and the temperature is held relatively low (70–80°C), with higher temperatures resulting in darker wood.

In chemithermomechanical refining, the wood chips are presteamed with chemicals at temperatures above 100°C, followed by first-stage refining above 100°C and atmospheric second-stage refining. CTMP and TMP are the most widely used mechanical refining processes.

Postprocessing of Mechanical Pulps

Refining of Fiber Rejects

Since only part of the wood is separated into fibers during the first mechanical pulping stage, the fiber bundles must be separated from the fibers and further refined. The separation process consists of a series of screens and centrifugal cleaners. In addition to separating the fiber bundles (sieves), course fiber, sand, and other inorganic materials are removed at this stage. The screens and cleaners are arranged in cascade sequence, such that the amount of material to be disposed is minimized. The fiber rejects from the screens and cleaners consists of fiber bundles and course undeveloped fibers; these are further refined at either low consistency (3–5%) or at high consistency (30–50%) in a single-disk refiner. High consistency increases the refining intensity and normally produces superior fiber properties.

Bleaching of Mechanical Pulps

While increasing brightness is the bleaching objective for both mechanical and chemical pulps, the means through which this is accomplished are significantly different. With chemical pulps, bleaching is accomplished by removing the lignin remaining in the pulp after chemical pulping and brightening the other pulp constituents. This is often referred to as true bleaching. With mechanical pulps, bleaching is accomplished by brightening the color-containing compounds (chromophores), which are primarily lignin structures.

Pulp brightness is dependent on wood species, wood storage, the pulping process, and the bleaching process. There are considerable color differences between wood species and between sapwood and heartwood. For example, loblolly pine (*Pinus taeda)* has a typical brightness of 50%, while black spruce *(Picea mariana)* has a typical brightness of 67%. The cellulose and hemicelluloses are almost colorless and contribute little to mechanical pulp's color. While the extractives are yellow and reduce brightness, they are present at relatively low levels. Since lignin is present at high levels and is dark in color, it is the primary compound responsible for the darker color of mechanical pulps.

Wood will darken during storage, with unbarked logs darkening more than debarked logs. Although some of this darkening can be removed by bleaching, the final pulp will almost always be darker in color. To preserve brightness, unbarked logs have been stored underwater. Another reason for darkening of mechanical pulp is the condensation of colorless phenolic groups that form color compounds when they condense, a development that is accelerated at the high temperatures used in some of the mechanical pulping processes.

Some of the mechanical pulps, such as those produced from black spruce, have a high enough initial brightness for use in some applications, such as newsprint, without brightening. Other mechanical pulps need to be bleached because the processes and species used for their production result in low brightness levels, or because the product requires a higher brightness level.

Both reductive and oxidative bleaching are used with mechanical pulps. The objective of bleaching mechanical pulps is to convert the chromophores nonlight-absorbing compounds – to brighten the pulp. In addition to brightening the pulp, bleaching also reduces the extractive content of the pulps. The reductive agents include sodium dithionite–sodium hydrosulfite ($Na_2S_2O_4$), sodium bisulfite ($NaHSO_3$), formamidine sulfininc acid (FAS HO_2S-CNH-NH_2), and borohydride; and the oxidative agents include hydrogen peroxide (H_2O_2), sodium hypochlorite (NaOCl), and ozone (O_3). Of these bleaching agents, the most common are sodium dithionite and hydrogen peroxide.

Peroxide Bleaching

Both high pulp consistency and high pH increase the brightness levels that can be achieved with peroxide bleaching. Therefore the consistency is normally adjusted to 15–20% and the pH to about 11.5. There is an increase in brightness with increasing peroxide dosage up to a peroxide dosage level of about 4% based on (OD, % oven dried, ISO 287) pulp. Brightness increases of about 15 points, (% ISO), can be achieved with 4% addition of hydrogen peroxide.

Dithionite Bleaching

Sodium dithionite bleaching is usually performed at a pH of 6.0–6.5 and at 8–12% consistency. The normal dosage levels are from 0.5–1.0% and result in a four- to eight-point increase in brightness. An addition level of 2.0% sodium dithionite on OD pulp increases the brightness by about 10 points, % ISO.

Two-Stage Bleaching

The bleaching effects of peroxide and dithionite tend to be additive and two-stage processes are in operation. These consist of a medium peroxide stage followed by sulfur dioxide or sodium bisulfite acidification of the pulp to destroy the residual peroxide, thickening to high consistency and dithionite bleaching. Brightness gains from 15 to 20 points are achieved with two-stage processes.

Transitional Metal Ion Removal

A key variable in mechanical pulp bleaching is the presence of transitional metal ions, such as iron or magnesium. These ions catalyze the decomposition of both hydrogen peroxide and sodium dithionite. In addition to decomposing the bleaching agents, they also accelerate color reversion of the bleached pulp. Transitional elements need be avoided by using evaporator condensate in the bleaching plant or by the use of chelating agent, the most common being either ethylenediaminetetraacetic acid (EDTA) or diethylenetetraminepentaacetic acid (DTPA).

Color Reversion of Mechanical Pulps

Color reversion, either photoyellowing or thermal darkening, is the most significant hindrance for further acceptance of mechanical pulps. The optical and strength properties of CTMPs are sufficient for use in most printing paper grades. Unfortunately, CTMP darkens during storage or on exposure to light (photoyellowing). Photoyellowing of lignin-containing paper can lead to a brightness decrease of more than 30 points in a short time (6–8 months) compared to only a 3-point decrease with kraft pulp. Although wood pulps may be bleached to various brightness levels, all pulps diminish in brightness with age. Brightness reversion has been studied with various high-yield pulps, such as GW, TMPs, and CTMP. Progress on extending the brightness of high-yield, lignin-containing pulps has come slowly. Although many techniques for reducing color, including free radical scavengers (such as ascorbic acid), ultraviolet absorbers or chemical modification of the chromophores have been proposed, there is no accepted commercial process for eliminating or reducing color reversion of mechanical pulp.

Mechanical Pulp Properties

Fiber properties depend on the pulping process and type of wood, and are influenced by the species, percentage of juvenile wood, and the earlywood (springwood) to latewood (summerwood) ratio. The fiber properties that are considered the most important in determining paper properties are fiber length, cell wall thickness, and juvenile wood percentage. In comparing mechanical pulps to chemical pulps, mechanical pulp fibers are stiffer, shorter, and contain a higher level of lignin than do chemical pulps. In comparing the different mechanical pulping processes, CTMP and TMP bond better than do GW or RMP. Therefore, less chemical reinforcing pulp is required with TMP and/or CTMP than is required with GW. Conversely, the incorporation of GW would increase light scattering more than TMP or CTMP.

The Future

Mechanical pulp usage is expected to increase by about 4% per year. The current trend of decreasing fine paper basis weight is expected to continue, leading to increased use of mechanical pulps for their high opacity and bulking attributes. These changes will likely increase the need for strength and brightness of mechanical pulps. This, together with the need to decrease the electrical refining energy, will result in more complex mechanical pulping processes with new pretreatments to decrease energy usage and improve the fiber properties. The strength properties of mechanical pulps will continue to improve, decreasing the need for chemical pulps in nonpermanent printing grades. Recycled fiber, which can be produced with less energy than mechanical pulps and can replace mechanical pulps in many of the current grades, is the principal competition to mechanical pulping. The continual growth of recycled fiber may constrain the growth of mechanical pulps.

Chemical Pulping

R G Aravamuthan, Western Michigan University, Kalamazoo, MI, USA

Introduction

Pulping processes reduce wood or any other fibrous raw material to a fibrous mass. Chemical pulping essentially dissolves the noncellulosic components in wood, mainly lignin, and thereby liberates the fibers. This process, also known as 'delignification,' centers around the removal of ligneous binding material, but, in the process, certain hemicellulosic as well as cellulosic components are dissolved. Once the pulping process becomes less selective (in the removal of lignin as compared to cellulose and hemicellulose), the process is stopped; further processing of pulp proceeds via extended delignification and bleaching processes. Although the bleaching process is intended to bleach the 'brown' unbleached pulp into bright white pulp, the initial stages in a multistage bleaching process are more aptly called delignification since they essentially contribute to additional and preferential lignin dissolution.

In a chemical pulping process, upwards of 80% of wood lignin is removed with some concomitant carbohydrate (mainly hemicellulose and some cellulose) dissolution. The overall yield of pulp in this stage can be expected to be around 50% of the original wood. Further delignification cannot be effectively carried out by conventional pulping chemicals and is hence left to bleaching chemicals.

Two major chemical pulping processes are sulfite pulping and kraft pulping. Sulfite pulping can be carried out at different pH levels with different bases – calcium at low pH (1–2), magnesium (3–5), and ammonium and sodium over the entire range of pH. The pH levels used in sulfite pulping cover the entire range of 1–13 (1–2, acid sulfite; 3–5, bisulfite; 5–7 neutral sulfite (semichemical) – NSSC; 9–13, alkaline sulfite). On the other hand, kraft pulping is a distinctly alkaline process and works in the range of pH 11–14, using the cooking chemicals of sodium hydroxide and sodium sulfide (the reactive species being the hydroxide and hydrosulfide ions).

History

The first commercial sulfite pulp was used in 1874, while the kraft process was commercially used almost a decade later (1885). However, the superior strength properties obtained by kraft pulp came to be recognized early in its development and many soda mills (using only sodium hydroxide) converted to the kraft process to compete with the sulfite mills. Around 1930, with the introduction of the Tomlinson recovery furnace, the kraft process gained favor over the sulfite pulp mills. The one major disadvantage of the alkaline processes (kraft or soda) was overcome with the use of powerful bleaching agents like chlorine, chlorine dioxide, and other chlorine compounds.

Sulfite pulp mills, until 1951, were mainly using calcium base without any efficient chemical recovery system. Sulfite mills, not to be left behind, began to use more powerful bases such as magnesium, sodium, and ammonium that could be used under less acid cooking conditions and were amenable to efficient recovery systems. With the advent of chlorine dioxide as a pulp bleaching agent in the 1950s, the last advantage of sulfite pulps over kraft pulps – specifically, higher brightness and/or better bleachability – was overcome by kraft pulps.

By 1990, the world annual pulp production from sulfite mills was only about 8% and the kraft pulping process had become the leading chemical pulping process. Recent investments in sulfite pulp mills have come in the form of the development of alkaline sulfite processes and the introduction of pulping additives such as anthraquinone, which has been very successfully applied earlier in the alkaline processes – kraft and soda.

On the other hand, in the kraft pulping process, current modifications center on continuous process improvements to improve the yield and selectivity of delignification in the final stages, alleviating the environmental impact of the process, and designing a better recovery system.

Sulfite Pulping

The sulfite pulping liquid is prepared by absorbing sulfur dioxide (prepared by burning sulfur with a controlled excess of oxygen and quickly cooling the product gas to around 200°C to prevent further oxidation to sulfur trioxide) into different bases. The reactions are:

$$SO_2+H_2O \rightarrow H_2SO_3 \quad (1)$$

$$CaCO_3+H_2SO_3 \rightarrow CaSO_3+CO_2+H_2O \quad (2)$$

$$CaSO_3+H_2SO_3 \rightarrow Ca(HSO_3)_2 \quad (3)$$

The sulfite pulping terminology can be explained by equation 3. H_2SO_3 is true free SO_2; since $Ca(HSO_3)_2$ leads to one-half $CaSO_3$ and one-half H_2SO_3, free $SO_2 = H_2SO_3 + 1/2\ HSO_3^-$ and combined $SO_2 = SO_3^{2-}$ and $1/2\ HSO_3^-$. The absorption product is later fortified by additional SO_2 absorption from digester relief gases under higher pressure. A higher percentage of free SO_2 is formed with a calcium-based liquid compound, compared to other bases. The effectiveness of sulfite pulping depends on the diffusion of SO_2 and the base ion into the wood. The diffusion process is helped by monovalent ions like Na^+ and NH_4^+ as well as higher pH. Lack of such diffusion leads to polycondensation and dark pulp ('burnt chips'). Any process that hinders such diffusion, like crushed chips from blunt chipper knives, leads to burnt cooks. The acid sulfite pulp with Ca as the base conducted under low pH is more susceptible to such problems. A slow heating period, relatively long cook time, and a low cooking temperature (130°C) are characteristic of acid sulfite cooks. In addition, the acid sulfite cooks are not amenable to woody materials with resins such as Douglas fir or pines. In the case of monovalent bases, due to more rapid penetration and lower free SO_2, faster heating times, higher temperatures, and shorter cooking times can be achieved.

Delignification is achieved by the formation of lignosulfonic acids, which become soluble in the presence of base. In addition, the lignosulfonic acid undergoes cleavage into lower-molecular-weight fragments to make them soluble. The process also leads to acid hydrolysis of hemicelluloses, which are then dissolved. This hemicellulose dissolution is sometimes taken advantage of in making hemicellulose-free pulps which are needed for dissolving grades.

To aid in more complete delignification and better hemicellulose retention and/or to increase the species-friendliness of the process, several two-stage sulfite processes have been tried with an acid pH (3–4) in the initial stage followed by neutral (6–6.5) stage (magnefite process) or alkaline pH conditions (pH 9–10 in Sivola process) in the subsequent stage. Complementary processes starting with high pH (5–6) in the initial stage followed by low pH (1.5–2 in two-stage acid and 3–4 in Stora process) in the second stage are also in vogue.

As explained earlier, the future of the sulfite process on a large scale does not seem bright, though special sulfite pulping systems like NSSC (high-yield pulp), sulfite treatment in chemithermomechanical pulping (CTMP), sulfite-AQ process or alkaline sulfite with anthraquinone and methanol (ASAM) may hold their own in specific niche markets.

Sulfite pulps find their market in bond and writing or reproducing papers that require good formation but only moderate strength and in tissues where softness, bulk, and absorbency are the main characteristics. Sulfite pulps are also used to produce grades such as greaseproof and glassine that need pulps with high hemicellulose content due to its relative ease of delignification.

Kraft pulping

The kraft process uses the cooking chemicals of NaOH and Na_2S and an excellent chemical recovery process. The make-up chemical is provided in the form of sodium sulfate (hence the name sulfate process) or salt cake. The sodium sulfate is reduced in the chemical recovery furnace to Na_2S and the other sodium components are converted to Na_2CO_3. The Na_2CO_3 is converted in the causticizing cycle to NaOH by the use of lime. The lime itself is regenerated by calcining the $CaCO_3$ formed in the causticizing reaction. The various reactions are as given below:

$$Na_2SO_4 + 4C \rightarrow Na_2S + 4CO \text{ (reduction}-\text{furnace)} \quad (4)$$

$$Na_2CO_3 + CaO + H_2O \rightarrow CaCO_3 + 2NaOH \text{ (causticizer)} \quad (5)$$

$$CaCO_3 \rightarrow CaO + CO_2 \text{ (lime kiln)} \quad (6)$$

The cooking liquid thus consists of NaOH, Na_2S, and other inerts (Na_2SO_4, Na_2SO_3, etc.) as well as unconverted Na_2CO_3. The effective cooking species is not Na_2S but NaHS, generated as follows:

$$Na_2S + H_2O \rightarrow NaHS + NaOH \quad (7)$$

Hence, in the cooking liquor, NaOH + one-half Na_2S is known as effective alkali and NaOH + Na_2S is known as active alkali. Other terms that are used in kraft cooking are causticity (NaOH/NaOH + Na_2CO_3) and sulfidity (Na_2S/Na_2S + NaOH). Sulfidity has an important role to play in kraft cooking in that HS^- helps in breaking specific lignin bonds and hence in delignification. The extent of sulfidity is also found to influence the transition point between bulk and residual phases of delignification. Higher sulfidities also help to preserve cellulose viscosity during cooking.

Process Cycles

On the whole, the kraft pulping process consists of two cycles (**Figure 1**): (1) pulping/cooking liquor cycle, and (2) causticizing and lime cycle. The pulping of wood chips is done with white liquor containing the active chemicals (NaOH and Na_2S). The residual black liquor, consisting of reaction products of lignin and solubilized carbohydrate moieties, is then evaporated and burnt in the recovery furnace. The inorganic smelt (Na_2CO_3 and Na_2S), dissolved in water or weak white liquor and called green liquor, is then causticized to convert the Na_2CO_3 to NaOH to reform the white liquor. The causticizing and lime cycle, as explained earlier, uses quick lime to convert Na_2CO_3 to NaOH, which generates calcium carbonate (lime mud). The lime mud is washed, filtered, and pressed, and then burnt in a lime kiln to regenerate CaO to be used in the causticizing cycle.

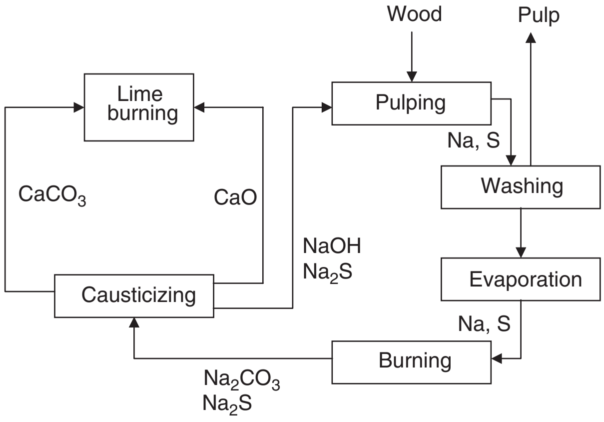

Figure 1 The kraft process.

Batch and Continuous Processes

The kraft cooking process is conducted either in batch or continuous digesters, with some small process variations. In batch cooking, the digester is packed with wood chips and liquor, and the contents are heated up according to a predetermined schedule with direct or indirect steam, usually with forced circulation through the aid of liquor circulation pumps that can turn over the liquid contents of the digester about once every 10 min. The maximum temperature in a kraft cooker is between 160 and 175°C and the cooking time is adjusted to obtain a particular yield or delignification. Cooking time is also adjusted for any variations in the actual process temperature. After cooking, the pulp is discharged into a blow tank wherefrom the blow vapors are passed on to heat recovery systems via accumulator and heat exchangers. The heating-up period in the bath digester allows for impregnation, which is aided by the alkaline nature of the cooking liquor. The capillary penetration of chemicals in a longitudinal direction is six times that of diffusion of chemicals in a radial direction (across the fiber wall).

In a continuous digester, the chips are first passed through a steaming vessel where air and other noncondensables are purged. This helps give better penetration of chemicals into chips. Hence, chip thickness is also an important variable in kraft pulping and leads to fewer screen rejects. However, it is not as critical as in sulfite pulping. The preheated chips and the liquor then enter the continuous digester where they move through different zones – impregnation, heating, cooking, and washing. Each of these zones is maintained at different temperatures and finally the pulp is discharged at the bottom of the digester at a comparatively cooler temperature of around 80°C.

The auxiliary components required for a continuous digester, although more complex than those for the batch digesters, are of lower capacity due to constant leading. The equipment itself is more compact and requires less space. Also, there is better energy recovery and reuse, leading to less steam requirement. However, one major advantage of the batch system is that it offers greater operating flexibility and ease of start-up and shutdown. Also, more efficient turpentine recovery is achieved from batch digesters due to the scheduled relief gas flows throughout the cooking cycle. Grade change or species change in a continuous digester should be planned ahead to reduce variations in product quality. Some of the recent improvements in batch digester systems, such as rapid displacement heating, lead to better heat recovery and reuse in bath systems. The computer control systems that are available for batch digesters have reduced the fluctuations in steam demand from batch units ('resource leveling').

Lignin Reactions

The chemicals that penetrate into fiber lumens and diffuse into fiber walls react with lignin through OH^- and HS^- and break major lignin bonds. The fragmented lignin is then dissolved. In the latter parts of the cooker, the lignin fragments in solution can take part in condensation reactions and be readsorbed on the fiber surfaces, resulting in dark cooks. HS^- reduces the possibility of such condensation reactions by blocking some reactive groups. Along with lignin, some of the carbohydrate is removed during the cooking process. The carbohydrates are susceptible to primary and secondary alkaline 'peeling' and alkaline hydrolysis reactions. In a typical kraft cook, about 80% of lignin, 50% of hemicelluloses, and about 10% of cellulose can be brought into solution.

The delignification reactions proceed in three distinct phases — initial, bulk, and residual. Kraft cooks are typically terminated at the end of the bulk delignification phase, since delignification slows down in the residual phase and condensation reactions increase. Also, during the residual phase, the carbohydrate reactions continue, leading to the loss of viscosity and strength in pulp. The effective result is a dark and hard-to-bleach pulp with lower strength properties. The delignification rate reactions in the three phases can be represented by the following equation:

$$-\mathrm{d}L/\mathrm{d}t = kL^a[\mathrm{OH}^-]^b[\mathrm{HS}^-]^c \qquad (8)$$

Thus, the delignification rate depends on the extent of the remaining lignin and the activities of the reactive species. The delignification kinetics is of first order with respect to lignin ($a = 1$); the values of b and c vary with the phases of delignification (**Table 1**).

Thus, the initial phase of delignification, in which there is rapid lignin removal, is independent of HS^- and OH^- and is characterized as an extraction process. This phase is diffusion-controlled with low activation energy of 40 KJ mol^{-1}. This stage removes approximately 20% of the lignin, while the bulk stage removes upwards of 60% of the lignin – mostly after major lignin bonds are broken. Delignification in the bulk stage depends on both OH^- and HS^-, while the residual-stage delignification depends only on OH^-. However, in the residual stage, OH^- is bound to be low and cooking is hence stopped at this point to avoid the effects of condensation previously mentioned.

The bulk stage of delignification has been extensively studied and it has been found that the reaction rate constant k follows the Arrhenius equation, $k = k_0 e^{-E/RT}$, where the activation energy E is about 135 kJ mol^{-1}. The kraft cooker is often controlled on the basis of H-factor, which is the relative reaction rate integrated over time. The relative reaction rate is defined as k/k_{100} and by an arbitrary assignment of a value of 1 for k_{100}. Under these conditions, the relative reaction rate is given by exp $(43.2 - 16.113/T)$ where T is the temperature in Kelvin scale. Extensive relative reaction rates have been tabulated for temperatures spanning the heating

Table 1 Values of b and c

	Initial phase	*Bulk phase*	*Residual phase*
b	0	0.7	0.7
c	0	0.4	0

and cooking range and the H-factor for any cooker is calculated on the basis of the measured temperature–time profile of a kraft cooker. The variance in relative reaction rates with temperature is a measure of relative delignification rates at a specified concentration (activity) of the reactive species.

Carbohydrate Reactions

Similar reaction rates have been determined for carbohydrate reactions in kraft cooking with two main differences: (1) activation eenergy of cellullose chain cleavage is 179 $\mathrm{kJ\,mol^{-1}}$ (42.78 $\mathrm{kcal\,mol^{-1}}$); and (2) cellulose chain cleavage in all three phases only depends on OH^-

$$-(\mathrm{d}c/\mathrm{d}t) = kc^a[\mathrm{OH}^-]^b\ c \quad \text{where } a, b = 1 \qquad (9)$$

throughout the cook. A factor similar to H-factor, defined for cellulose cleavage, is G-factor. The relative effect of temperature on the G-factor is much higher than in the case of the H-factor. That is the major reason why there is a limit on the maximum temperature of a kraft cooker. Recent modifications in kraft cooking have sought to reduce the cooking temperature as far as possible (**Table 2**).

The carbohydrates (cellulose and hemicellulose) are susceptible to peeling (removal of one end-unit at a time) and alkaline hydrolysis (a random cleavage of the polymer molecule) followed by secondary peeling. The hemicellulose content is significantly reduced by these reactions while there is relatively low loss of cellulose – about 10% – due to the low accessibility of cellulose chains by virtue of their crystallinity. The acidic products of such reactions also consume the alkali in the cooking liquor. The reactions involving carbohydrates and the neutralization of acidic components start rather early in the cooking process. To determine the extent of the loss of cooking chemicals in such reactions, online cooking liquor analysis is carried out in digester operations and the sampling point is determined on the basis of the accumulated G-factor. The cooking time is then controlled for a calculated H-factor which depends on the targeted lignin removal and the cooking liquor strength ($OH^- + HS^-$ activities). About 90% of the extractives (fatty and resin acids) are removed during the initial phase of the cook and the sodium salts can later be removed from the black liquor by acidulation in the form of 'tall oil.' Volatile turpentine is recovered from the vapor relief during cooking.

The kraft process is also characterized by redeposition of xylans from liquor on to fibers in the later stages of cooking. The kraft pulp consists of these five carbon sugars (pentosans), which are not conducive to producing dissolving grade pulp. In such a case, the kraft cooking process is preceded by an acid prehydrolysis stage in which the wood chips are exposed to direct steaming for about 2 h and the natural wood acids present are allowed to hydrolyze the hemicellulose to soluble sugars at high temperatures (170°C). This, of course, reduces the pulp yield by 5–7%, compared to normal kraft cooking.

Table 2 Ratio of temperature in cellulose and lignin

	Temperature		
	160°F	*170°C*	*Ratio*
Cellulose – G-factor	3960	9100	3.1
Lignin – H-factor	398	921	2.3
Ratio	7.4	9.9	

Extended Delignification

Extended delignification is practiced in many commercial kraft pulping operations to reduce the bleach chemical cost and bleach plant pollution loads. This seeks to fine-tune the kraft process to achieve additional delignification without the deleterious efffects of a residual delignification phase. The extended delignification involves maintaining high sulfidity, leveling out the alkali concentration profile throughout the cook, decreasing dissolved lignin concentration, cooking at a low temperature, and cold blow. This has resulted in the multistage addition of cooking liquor, removal of spent liquors at various stages, and low temperature/longer-duration cooks, and extensive equipment modifications to achieve all of the above.

The other type of extended delignification is oxygen delignification, which is compatible with the kraft process and is a subsequent process step. The oxygen-stage effluent can be added to black liquor and processed through the traditional kraft recovery cycle, thereby reducing the bleach plant pollution loads.

Pulping Additives

Another disadvantage of the kraft pulping process – the low yield from wood due to carbohydrate degradation – is overcome by using pulping additives such as polysulfide, borohydride, and anthraquinone. While all of these protect carbohydrates from the peeling reaction by oxidizing (polysulfide, anthraquinone) or reducing (borohydride) the end groups of carbohydrate chains, anthraquinone is the only reagent which has a redox cycle of its own. In the oxidation cycle, it protects the cellulose chain, and in the reduction cycle it leads to lignin fragmentation. Use of small levels of anthraquinone (about 1 $\mathrm{lb\,t^{-1}}$

of pulp) increases the yield (2–3%) and lowers the effective alkali requirement as well as increasing the delignification rate. The other two compounds have not found favor with the industry either because of the cost or because of the associated pollution problem due to sulfur compounds.

Control Parameter

A major control parameter in kraft pulp is a target kappa number (which directly relates the percentage of lignin left in pulp). Thus, a lower kappa number indicates a higher level of delignification. The higher the *H*-factor and/or active alkali, the lower will be the kappa number. The target kappa number is based on one or more of the following: (1) maximum pulp strength; (2) limitations on recovery loading; (3) maximum screened unbleached pulp yield; and (4) maximum bleached pulp yield. The cooking is essentially controlled by using the *H*-factor as a primary variable based on a desired kappa number and the cooking liquor strength from online analyzers. The desired *H*-factor is maintained in the batch digester by adjusting time and/or temperature, while in the continuous digester it is done by manipulating the temperature.

Pulp Properties

Softwood kraft pulps produce the strongest papers and are used in wrapping, sack, and liner papers. Bleached kraft pulps are used, along with high-yield pulps, in magazine-grade or newsprint furnish to provide additional strength and runnability on high-speed machines. Bleached grades are also used for toweling and boards. Unbleached grades for packaging applications are cooked to a higher kappa number to maximize the screened unbleached pulp yield while the bleached grades for writing, printing, and tissue applications are cooked to a lower kappa number.

Pulp Processing

Chemical pulps, as they come out of the blow tank, are fiberized enough to pass through knotters that can remove irregularly shaped reaction wood pieces, overthick chips, and other uncooked chips. Knots are generally defined as the pulp that is retained on 3/8 in. perforated plate. The removed knots can be recycled to a digester for recooking. The knotters can be atmospheric vibrating knotters or pressure screen knotters. The former have been superseded by the latter due to the fact that the open-type design generates foam and liquor splashing and the foam generated hinders the subsequent washing operation. The major disadvantage of the pressure knotter is that the knotter rejects should be processed through a secondary screen to recover the good fiber rejected along with the knots.

The pulp is then washed in multiple stages to remove the residual liquor from the pulp. This helps to reduce the costs of further processing and to recover the maximum amount of spent chemicals. The aim is to do so using a minimum amount of wash water, thereby reducing the dilution and consequent evaporation costs. Washing is done using any of the following: a battery of countercurrent rotary vacuum washers, rotary pressure washers, atmospheric or pressurized diffusion washers, or horizontal belt washer or dilution/extraction equipment.

Washing can be characterized either as displacement or diffusion washing. In displacement washing, a thick layer of pulp is built on a screen and wash water is applied to displace the liquor in the sheet and the displaced liquor is drained either by vacuum or forced out by pressure. Three or four stages are generally used to achieve an overall removal of about 99%, since the displacement for a single stage rarely exceeds 80% and can vary from stage to stage depending upon factors such as fiber mat drainage characteristics, air entrainment, pulp temperature, and pulp hardness and freeness.

Pulp slurry feed to a washer is prepared by mixing the filtrate of a particular stage with the exiting stock from a previous stage. In addition, the filtrate from a particular stage is also used as wash liquor in the previous stage. A countercurrent operation is maintained by balancing the liquor flows throughout the system, with fresh wash water being added to the final washer. The fresh water flow rate is controlled by monitoring the dissolved solids concentration in the exit stock from the final washer.

Diffusion washing is marked by a relatively long period of contact between the pulp and the wash liquor which allows the liquor solids to diffuse from the fiber structure. The diffusion rate depends on the temperature, concentration gradient, and fiber structure. Since the fibers are submerged, there is no air entrainment. The time of contact can vary between 10 min per stage in a multistage diffusion washer to about 2–4 h at the bottom of a Kamyr continuous digester.

Rotary pressure washers are similar to vacuum washers, but have some advantages: (1) a single washer can be operated with two or three displacement stages; (2) due to the high pressure, a high-temperature wash liquor can be used without the fear of fluffing the pulp; and (3) the closed vapor circulation system helps to prevent pollution.

The horizontal belt washer resembles a Fourdrinier paper machine in that the pulp suspension is distributed on a moving filter belt from a headbox to form a thick mat. The displaced filtrate is collected at the bottom and the filtrate from one section is used as wash liquor in the previous section in a classic countercurrent system. Unlike the rotary washer system, there is no mixing and reforming of pulp between stages.

The dilution/extraction system consists of diluting a pulp slurry with a weaker liquor and rethickening. Modern extraction presses which can thicken the pulp to a consistency of 30–40% have made such a system, operated in multistages, comparable with regular washers.

The diverse washing systems are often compared in terms of a single efficiency factor, viz., Norden efficiency factor, defined as the number of mixing stages that will give the same result as the washing equipment under consideration when operated at the same wash liquor ratio. From the computed cumulative Norden factor of the proposed equipment system and the dilution factor proposed, the anticipated washing efficiency of the system can be predicted from literature data.

The washed pulp is then screened through pressurized contrifugal screens with either centrifugal (outward) or centripetal (inward) flow or both. The screen perforations can be either taper-drilled holes or slots with relief on the accept side. Slots are oriented perpendicular to the direction of rotation so that the long dimension of the debris is presented to slot width. Slots, with their widths normally smaller than hole diameter, are more effective in removing smaller cubical debris. However, with screen open areas in the 3–7% range, compared to 10% for screens with holes, slotted screens have lower throughputs. The screen cleanliness efficiency is defined as $1-(S_a/S_i)$, where S_a and S_i are weight fractions of debris in the accepts and inlet flow, respectively. The cleanliness efficiency depends on the perforation size and type, and percentage reject rate.

The screened pulp may then be centricleaned by employing centrifugal force (density differences) and fluid shear (particle shape). The stock enters tangentially and is rotated by inlet guides. As the stock flows inward, the velocity increases, resulting in high centrifugal force near the center which carries the dense particles outwards and away from the accepted pulp. The dirt (which is heavier) held in the downward current continues toward the tip under increasing force (due to narrowing diameter). The smaller the debris size to be removed, the smaller should be the diameter of the cleaners to be employed. The contracleaning system is normally operated in three stages in a cascade sequence (with the rejects of the primary being fed to the secondary, and the secondary accept being fed to the primary, and so on) so that the overall rejected fiber is usually less than 1% while a reject rate of 10–20% is maintained in each stage to ensure good cleaning efficiency.

The cleaned pulp is then thickened using various filters (10–15% consistency), gravity thickener (4–8%), screw extractor, or various presses (>20%) before being stored in high-density chests/towers. Integrated pulp mills often store the pulp at 10–15% consistency. Nonintegrated operations can deliver pulp in wet laps (40–45%) or dry laps (80–85% oven dry) using equipment similar to the paper machine. Besides steam cylinder drying of pulp laps, pulp can be dried in air float dryers or flash-dried after prefluffing the pulp, using hot air as a drying medium.

Bleaching of Pulp

T J McDonough, Institute of Paper Science and Technology, Atlanta, GA, USA

Introduction

The term ‘bleaching,’ when used in reference to wood pulp, means chemical treatment of the pulp to increase its ability to reflect visible light or, in other words, its brightness. The color of unbleached pulp is practically all due to the lignin it contains, so bleaching necessarily implies that the lignin is either decolorized or removed. Chemical pulps contain relatively small amounts of residual lignin, so it is practical to bleach them by removing the lignin. Mechanical pulps, on the other hand, contain so much lignin that to remove it would require large amounts of bleaching chemicals and would be prohibitively expensive. Consequently, mechanical pulps are bleached by decolorizing the lignin instead of removing it. Since it is not feasible to decolorize the lignin completely, bleached mechanical pulps are generally not as bright as bleached chemical pulps. The latter are virtually free of lignin and contain only polysaccharides, which are practically colorless.

In addition to increasing brightness, bleaching simultaneously improves other desirable pulp properties by removing contaminants such as extractives and small particles of bark or incompletely pulped wood. For specialty pulps, such as dissolving pulps, the conditions of the bleaching process can be adjusted to provide for removal of undesirable hemicelluloses. In some applications these other properties are even more important than brightness and the pulp may have to be bleached to a brightness that is higher than needed, to achieve the required levels of contaminant removal.

Lignin removal is accomplished by treating the pulp alternately with oxidizing agents and alkali. Lignin is much more susceptible to oxidation than cellulose and the other polysaccharide components of the pulp, and is selectively removed. Nevertheless, the polysaccharides are not completely resistant to attack and can be damaged if the bleaching process is not carefully selected and controlled. The damage that does occur causes a small amount of the polysaccharide fraction to dissolve and is accompanied by depolymerization of the remainder. Such depolymerization, if it is sufficiently extensive, can result in a loss of pulp strength. Its extent is monitored by dissolving a sample of the pulp in a cellulose solvent and measuring the viscosity of the resulting solution. Some bleaching agents are less likely to damage cellulose than others and are said to be more selective.

Most chemical pulp bleaching sequences use chlorine dioxide to accomplish at least part of the required lignin oxidation. They generate an effluent that contains lignin degradation products and other organic materials, some of which are chlorinated. Since the effluent also contains chloride ion and other chlorine-containing ions, it cannot be recycled and burned in the mill's chemical recovery system. Consequently, pulp bleaching processes generally have the potential to affect the environment and must be selected and operated with due regard for the environment.

We can summarize the above introduction to pulp bleaching in the form of a working definition. Bleaching is the treatment of pulp to remove or decolorize its lignin component and thereby increase its brightness and other desirable properties while preserving pulp yield and strength, with due regard for potential effects on the environment.

Significance

Bleaching ranks among the most important of the processes used to manufacture pulp and paper. **Table 1** contains estimates of the amounts of the different kinds of pulp that the global pulp and paper industry produced in 2001. World production of bleached chemical pulp amounted to 78.8 million tonnes, or more than 44% of total pulp production. This figure underestimates the total amount of pulp bleached, since it does not account for the bleaching of substantial proportions of other pulp types, such as mechanical, nonwood, and deinked pulps. It would not be unreasonable to assume that nearly two-thirds of global pulp production benefits from some sort of bleaching process.

Kraft Pulp Bleaching Stages and Their Development

Hypochlorite

In the early part of the twentieth century, bleaching was a simple batch process that relied almost exclusively on calcium hypochlorite, made by bubbling chlorine gas into a lime slurry. The hypochlorite (H) stage was begun by adding the chemical to a warm suspension of unbleached pulp at low consistency. The stock was slowly agitated until the desired degree of bleaching had been achieved, after which the pulp was washed free of the spent bleach liquor and reaction products. The next step in the development of the technology was introduction of two-stage (HH) bleaching, in which only part of the hypochlorite was added and allowed to react, after

Table 1 Estimated 2001 world pulp production by type (millions of metric tons)

Pulp type	*Production*
Bleached kraft	76.3
Unbleached kraft	32.4
Bleached sulfite	2.5
Unbleached sulfite	1.1
Semichemical	7.0
Mechanical	34.7
Nonwood	14.3
Unspecified	10.0
Total	178.3

which the pulp was washed and subjected to a second stage, similar to the first. This simple modification of the process had two beneficial effects. First, the removal of dissolved but still oxidizable reaction products after the first stage reduced overall chemical consumption. Second, the reduction in the maximum and time-averaged concentrations of the oxidizing agent reduced its propensity to attack and degrade the cellulose and other polysaccharide components of the pulp. This subtle introduction of stagewise bleaching was a seminal event in the development of today's multistage bleaching sequences.

Chlorine

The commercial introduction of chlorine gas as a bleaching agent was a similarly significant milestone in the development of modern bleaching technology. The first reported commercial chlorination (C) stage was developed at the Nekoosa-Edwards Paper Co. in 1930 and 1931. It was based on the earlier observation by Cross and Bevan that lignin is rapidly chlorinated and that the chlorinated lignin is soluble in alkali and can be removed in a caustic extraction (E) stage following the C stage. Lignin removal in C and E stages allows final brightening in a subsequent H stage with a much smaller application of hypochlorite than would be necessary to achieve the same result in the single-stage process or in the two-stage HH sequence. In addition, the high selectivity of chlorine and the reduction in the amount of the relatively nonselective hypochlorite applied gave a stronger bleached pulp. Finally, it proved possible to reach higher brightness levels in the multistage CEH process. This development marked the advent of the modern multistage bleaching sequence, in which the early stages remove the bulk of the residual lignin, sometimes without significant brightness increase, and the later stages cause large gains in brightness by removing the last traces of residual lignin.

Chlorine Dioxide

The commercialization of chlorine dioxide use in the early 1940s took all of these advances one step further. WH Rapson, who was at the time an employee of Canadian International Paper Company, pioneered the use of chlorine dioxide in North America. Commercial chlorine dioxide bleaching began at that company's mill in Temiscaming, Quebec in the summer of 1946. Almost simultaneously, two Swedish mills started up similar systems. Chlorine dioxide is a powerful brightening agent and is immeasurably more selective than hypochlorite. Adding a chlorine dioxide (D) stage after the hypochlorite stage to give a CEHD sequence made it possible to achieve much higher brightness levels without compromising pulp strength. In the years following its first full-scale application, chlorine dioxide displaced more and more hypochlorite, and by the 1960s the CEDED sequence had become the standard for the industry.

As well as being an efficient brightening agent for application in the later stages of a bleaching sequence, chlorine dioxide can assume a role similar to that of chlorine, earlier in the sequence. Used in this way, chlorine dioxide oxidizes lignin while it is still present in relatively large amounts and renders it soluble in a subsequent alkali extraction stage. For many years, however, chlorine dioxide was considered too expensive to be used as a complete replacement for chlorine and its use at an early stage in the sequence was restricted to replacing only part of the chlorine in the chlorination stage. This was practiced for either of two reasons – to prevent loss of pulp strength, as indicated by excessive viscosity loss, or to improve delignification efficiency. In the former application, only small fractions of the chlorine were replaced, usually in the neighborhood of 10%. Such a small amount of chlorine dioxide, when added at the same time as the chlorine or shortly afterwards, serves to neutralize free radicals responsible for cellulose degradation during chlorination. When used to improve delignification efficiency, larger fractions of the chlorine were replaced, typically about 50%. This level of substitution results in a significant increase in apparent lignin removal, as measured after the alkali extraction stage that follows the chlorination stage. When used in this way, the chlorine dioxide is added to the pulp before the chlorine. The use of substitution levels much higher than 50% results in a loss of efficiency and 100% substitution usually requires more than the theoretical amount of chlorine dioxide.

In spite of this loss in efficiency, complete replacement of chlorine by chlorine dioxide began in the late 1980s in Sweden and has since become widespread. The practice began in response to new environmental regulations and environment-related market pressures. The potential of bleaching effluents to affect the environment is usually estimated by characterizing them in terms of the results of several different chemical test methods. One of these is a method for determining the effluent's content of adsorbable organic halide, abbreviated as AOX. In effect, AOX is an estimate of the total amount of chlorine in organic compounds found in the effluent. Some organic chlorine compounds are highly toxic, notably chlorinated dibenzodioxins (dioxins), chlorinated dibenzofurans (furans), and highly chlorinated phenolic compounds. Since it is much easier to measure AOX than to measure amounts of individual toxic compounds, most jurisdictions have adopted AOX as a basis for regulation (in spite of the fact that most of the organic chlorine compounds found in bleaching effluents are not toxic). In general, AOX limits have been set at very low levels by the environmental authorities in pulp-producing countries, effectively forcing the industry to phase out the use of molecular chlorine. Its complete replacement by chlorine dioxide gave rise to the term 'elemental chlorine-free' bleaching, or ECF bleaching. Bleaching with chlorine dioxide generates far less AOX than bleaching with the equivalent amount of chlorine. It also generates no detectable levels of dioxins or highly chlorinated phenolic compounds and usually generates no detectable levels of furans.

Hydrogen Peroxide

Hydrogen peroxide is similar to chlorine dioxide, in that it can be applied at a later stage in the bleach sequence to attain high brightness. Though not as highly selective as chlorine dioxide, a hydrogen peroxide (P) stage does not adversely affect pulp strength if the bleaching conditions are appropriately chosen. Both hydrogen peroxide and chlorine dioxide found wide application, but the generally greater cost-effectiveness and selectivity of chlorine dioxide resulted in its being more widely adopted. Although, as noted above, the CEDED sequence had become the standard for the industry by the 1960s, hybrid sequences such as CEHD and CEDP were still in common use. More recently, technologies have been developed for using peroxide to remove significant amounts of lignin earlier in the bleaching sequence while simultaneously brightening the pulp. These methods employ forcing conditions of high temperature and pressure to accelerate the normally sluggish reaction of hydrogen peroxide with lignin. The use of such forcing conditions is only feasible if the pulp is pretreated to remove traces of transition metal ions, which would otherwise catalyze decomposition of the peroxide. This is achieved by inserting a chelating agent (Q) stage ahead of the peroxide stage. A chelating agent commonly used for this purpose is diethylenetriaminepentaacetic acid (DTPA). Peroxide may also be used to enhance the effectiveness of alkali extraction stages and oxygen stages. Conversely, oxygen may be added under pressure to give a pressurized peroxide (PO) stage as part of a strategy to impose forcing conditions in the peroxide stage. The advent of this practice during the 1990s has blurred the distinction between peroxide and oxygen stages.

Oxygen

During the period of chlorine dioxide's ascent, research was being conducted on two other promising bleaching agents – oxygen and ozone. Oxygen, when applied together with alkali in an oxygen delignification (O) stage, is capable of removing much of the residual lignin in a kraft pulp, but its low solubility and its tendency to be nonselective (especially in the presence of trace amounts of one or more transition metal ions, notably iron, manganese, or copper) slowed the development of oxygen delignification processes. Ozone is even more reactive toward lignin than oxygen but its tendency to be nonselective similarly hindered its commercialization. Oxygen was the first of the two to achieve the status of a commercially viable bleaching agent, owing in part to the discovery of a cellulose 'protector' by Robert and coworkers in France in the early 1960s. They found that adding a small amount of magnesium ion to the pulp before oxygen bleaching deactivated trace metal ions and allowed about half of the residual lignin to be removed without affecting pulp strength. Soon after this, in 1970, a mill in Enstra, South Africa, started up the first commercial oxygen delignification system. The significance of this development lay in its potential for decreasing the environmental impact of the bleach plant. Unlike the effluents from C stages or stages following C stages, oxygen-stage effluents do not contain significant amounts of chloride ion, so they can be recycled to the mill's chemical recovery system and ultimately destroyed by burning in the recovery furnace. The quantities of materials discharged to the environment are roughly proportional to the amount of lignin in the pulp entering the bleach plant. Consequently, removal of, for example, 50% of the lignin in an oxygen stage before conventional bleaching (such as in an OCED sequence) can result in a roughly 50% reduction in bleach plant discharges.

In addition to being used to reduce the lignin content of the pulp entering the bleach plant, oxygen can be used in the bleach plant itself. The earliest such application appeared in about 1980 and consisted of reinforcement of the first caustic extraction stage. Oxygen is dispersed in the pulp after addition of alkali, transforming the E stage into an (EO) stage. The result is more efficient removal of lignin that has been solubilized by the preceding oxidative stage (then C, now D). The benefit can be realized either in the form of reduced cost for bleaching agents in the succeeding stages of the sequence or reduced AOX, by decreasing the application of chemical in the stage preceding the (EO) stage. Adding both oxygen and hydrogen peroxide to the extraction stage has an even greater effect than adding oxygen alone. The result is an (EPO) stage. A related but more recently developed use of oxygen in the bleach plant combines it, under pressure, with hydrogen peroxide, giving a (PO) stage.

Ozone

Ozone has even greater potential than oxygen for lessening the effects of bleaching on the environment because its greater reactivity, at least in principle, allows it to remove nearly all of the lignin in a form that is recyclable to the recovery system. That same reactivity, however, can lead to cellulose degradation and loss of pulp strength if the ozone is not applied uniformly and in controlled amounts, under appropriately selected conditions. Because of these demanding requirements, the commercial application of ozone took a long time after the initial discovery of its bleaching power. In 1992, however, Union Camp Corporation announced that it had successfully developed a viable ozone (Z) stage capable of selectively delignifying kraft pulp. That company started up a 1000-ton per day bleach plant incorporating both ozone and chlorine dioxide stages, the sequence being OZED. Since then, many other commercial ozone stages have been put into operation, though not all of them are placed in such a way that their effluents can be recycled to the recovery system.

Ozone may be used in close combination with chlorine dioxide by sequentially adding the two chemicals in the same stage. The resulting stage may be designated (DZ), (ZD), (D/Z) or (Z/D), depending on the order of addition and the time that is allowed to elapse between additions of the two chemicals.

Hemicellulose-Degrading Enzymes

In 1987, Finnish researchers proposed the idea of using hemicellulose-degrading enzymes as pulp-pretreating agents to facilitate subsequent bleaching. Although they do not themselves remove lignin from the pulp, xylanases were shown to be capable of rendering the lignin in unbleached pulp to be more readily removed by subsequent treatment with chlorine dioxide and alkali. The xylanase (X) stage typically results in reductions in chlorine dioxide requirements of approximately 5 kg per ton of pulp. The technology has been commercialized in a significant number of bleached kraft mills.

Prehydrolysis

Another significant discovery emerged from Finnish research laboratories during the 1990s. This was the finding that a significant fraction of the oxidizable material (as measured by the kappa number, a test designed to estimate the amount of residual lignin in pulp) is not lignin. This material, hexenuronic acid, is formed from xylan during kraft pulping, and consumes chlorine dioxide during bleaching. Since hexenuronic acid is also susceptible to removal by acid hydrolysis, this discovery led to the development of an acid hydrolysis (A) stage that can be used as a pretreatment to reduce the requirement for chlorine dioxide significantly during subsequent bleaching. Since hardwoods contain much more xylan than softwoods, hardwood pulps contain more hexenuronic acid than softwood pulps. The prehydrolysis process has been commercialized in hardwood pulp bleach plants at several mills.

Bleaching Sequences

Successive incremental additions of any bleaching chemical result in progressively smaller incremental effect, regardless of whether the effect in question is lignin content reduction, brightness increase, or some other property change. Furthermore, an asymptotic limit is approached that usually falls far short of the desired target level and high total chemical charges are needed to approach the limit. On the other hand, if chemical addition is stopped at some economical level and the pulp is washed before the same chemical is again incrementally added, the incremental increases in effect are initially larger than if the washing step had been omitted. To illustrate, a DD sequence requires less chlorine dioxide than a single D stage to reach a given brightness and is capable of reaching a higher brightness. Furthermore, if the bleaching chemical in question is an acidic oxidant, such as chlorine dioxide, the effect is strongly enhanced by intermediate alkali extraction. Thus, a DED sequence requires much less chemical to reach a given brightness and is capable of reaching a much higher brightness. By extension, a DEDED sequence requires still less chemical and is capable of reaching an even higher brightness.

Notation

As is already apparent from the preceding paragraphs, a system of shorthand notation has evolved for designating the individual stages that make up a bleaching sequence. The uppercase letters appearing in parentheses are used to represent the stages to which they refer. A single uppercase letter represents a bleaching stage that consists of a mixer, a retention vessel (usually a tower), and a washer. A stage to which two chemicals are added sequentially without intermediate washing is represented by an ordered combination of letters within parentheses, with or without an intermediate '/,' depending on whether the time elapsed between the two chemical additions is greater or less than 1 min. Simultaneous addition is indicated by using a '+' instead of a '/.' Examples are D, (ZD), (D/Z), and (C+D). A bleaching sequence is then represented by an ordered combination of stage designators, D(EPO)DED, for example. Numerical subscripts are sometimes used to denote the position of a stage within the sequence, for example, D_0(EPO)D_1ED_2.

Partial Bleaching Sequences

One may consider a chemical pulp bleaching sequence to be made up of two partial sequences, a delignifying partial sequence and a brightening partial sequence. The purpose of the former is primarily to remove lignin, rather than to increase brightness. The purpose of the latter is primarily to increase brightness by removing the small amount of remaining lignin and perhaps decolorizing traces of lignin that remain with the bleached pulp. **Table 2** provides lists of delignifying and brightening partial sequences. Any one of the former can be combined with any one of the latter to create a full bleaching sequence, capable of bleaching softwood kraft pulp to brightness values in the range 80–90, depending on the particular sequence. Note that the partial sequences listed in the table are only examples; many more could have been included.

Table 2 Examples of delignification and brightening partial bleach sequences

Delignification	*Brightening*
CE	H
(C+D)E	HEH
(DC)(EO)	HED
D(EPO)	D
ODE	DD
OD(EO)	DED
OXD(EPO)	DEDP
OXQP	DPD
OZ	(EPO)P
OOQP	PP
OQPZ	Q(PO)

ECF and TCF Sequences

As already noted, sequences based on the use of chlorine dioxide without any use of molecular chlorine are termed elemental chlorine-free (ECF) sequences. Sequences that use no chlorine compounds or molecular chlorine are referred to as totally chlorine-free (TCF) sequences. The latter sequences generally have higher costs and are less able to achieve high brightness and high strength simultaneously. With reference to **Table 2**, examples of ECF sequences are D(EPO)DED, OD(EO)D, and OZED. Examples of TCF sequences are OXQPPP and OQPZQ(PO).

Process Conditions

The operating state of a bleaching stage is generally characterized in terms of chemical charge, consistency, time, temperature, and terminal pH. Some bleaching stages, such as a brightening D stage, are invariably operated within a narrow range of conditions that have been determined to give near-optimum results. Others, such as the oxygen stage, exist in a variety of different forms, each with its own range of operating conditions. Thus oxygen stages may be operated at medium consistency (10–14%, MC) or high consistency (20–27%, HC) and initial chlorine dioxide (D_0) stages may be operated at low consistency (3.5–4%, LC) or MC. Typical process conditions for some bleaching stages are given in **Table 3**.

Bleaching of Mechanical and Other High-Yield Pulps

Among the principal virtues of mechanical pulps are their very high yields. Unavoidably associated with such high yields are correspondingly high lignin contents. Since the lignin content of the wood raw material may be as high as 30%, mechanical pulps may have lignin contents approaching this figure. This precludes bleaching by lignin removal, which would negate the yield benefit and consume inordinately large amounts of bleaching chemicals. Consequently, high-yield pulps are bleached with chemicals that decolorize lignin instead of removing it, sometimes referred to as lignin-preserving bleaching agents.

The two main bleaching chemicals used for this purpose are sodium dithionite (commonly known as sodium hydrosulfite) and hydrogen peroxide. Bleaching with hydrosulfite, a powerful reducing agent, is used when the required brightness increase is relatively small. The maximum brightness increase achievable depends on the wood species, but is almost never greater than 10 points. To illustrate, a mill making thermomechanical pulp as the main component of a newsprint furnish may use hydrosulfite to increase the brightness of the pulp from 55 to 60, a value typically required for newsprint. Hydrosulfite bleaching is conducted at low or, less often, at medium consistency and at the highest feasible temperature, usually 60–70°C. It is necessary to exclude air, since oxygen rapidly destroys hydrosulfite.

The ability of hydrogen peroxide to serve as a lignin-preserving bleaching agent may seem counterintuitive, given the above reference to its use as a delignifying agent for chemical pulps. It is found, however, that if the conditions are appropriately

Table 3 Typical process conditions for individual bleaching stages

Stage	*O*	*D*	*(EPO)*	*D*	*E*	*Z*	*Q*	*P*	*(PO)*	*A*
Variant	Medium consistency	Delignifying		Brightening	Second extraction	Medium consistency

DTPA, diethylenetriaminepentaacetic acid.

chosen, the action of the peroxide will be limited to destruction of chromophoric structures within the lignin without degrading it to the extent that it would dissolve and be removed. The conditions are milder than those used to delignify chemical pulp and include the use of sodium silicate and magnesium sulfate to stabilize the peroxide toward metal-catalyzed decomposition. Bleaching is usually conducted at the highest possible consistency, a temperature in the range 40–60°C, and in the presence of sufficient alkali to result in a terminal pH of about 10.5. Under favorable conditions, peroxide bleaching may be capable of raising the brightness by 20 points or more, so it is used when the brightness gain needed is greater than can be achieved with hydrosulfite alone. Still higher brightness gains can be achieved by sequential bleaching with peroxide and hydrosulfite, usually in that order, though the brightness gains are far from additive. Hydrosulfite applied after a peroxide stage may result in only 1–3 points brightness increase.

Bleaching of Recycled Fiber

Recycled fiber often contains chemical pulps mixed with mechanical pulps, chemimechanical pulps, or both. For this reason recycled pulps are usually bleached with lignin-preserving bleaching agents. Complicating factors not encountered in the bleaching of virgin pulps are incomplete ink removal, the presence of dyes, and the greater contribution of resistant chromophores to the color of the pulp, the less resistant ones having been removed during virgin fiber processing. All of these factors are obstacles to the attainment of high brightness. Hydrogen peroxide may be used during repulping or deinking, to prevent alkali-induced yellowing and perhaps achieve some degree of brightening, and may also be used in a subsequent bleaching stage. Dithionite may be used subsequently for 'color stripping' or decolorization of dyes. Another powerful reducing agent, formamidine sulfinic acid (FAS) may be used for the same purpose. FAS is more expensive than hydrosulfite, but may be cost-effective. Ozone can also be used for color-stripping. Because of the extreme variability in the characteristics of recycled fiber feedstocks, it is difficult to generalize further. Experimentation is necessary to identify appropriate bleaching processes and conditions for any given recycled fiber supply.

Bleaching Equipment

A pulp bleaching stage normally consists of a mixer, a pump, a retention tower, and a washer. Good mixing is a critical prerequisite for efficient bleaching and good bleached pulp quality. Mixing equipment found in bleach plants may be of several types: continuous stirred tanks, peg mixers, static mixers, and high-shear mixers. High-shear mixers, introduced in the early 1980s, have allowed efficient fiber-scale mixing to be achieved at medium consistency and have enabled medium-consistency applications of gaseous bleaching chemicals that were previously impossible. These include medium-consistency delignification with oxygen or ozone and oxygen-reinforced alkaline extraction. High shear is created by passing the pulp suspension through a narrow gap between two surfaces moving at a high velocity relative to one another.

Bleaching towers are vertical, cylindrical, plug-flow reactors that provide the necessary time for micro-scale chemical concentration gradients to be evened out by diffusion and for the bleaching reactions to be completed. There are three basic types: downflow, upflow, and upflow–downflow. Downflow towers are used for bleaching chemicals that are not gases under normal conditions. Upflow towers are used for stages employing gaseous bleaching chemicals. The hydrostatic head of the pulp column provides sufficient pressure to prevent loss of gas from the pulp suspension before it has had time to react. Upflow–downflow towers combine the advantages of both component types. The pulp and bleaching chemical enter at the base of the upflow tube, which provides the hydrostatic head necessary to keep gaseous bleaching chemicals in solution. It provides sufficient retention time for much of the bleaching chemical to be consumed by the pulp, thus reducing the likelihood of gas loss at the top of the tube. The pulp then falls into the downflow part of the tower, where the reaction is completed. The retention time can be controlled by controlling the depth of the pulp bed in the downflow part of the tower.

The pulp emerging from a bleaching stage is generally washed before entering the next stage. This removes organic material that would otherwise consume chemical in the next bleaching stage, as well as spent and residual bleaching chemical. The type of washer most often used is the rotary drum filter, though diffusion washers and wash presses may also be used.

Figure 1 is a schematic representation of a generic bleaching stage, showing the washer following the previous stage, a steam mixer discharging to a standpipe feeding a stock pump, a high-shear chemical mixer, an upflow–downflow tower, and the bleached pulp washer.

Novel Bleaching Systems

Most of the bleaching systems discussed above have found wide commercial application. Some newer technologies have been implemented only recently and can, at the time of writing, be found in only a few operating mills. Still others are at the research stage and may hold promise for the future.

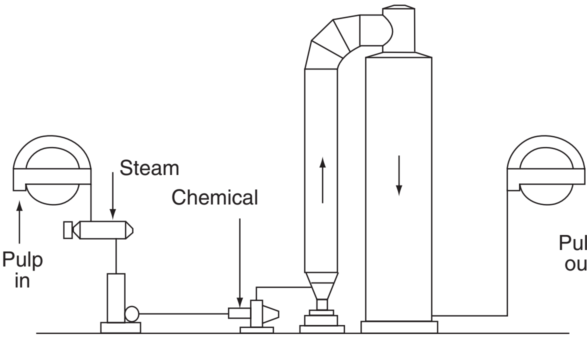

Figure 1 Schematic representation of a generic upflow–downflow bleaching stage. Reproduced with permission from Dence CW and Reeve DW (eds) (1996) *Pulp Bleaching: Principles and Practice*. Atlanta, GA: TAPPI Press.

Peracids

Peracids, more correctly called peroxyacids, are analogs of hydrogen peroxide in which one of the hydrogens is replaced by an acyl group. They can be prepared by reacting an acid with hydrogen peroxide. Acetic acid gives peracetic acid and sulfuric acid gives peroxymonosulfuric acid, also known as Caro's acid. Both of these peracids are selective pulp-delignifying and brightening agents. They are more reactive than hydrogen peroxide and therefore can be used under milder reaction conditions. Peracetic acid is currently being used for pulp bleaching in a few mills in Europe.

Dimethyldioxirane

Dimethyldioxirane is derived from acetone by inserting a peroxidic oxygen into the carbonyl group, forming a molecule with a reactive, three-membered ring. It is both reactive and selective, but would have to be generated on site because of its relative instability. In principle, its generation is straightforward, involving preparation of Caro's acid from sulfuric acid and hydrogen peroxide, followed by reaction of the Caro's acid with acetone. However, the economics of the system depend on cheap and efficient recovery of both acetone and sulfuric acid, an engineering challenge that has not yet been met.

Lignin-Degrading Enzymes

The most important member of this class is laccase. Early attempts to bleach pulp with laccase failed because the laccase molecule is too large to diffuse into the pulp fiber, where the lignin is located. This problem was partially solved in the early 1990s, when it was discovered that certain compounds can serve as 'mediators.' Such a compound diffuses into the fiber and oxidizes lignin, thereby being reversibly converted to its reduced form. The reduced mediator diffuses out of the fiber into the bulk medium, where it is reoxidized by laccase, regenerating the oxidized form, which is capable of again diffusing into the fiber and further oxidizing lignin. Furnishing oxygen to reoxidize the laccase completes the cycle. The process is not yet commercial, since the known mediators are too expensive. It is possible that further research will solve this problem.

Polyoxometalates

Another process that has not yet reached the point of commercialization employs polyoxometalates (POMs), metal oxide anions (heteropolyanions) formed from simple oxides of vanadium, molybdenum, or tungsten. They have oxidized forms that are capable of oxidizing lignin and being regenerated by oxidation with oxygen or hydrogen peroxide. Current research envisages a zero effluent concept: an aqueous solution of POM is applied to the pulp under anaerobic conditions. It oxidizes and degrades the lignin and itself becomes reduced in the process. The spent liquor containing the reduced POM and the dissolved organic material (mostly oxidized lignin) is separated from the pulp and oxidized with oxygen at high temperature. The reduced POM catalyzes the destruction of the organic material, converting it to carbon dioxide and water. At the same time, the oxidized form of the POM is regenerated and can be used again for bleaching. From an environmental standpoint, this conceptual process is extremely attractive, since it emits only carbon dioxide and water and uses no chlorine compounds. However, considerable engineering development is still needed to realize the extremely high POM recoveries that would be needed to make it economically feasible.

Introduction

Innovation in advancing technologies for production of pulp and paper has been driven, by and large, by the needs to reduce the environmental impact of pulp mills or to enhance the yield in processes of conversion of wood to fibers. 'Fiberization' of wood chips is carried out in two categories of processes. One, chemical pulping, relies on removing the lignin that binds the cellulose fibers together by chemical delignification processes. The other is based on mechanical fiberization of the wood while retaining much of the lignin. The resulting pulps have significantly different properties. The chemical pulps are used in the manufacture of paper or packaging materials that require the fibers to have excellent mechanical properties or to have high brightness for the manufacture of fine papers. The mechanical pulps are used as fillers or in the manufacture of papers that do not require fibers of high strength. Some chemical pulps are also used as a source of high-purity cellulose for the manufacture of cellulose derivatives or for the production of regenerated cellulose fibers. We will touch upon some advances in both arenas.

Much of the chemical pulping industry is focused on use of the kraft pulping process, and efforts to make the process more efficient continue; both pulping and bleaching operations have been modified and improved.

Pulping and bleaching processes are subjects of separate articles (*see* **Pulping**: Bleaching of Pulp; Chemical Pulping; Mechanical Pulping). Since both involve delignification of wood fibers, there is some continuity in the processes and the boundary between them can occur at different levels of delignification, depending on the conditions and operational choices at each mill. It is well to consider the operational differences between them however.

The pulping process begins with wood chips and delignifies them to a point where the individual fibers that make up the chips are free to separate from each other. Pulping operations are intended to fiberize the wood by removing much of the lignin. If the pulp is to be used for the manufacture of container board, it can be used at the point where the lignin content has been reduced to between 8% and 10%. The kraft process (*see* **Pulping**: Chemical Pulping) is based on using a mix of NaOH and NaSH in the white liquor to digest the wood in an alkaline anaerobic environment. The lignin and polysaccharide degradation products solubilized in the process are then burned, after concentration of the black liquor, to recover both the energy content and the inorganic components. The inorganics are then causticized again and recycled into the digesters.

When the pulp is to be used to manufacture white papers, it is necessary to continue the delignification until the pulp has less than 1% lignin. At that point it is subjected to a bleaching process, often thought of as brightening, that removes the remaining lignin and oxidizes residual color bodies so they can be solubilized during extraction to give a white pulp of high brightness. These processes are usually based on creating an oxidizing environment that can both delignify and bleach. The transition from pulping in an anaerobic alkaline environment to bleaching in an oxidizing environment can occur at different levels of lignin content. It can be as high as 10% lignin, where the early oxidative delignification step is thought of as an extension of the pulping or a pretreatment prior to bleaching. But it can also be as low as 3% when the extended cooking of the pulp under anaerobic alkaline conditions is used to achieve the maximum delignification prior to the entry into the oxidizing environment.

The innovations to be described in this article are in processes at different points in the delignification. Some are intended to improve the efficiency and selectivity of the alkaline anaerobic pulping environment while also reducing the need to use sulfur or eliminating it entirely. Others are based on the application of oxidative environments in manners that require little or no chlorine-based bleaching agents or create a more selective environment. Selectivity is defined as the removal of lignin and its degradation byproducts, with minimal damage to cellulose and other cell wall polysaccharides.

Some important advances in the technology of mechanical pulping will also be described, as will be some innovations with respect to preparation of fibers and pretreatments applied prior to transfer to the paper machine.

Chemical Pulping

Kraft Process

As noted earlier, the kraft process is the most common chemical pulping process (*see* **Pulping**: Chemical Pulping). The chipped wood is introduced into an anaerobic alkaline environment under conditions that result in maximizing the solubilization and removal of lignin, while minimizing the degradation or removal of cell wall polysaccharides, principally cellulose. The pulping process is usually stopped at a lignin content of 4–5% because further treatment under these conditions results in unacceptable losses in cellulose or degradation of the mechanical properties of the fibers. In recent years, however, ways have been found to extend the kraft pulping process to somewhat lower lignin contents without extensive reduction in pulp strength. For continuous digesters, the system is called modified continuous cooking (MCC); for batch digesters, one version of the system is called rapid displacement heating (RDH). In these systems the alkali concentration in the digester is manipulated so as to reduce the damage to the cellulose and hemicelluloses during pulping. The guiding principle in these systems is creation of a countercurrent flow of the pulping chemicals and wood chips. Their aim is to keep the concentration of alkali lower and more uniform throughout the cooking process and also to minimize the concentration of dissolved lignin at the end of the cook. A major problem with these systems is that pulp yield can be substantially reduced. This is in contrast to oxidative delignification, where delignification to the same lignin content results in significantly higher pulp yields. The use of MCC or RDH to reduce the lignin content results in reduction of the organics in the effluent stream as much of the lignin removed in the later delignification is sent to the recovery boiler. This of course is also true of the oxidative delignification processes. Both MCC and RDH systems are employed in many mills. Others rely on oxidative delignification using either oxygen or ozone to carry out the delignification from about 5% to less than 1% before transfer to the bleach plant.

Other Alkaline Pulping Processes

While it can no longer be regarded as a recent innovation, the use of anthraquinone (AQ) as a pulping catalyst has been developed further in recent years. It is usually used to enhance the effectiveness of kraft pulping; in some instances it has also been used with soda pulping, that is, without sulfur.

Recently, it has been shown that octahydrodimethyl-anthraquinone (ODiMAQ) is a much more effective delignification catalyst than is AQ. It is thought that ODiMAQ can be produced for about the same cost per unit weight as AQ. It is anticipated that soda–ODiMAQ cooking will be more attractive economically than soda–AQ. If oxidative delignification is introduced early in the delignification process, at the level of 8–10% lignin content, it may well be that the soda–ODiMAQ treatment is more effective than soda–AQ. If followed by oxidative delignification, it may become an option for sulfur-free pulping.

Polyoxometalates in Pulping

Over the past decade a new oxidative delignification system has been developed. Although it has been developed primarily in the context of bleaching, it is likely to be useful in early delignification. Here it would be a replacement for MCC, RDH, oxygen, or ozone delignification. It is based on the use of polyoxometalates (POMs) as regenerable selective oxidants.

The POMs are designed to mimic the action of oxidative enzyme systems that can oxidize and solubilize lignin without damaging the cellulose. They are inorganic cluster anions that are similar to the structures of many minerals. Certain of these POMs in aqueous solution are very selective in oxidizing the lignin of kraft pulp under conditions that result in little damage to the cellulose and hemicelluloses. To minimize damage to the pulp, the delignification must be carried out under anaerobic conditions. After reaction with the pulp, the solution can be filtered off and regenerated. Some of the POMs that are very effective in delignification can also be readily regenerated with oxygen under relatively mild conditions. During the regeneration, these same POMs act as oxidation catalysts for the wet oxidation of the solubilized lignin and carbohydrate fragments to carbon dioxide and water. The reduced POMs are readily washed from the pulp and can be recovered for regeneration with very little loss. Thus, the overall POM delignification process is a two-stage process that selectively delignifies pulp in water using oxygen as the only consumable in the regeneration process; there are no liquid waste or toxic byproduct steams. Of the POMs studied to date, $Na_6[SiV_2W_{10}O_{40}]$ best fulfills the requirements of both the delignification stage and the regeneration and wet-oxidation stage. In multicyclic experiments, it has been found to be thermodynamically stable in both stages. Other POMs are currently being synthesized and evaluated for their effectiveness.

In studies of high-lignin pulps, it has been shown that significant increases in yield can be achieved by stopping kraft or soda–AQ cooks at relatively high lignin content (8–10%) and delignifying the pulps further to bleachable levels with aqueous solutions of a POM. POM delignified kraft pulp was found to give higher yield and stronger pulp than did POM-delignified soda–AQ pulp. It was thought that a higher level of AQ than that used (0.20%) might yield results equivalent to those of kraft pulp.

In a recent study, lodgepole pine chips were cooked to a lignin content near 9% with soda–ODiMAQ and then further delignified to a lignin content of about 4% with aqueous solutions of POM. The yield and strength results from these pulps were then compared with previous results from kraft and soda–AQ cooking of the same wood followed by delignification to the same lignin levels with the same POM. Favorable comparisons were also made with pulps produced from the same chips and delignified to about 4% lignin content by single-stage kraft, soda–AQ, and soda–ODiMAQ methods.

Although a considerable amount of work has been done on suppressing the odor emitted from the kraft process, the problem still persists. At some future date, the public is likely to demand that the kraft process be abandoned. Then the soda–ODiMAQ pulping followed by the POM delignification system is a feasible alternative. The pulp yield is significantly higher than that of the kraft process and the pulp strength, although somewhat less than that of kraft pulp, is more than adequate. Soda–AQ followed by POM delignification may also be feasible, although since AQ and ODiMAQ are equivalent in cost, based on overall yield data available at present, soda–ODiMAQ may be preferred.

Bleaching Chemical Pulps

The increased emphasis on reducing the environmental impact of pulp bleaching has led to exploration of the use of enzyme systems. In an effort to achieve this goal, research has increased toward enzymatic treatments. There are two fundamental approaches: the first is to enhance the removal of lignin by traditional bleaching chemicals. The application of xylanases in commercial systems is indicative of the promise of this approach. The second approach has been to use enzymes that act directly on lignin. The work here has focused largely on manganese peroxidase- and laccase-mediator systems. There are currently economic limitations to their commercial implementation. Additionally, POMs are being developed as inorganic analogs to enzymes in the direct oxidation of lignin.

Polyoxometalates in Bleaching

It has been shown that POMs can be used to delignify even high-lignin pulps to very low-lignin contents without excessive damage to the pulp. Only a single brightening stage would be required to attain high brightness after POM delignification. Based on present knowledge, it seems that the POM bleaching process is well adapted to facilitate the TCF kraft mill and bleach plant. Only effluent from the final brightening stage would go to the kraft recovery cycle. The POM delignification and regeneration/wet-oxidation cycle would be self-contained and would not contribute effluent to the kraft recovery cycle. This would either increase pulp mill capacity or reduce the size of the required kraft recovery furnace. POM bleaching is a novel technology that may revolutionize the bleaching of chemical pulps.

Xylanase Treatment

The application of xylanases to fibers between chemical pulping and the bleaching sequence is being rapidly implemented in mills worldwide. This has occurred for many reasons. Xylanase treatments can be implemented successfully with softwood, hardwood, and other lignocellulosic pulps. Reduced chemical loads are required for the bleaching sequence; if chlorine or chlorine dioxide is used, effluent properties, such as aromatic organic halides (AOX), chemical oxygen demand (COD), and color are reduced. Higher-brightness ceilings can be reached. Implementation of xylanase treatment into current industrial bleaching sequences can be done without extensive capital costs.

In general, the xylanase treatment is placed after the pulping and oxygen delignification steps and prior to chlorine, chlorine dioxide, and hydrogen peroxide steps; mills have implemented xylanase before or after ozone bleaching stages. In general, the higher the lignin content is prior to the xylanase application, the greater the reduction on subsequent chemical consumption or brightness gain. If hydrogen peroxide will follow, the xylanase treatment can be combined with chelation. Although the optimum reaction conditions vary with different xylanases, the pH generally lies between 4 and 9, with the temperature between 40 and 80°C. The xylanase is generally applied as a concentrated liquid at a rate near 100 ml per ton of pulp; too much can cause yield losses. Recent work has also found that mixtures of xylanases can have an improved effect. Most of the problems encountered with the xylanase treatment in mills have been due to poor mixing, reactor channeling, or poor pH and temperature control.

There are several proposals for the mechanism of xylanase efficacy. Xylanase may remove from the pulping process the reprecipitated xylans that have covered the lignin and limited access of subsequent bleaching chemicals. Or the removal of residual xylan in the cell walls may allow entrapped lignin to diffuse more easily out of the pulp fiber. Additionally, xylanases may play a role in altering lignin–carbohydrate bonding or in removing hexyneuronic acid groups.

Oxidative Enzyme Treatments

The extracellular ligninolytic enzymes of white-rot fungi have been the focus of significant development efforts over the past several years. These include lignin peroxidases (LiP), manganese peroxidases (MnP), and laccase, which can be used to replace chemical bleaching stages. While these enzymatic treatments do not usually brighten pulp (the pulp, in fact, often becomes darker after treatment) they do increase the effectiveness of subsequent brightening stages.

Manganese peroxidases are used in conjunction with hydrogen peroxide and manganese. Some pulps do not require additional manganese as they either already contain a sufficient amount of accessible manganese or chelators can be added to liberate sufficient amounts for full activity. Manganese and lignin peroxidases need a hydrogen peroxide source to be effective. Problematically, however, too high a level of hydrogen peroxide can inactivate these peroxidases, so glucose oxidase systems have been studied recently in order to generate low levels of hydrogen peroxide continuously. While these enzymes have become more available, an economical source for industrial application in pulp and paper has yet to be found.

Laccases work with oxygen and a mediator, a low-molecular-weight compound. These laccase-mediator systems (LMS) can achieve 40–60% delignification of kraft pulps. Researchers have commonly used 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonate) (ABTS), 1-hydroxybenzotriazole (1-HBT), and violuric acid (VA) as mediators, but they are very expensive and may deactivate the laccase over time. Other mediators, such as extractives from wood and transition-metal complexes, are currently being studied. Furthermore, different laccases react differently with mediators and multistage laccase treatments, each with different mediators, will remove more lignin.

Laccases have also been used for reducing the energy of mechanical pulping. Peroxidases and laccases have also been used to polymerize and copolymerize materials with lignocellulosic fibers.

Mechanical Pulping

Mechanical pulping includes all processes that fiberize the wood chips with little or no application of chemicals. Not surprisingly, they require a considerable amount of energy, and they generally result in damage to the fibers. Thus two important goals are sought in advancing this technology. The first is to reduce the energy consumption in the mechanical refining. The second is to reduce the damage to the fibers. Recent developments have resulted in advances in both areas.

Biopulping

Biopulping is a process developed to improve the quality of mechanical pulps and significantly reduce the electrical energy required to pulp wood chips. High-yield mechanical pulps use wood resources efficiently, but consume considerable electrical energy during refining. The resulting pulp is considerably weaker than pulps produced by chemical pulping methods.

When wood chips are pretreated with an inoculum of fungi prior to refining, the wood chips become softened and more porous. Consequently, these treated chips are more easily broken apart when they are refined. The primary advantage of biopulping is the substantial savings in refining energy – as much as 30% depending on the wood species.

The biopulping procedure involves decontaminating wood chips with steam to eliminate competitive naturally occurring bacteria and fungi. Next they are sprayed with a dilute inoculum of a select fungus. Inoculated chips are incubated in an aerated chip pile for 2 weeks. Under warm, moist conditions the lignin-degrading fungi colonize chip surfaces and penetrate chip interiors with a network of hyphae. These treated chips are more readily broken apart during subsequent refining, saving as much as 30% of the electrical energy while producing more flexible, intact fibers compared to refining untreated chips. Various white-rot fungi have been used for biopulping; however, *Ceriporiopsis subvermispora* has proven to be very competitive both on softwoods and hardwoods and is one of the best energy conservers. Because this fungus consumes some of the pitch contained in the wood chips, both the toxicity and biological oxygen demand (BOD) content of mill process water are decreased and these pulps are more responsive to oxidative and reductive bleaching chemicals.

Because biopulping produces a superior mechanical pulp, it can be considered a viable alternative to chemical pulping and is a less costly alternative for constructing new mills because it requires simpler equipment and produces an effluent with reduced BOD. No additional equipment is required for biopulping in mechanical pulping mills. However, equipment for asepsis and inoculation, such as a conveyor system, steam, and inocula delivery, is needed.

Paper made from pretreated wood chips is stronger than paper made from conventional mechanical pulp and displays better optical properties, except brightness. Biopulping has been demonstrated successfully in mill trials in the USA and currently is being extensively trialed in a South American mill.

RTS

Thermal mechanical pulp (TMP) is the most common way to produce mechanical pulp. Wood chips are presteamed and passed through a pressurized refiner at high consistency. While this conventional process produces an acceptable mechanical pulp, considerable energy is required and pulp brightness is decreased. Recently a new refining process has been perfected. It has been termed RTS; it shortens the *r*etention time, lowers the *t*emperature of chip pretreatment, which is followed by rapid *s*peed refining through specially configured refiner plates. Use of this process significantly reduces the energy requirement and improves the brightness and quality of the resulting pulp. Savings are realized primarily from decreased energy consumption, but the decreased bleach requirement and higher-quality pulp also contribute to the desirability of this process.

Fiber Modification

In addition to the various innovations in fiberization of wood chips into pulps, a number of advances in the technology of fiber preparation have been reported. A few of these are included here. The first is related to enhancing the opacity of fibers through deposition of pigment particles within the papermaking fibers prior to formation on the paper machine. Two others are related to enhancing the recyclability of pulp fibers.

Fiber Loading

Fiber loading is a process for incorporating calcium carbonate made *in situ* and deposited within the lumen and cell walls of refined wood fibers during papermaking. This process requires two steps. First calcium hydroxide (hydrated lime) is mixed into moist pulp at high consistency. This alkaline mixture is then reacted with carbon dioxide within a pressurized refiner at ambient temperature. Calcium carbonate precipitates inside and on the surfaces of pulp fibers, where it is held tenaciously during subsequent papermaking.

Calcium carbonate is an important component of printing and writing papers. Papermaker's carbonate contributes opacity, smoothness, and brightness to high-quality paper; this filler also replaces some of the costly bleached kraft fiber.

Large paper mills often install a satellite plant on site to manufacture precipitated calcium carbonate (PCC) for their use. In conventional papermaking, a suspension of PCC is added to the pulp slurry prior to entering the headbox of the paper machine. Calcium carbonate added in this manner is located primarily between pulp fibers when made into paper. Fillers, such as PCC, interfere with fiber bonding essential to paper strength. Therefore, there is a limit to how much filler can be added without compromising the strength of paper.

In contrast, pulp fiber loaded with calcium carbonate has several distinct advantages over the conventional method of direct addition of PCC. Because a portion of the calcium carbonate formed during fiber loading is located within pulp fibers, more filler can be incorporated than by direct addition of PCC without losing paper strength. More filler incorporated within a paper furnish also reduces the amount of energy required to dry the paper.

Fiber loading has been demonstrated on mill scale. The only additional equipment required for manufacture is a pressurized chamber for introducing and reacting the carbon dioxide. Because the starting materials, hydrated lime and carbon dioxide, are inexpensive, this method of calcium carbonate production is cost-effective. Fiber loading can be used in small mills where a satellite PCC plant is not economically feasible.

All types of wood fibers can be fiber-loaded; this includes recycled fiber. Another benefit of paper made from fiber-loaded pulp is that the carbonate filler is better retained with the fiber during recycling than conventionally made paper. Disposal of sludge accumulated from paper fillers removed during recycling has become a major disadvantage of recycling mills. Fiber-loaded paper can minimize sludge production.

Enzymatic Deinking

Xerographic and laser-printed papers need to have the inks removed prior to recycling, but they are difficult to deink using conventional methods. This has resulted in a lower recycling rate for these types of papers at a time when they are being produced at growing rates. Cellulases have been shown to remove these toners and other contaminants from waste-paper pulps. In treatments, they are combined with nonionic surfactants, such as polyethylene oxide, and mechanical action. Cellulases likely improve deinking through several complementary mechanisms. They remove fibrils from the fiber surfaces and facilitate the removal of toner particles. Cellulases also separate fibrils from toner particles, which reduces toner particle size and makes them more hydrophobic for easier removal during the flotation and washing stages that follow. Researchers have recently improved cellulase action by linking surfactants directly on to the enzyme's amino acid groups.

Cellulases have also been shown to increase the freeness and flexibility and reduce the coarseness of dried fibers. They can also improve sheet density and smoothness. Cellulase treatments of recycled fibers may also reduce disintegration time and increase the bleachability of low-quality, recycled paper. However, excessive treatment can erode the fiber surface and ultimately reduce pulp strength.

Cellulase enzymes are commercially available and are used increasingly in the paper-recycling industry.

Pressure-Sensitive Adhesive Modification

The use of pressure sensitive adhesives (PSAs) has increased dramatically in the last decade. Prompted, in part, by consumer demand, adhesives were formulated to be more user-friendly – at least in their application. The problem caused by many of the PSAs did not surface until they entered the recycled-paper stream. Usually attached to envelopes in the form of self-sealing envelopes, postal stamps, and address labels, the PSAs became commingled with high-quality printing and writing papers. When subjected to high repulping temperature, alkaline pH, and vigorous agitation, many adhesives become plasticized, fragmented, or dispersed, enabling them to pass through pressure screens intended to retain and separate them and other macrocontaminants from recycling furnishes.

Because the US Postal Service (USPS) is a major user of PSAs in the form of stamps, labels, and postal stationery, it introduced and funded a research initiative to assure that the PSAs used in USPS products were recyclable. A consortium comprising adhesive manufacturers, printers, and recyclers was formed. A 5-year research program was undertaken to examine the recyclability of numerous PSA formulations. The essential characteristics of PSAs that made them removable under typical recycling conditions were identified. New guidelines for new PSA formulations were developed for adhesive manufacturers. Acceptable PSAs remain intact, thus were removed primarily by pressure screening, under typical warm, alkaline conditions used in recycling. Adhesives that were successfully removed during processing in pilot plant trials by pressure screening, cleaning, and flotation were subsequently confirmed in recycling mill trials. This research resulted in recyclable PSAs for the USPS products. The guidelines are likely to be adopted by other manufacturers of paper likely to be recycled.

Physical Properties

W E Scott, Miami University, Oxford, OH, USA

Structural Introduction

Paper has existed for over 2000 years and during that time it has found a myriad of uses, each of which requires its own unique set of paper properties. For example, high-quality printing papers need to be smooth, bright, opaque, dimensionally stable, and have good ink absorption characteristics. Paper towels, on the other hand, need to be soft, water-absorbent, and have a certain amount of strength when saturated with water. Neither of the two needs to have the strength characteristics required of packaging papers. In this article we will describe the most common paper properties referred to by papermakers and converters in their daily operations. For convenience, these properties will be grouped into the following four categories:

1. Structural properties.
2. Mechanical properties.
3. Appearance properties.
4. Barrier and resistance properties.

Lastly, we will consider the effects of atmospheric relative humidity on paper properties. Details about paper property testing will not be presented here unless they are necessary to define a specific property. You are referred to the Further Reading section for information about testing instruments and procedures.

The Structural Characteristics of Paper

Structural characteristics describe how the fibers are arranged in a sheet of paper. The topics of interest are listed in **Table 1**.

Basis Weight and Grammage

Papermakers keep track of their production in terms of tons produced and sell their products either on a weight basis or an area basis. This practice gives rise to the definition of the basis weight of paper as the weight, in pounds, of a predetermined number of sheets of a specified size. The number of sheets is known as the ream size. The size of the sheet is known as the basic size. The most common ream size is 500 sheets. There are a variety of basic sizes, several of which are listed in **Table 2**.

The system for specifying basis weight is very cumbersome. A simpler approach is taken in the SI system of units where the weight of paper is

expressed in terms of grams per square meter, or grammage. **Table 3** gives some typical values for the basis weight and grammage of different kinds of paper.

Thickness (Caliper) of Paper

The thickness, or caliper, of paper is defined as the perpendicular distance between the two principal surfaces of paper and paperboard under specified conditions. The thickness of paper and paperboard ranges from 0.0003 in. for capacitor paper to 1 in. or greater for some construction boards.

Thickness is a very important property for the end-use and converting requirements of most grades of paper and paperboard. For example, the overall thickness of a book is directly related to the thickness of the paper used. The thickness of index cards and file folders determines how many can be filed in a given space. Thickness uniformity is also very important for most papers.

Formation, Directionality, Two-Sidedness

Paper is made from a mixture of heterogeneous particles having different shapes, densities, and chemical compositions. This mixture is subjected to a sheet-forming process where the flows are accelerated and drainage and filtration occur in one direction. The sheet is pulled in one direction during drying and substances are added to the outer surfaces of the formed sheet. In addition, the two-dimensional nature of a paper web imposes severe constraints on the different ways that sheet components can arrange themselves. The specific paper properties related to material distribution are called formation, directionality, and two-sidedness.

Formation The overall uniformity with which fibers and other solids particles are distributed in paper determines the formation of paper. Formation is an important property for printing papers—poor formation produces poor print quality. In the extreme, poor formation can also influence the strength of paper and its ability to absorb fluids uniformly.

Directionality Many paper properties are directional in nature. In other words, a given paper property might have one value when measured along one direction of the sheet and another value when measured at right angles to the first direction. The source of this behavior lies primarily in the relative alignment of fibers in the paper web. Few, if any, fibers have their axes aligned in directions other than parallel to the plane of the sheet. In addition, within the plane of the sheet, a majority of the fibers will often have their axes oriented toward the direction of forward movement on the paper machine. This preferential orientation arises as a result of accelerating forces exerted on the fibers in the headbox and on the forming section of the paper machine. Tension exerted on the sheet during drying also serves to enhance the effect. The terms 'machine direction' or 'grain direction' are assigned to the direction of paper parallel to the direction of paper machine travel, while the direction at right angles to the machine direction is called the cross-direction, cross-grain, or against-the-grain direction. The major influence of directionality lies in its effect on many mechanical properties of paper.

Folding, creasing, and scoring can be done more readily along the grain direction. The higher machine direction stiffness is taken advantage of in the design of file folders and some types of packages. Because the directionality of paper is so important in converting operations, the grain direction of sheets will always be indicated on the container of paper shipped from the mill to the converter. With roll stock, there is no ambiguity as to which direction is the machine direction.

Two-sidedness In addition to influencing the fiber orientation in paper, the manufacturing process can lead to nonuniform distribution of components through the thickness, or z-direction, of the sheet. Near the bottom side of the sheet, which is in contact with the fourdrinier wire during web formation and which is referred to as the wire side, there is a relatively low concentration of filler and fines. As you move through the sheet toward the top side, which is called the felt side, the filler and fines content increases. The outer surfaces represent the two extremes in component distributions and have very different characters.

The differences between the wire and felt sides of paper are significant due to their influence on other properties. As a rule, the gloss and smoothness of the two sides will be different. The two sides act differently in printing and it is important to identify them when setting up printing presses.

Porosity of Paper

Ordinary papers are about 50% air, by volume. Some of the air is present inside fibers, but most of it resides in pores within the sheet structure whose diameters are on the order of 1 μm (1×10^{-6} m). The ratio of pore volume to total volume is called the porosity of the sheet. This property, while being fundamentally very important, is rarely measured in papers except occasionally in laboratory studies. However, a related property, air permeability, is often determined. Air permeability is defined as the property of a paper that allows air to flow through it under a pressure difference across the sheet. It is a structure-related property depending on the number size, shape, and distribution of pores in the sheet. It should be emphasized that air permeability is not a measure of porosity and the two terms should not be used interchangeably.

Smoothness or Roughness of Paper

It is common to say that paper has a 'smooth' or 'rough' texture, meaning that the surface irregularities are small or large. A wide range of surface textures are available in papers today, ranging from very smooth, highly calendered papers to rough, uncoated grades of paper produced from coarse softwood fibers.

The quality of a paper surface is often referred to as its finish, which may be spoken of as high or low, good or poor, smooth or rough. Finish combines all those characteristics encompassed by the senses of sight and touch and, although a useful term, is an indefinite one from a technical standpoint. Appearance and mechanical qualities may also contribute to the perceived smoothness of paper.

Smoothness is a very important property in a wide variety of paper. Some papers are intentionally given very rough surfaces, while others must be very smooth, and still others must be carefully controlled somewhere in between. Smoothness is important in printing papers and in paper that serves as coating rawstock. It is possible for a paper to be too smooth and exhibit a tendency to slip in converting processes.

The Mechanical Properties of Paper

A sheet of paper, by virtue of its structure, exhibits the same general mechanical attributes as other structures encountered by the engineer in the field of construction materials. The term 'strength properties' is often used to refer to these characteristics of paper. They determine the durability and resistance to applied forces exhibited by paper during manufacturing operations, converting processes, and end-use performance.

While the fundamental mechanical properties of paper have been studied extensively, the more useful mechanical properties are applied in nature and are used for quality control during the manufacture and converting of paper and for specification of the specific qualities associated with each paper grade. **Table 4** lists the most common examples of such mechanical properties.

The mechanical properties commonly adopted by the paper industry are designed to yield values representing the resistance of a sheet of paper to stresses of various kinds at the point of paper rupture. The tests are arbitrary, as shown by the different specimen sizes, conditions, and instruments specified by the various test methods.

Tensile Properties

In a tensile strength measurement, a paper specimen of defined width and length is clamped between two jaws. The test instrument then causes the separation distance between the two jars to increase, which exerts a tensile stress (pulling stress) on the specimen. A mechanism is provided which indicates the tensile force when the specimen ruptures. This force is referred to as the tensile breaking strength (**Figure 1**). Most instruments can also indicate the stretch and tensile energy absorption of the specimen simultaneously with the tensile breaking strength.

Table 4 Common mechanical properties

Tensile properties
• Tensile breaking strength
• Stretch
• Tensile energy absorption

Folding endurance
Bending stiffness

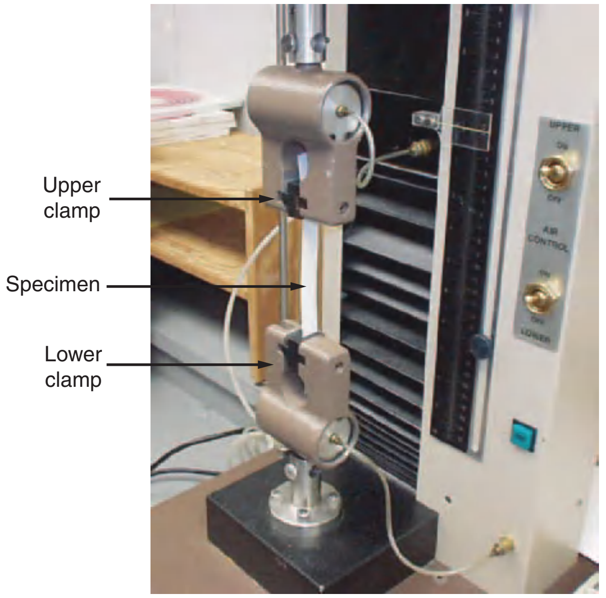

Figure 1 Illustration of a test specimen clamped in a tensile tester. During a test the specimen is stretched as the upper clamping jaw moves away from the fixed lower clamp. The tensile force being applied at the instant of rupture is called the tensile breaking strength. (TAPPI test method T 494 om-88.)

Tensile Breaking Strength

Tensile strength is a direct indication of the durability and potential end-use performance of a number of papers that receive direct tensile stresses in use, such as wrapping, bag, gummed tape, cable strapping, twisting papers, and printing papers. A certain minimum tensile strength is required of any paper that undergoes a web converting operation where it is subjected to tensile stresses while being pulled through the process. Printing papers are primary examples.

Stretch

The stretch of paper at rupture is usually expressed as a percentage of the original length of the test specimen. Stretch properties are important because they affect the way a paper withstands sudden impacts.

Tensile Energy Absorption

A tensile specimen absorbs energy during a tensile test. This phenomenon is known as tensile energy absorption (TEA) and it is directly related to a paper's ability to withstand sudden strains without breaking. TEA is strongly influenced by stretch and the most common way to increase the TEA in paper is to increase its stretch.

Tensile breaking strength, stretch, and TEA are known as directional tests because their values depend upon the direction (machine-direction versus cross-direction) in which a test specimen is cut.

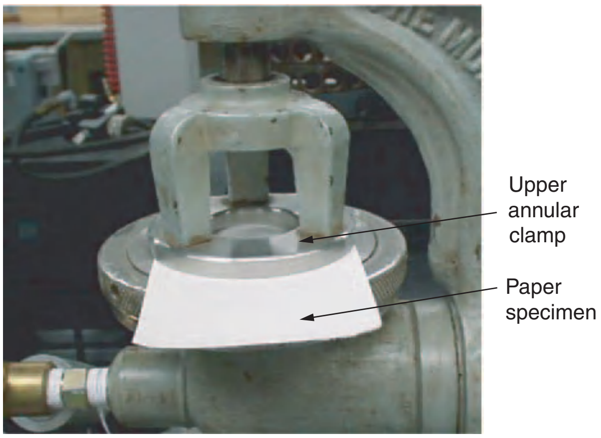

Figure 2 Bursting strength test. During the test a rubber diaphragm expands against the clamped test specimen causing the specimen to bulge into the annulus in the upper clamp. The test value is taken to be the pressure being exerted against the rubber diaphragm at the point of specimen rupture. (TAPPI test method T 403 om-91.)

Bursting Strength

Bursting strength is defined as the pressure required to rupture a paper specimen when it is held between annular clamps and subjected to pressure from one side. This causes the specimen to deform into an approximately hemispherical shape until failure occurs by rupture (**Figure 2**). The bursting strength test is one of the oldest tests used by the paper industry. The best use of the burst test is as a convenient, general indicator of strength or toughness of paper.

Tearing Resistance

The most common tearing resistance property used in the paper industry is called Elmendorf tearing resistance, after the specific instrument employed by the industry. The Elmendorf test measures the mechanical work required to continue a tear – which has already been started – through a fixed length of specimen using an Elmendorf tear tester. The mode of the tear is out-of-the-plane of the paper. **Figure 3** illustrates the tester.

The Elmendorf tear is particularly valued as a test for paper and paperboard, which will be subjected to tearing strains during converting or in end-use. Bags, wrapping papers, tissue papers, book, magazine and newsprint paper, and paperboard for bottle and can carriers are all papers or products where Elmendorf tear values are deemed important.

Elmendorf tearing resistance is affected by the direction in which the test is run, with the cross-direction tearing resistance being higher than the machine-direction tearing resistance in most instances.

Figure 3 Internal tearing resistance tester. A paper test specimen is clamped in a segmented clamp; the right side is fixed to the instrument base and the left side is attached to a segmented pendulum. The test specimen is slit along a line between the two clamp segments prior to the test. Thus, the test measures the force required to continue an internal tear within the paper specimen. During a test, the pendulum is released and swings upward (left to right in the figure), carrying the left clamp segment with it. This motion tears the paper specimen in a direction perpendicular to the plane of the paper in its original clamped configuration. The resistance exerted by the tearing specimen against the swinging pendulum is taken to be the internal tearing resistance. (TAPPI test method T 414 om-88.)

Folding Endurance

Many papers, such as currency and map papers, undergo repeated folding during end-use. The requirement here is one of durability or resistance to wear over a long period. In these instances, the folding endurance test is applicable.

As a rule, the machine-direction folding endurance is higher than the cross-direction folding endurance. Different papers exhibit a wide range of folding endurance values ranging from essentially zero double folds for very weak papers such as facial tissues to several thousand double folds for currency paper. **Figure 4** contains a picture of a paper specimen clamped in a folding endurance tester.

Bending Stiffness

Stiffness is defined as the resistance to a force causing a member to bend. Stiffness is very important to the end-use performance of many papers. For example, file folders and index cards must support themselves upright during use. Playing cards, posters, cups, and plates are also examples of paper that must have good stiffness in use. Stiffness is one of the most important mechanical properties of paperboard used in packaging. Packages must resist deformation, or bulging, when being filled and when the contents settle in a package while it is sitting on a shelf in the store. Folding cartons and corrugated shipping containers must also withstand bending stresses from loads imposed on them from containers stacked above.

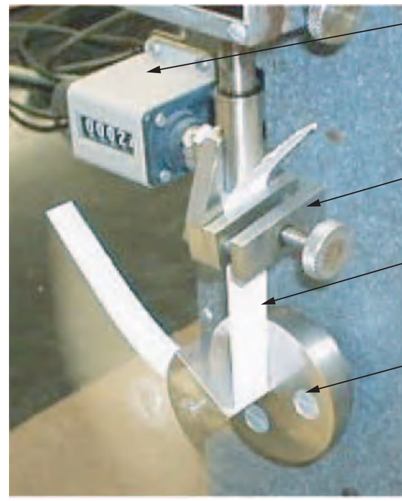

Figure 4 Folding endurance. In the folding endurance test the paper specimen is clamped between a rotating lower clamp and a stationary, spring-loaded upper clamp. The specimen is then subjected to a continuous folding motion of $\pm 135^\circ$ away from the unfolded configuration at the lower clamp while under tension from the upper clamp. The test value is taken to be the number of complete folds the specimen will undergo without rupture. (TAPPI test method T 511 om-96.)

Table 5 Factors affecting paper stiffness

Major	Thickness
	Young's modulus of pulp
	Restraint during drying
	Moisture content
	Surface treatments (wax, starch)
Minor	Fiber–fiber bonding
	Fiber orientation

A number of factors affect stiffness, several of which are listed in **Table 5**.

Stiffness can be thought of as a function of the product of Young's modulus and the thickness raised to the third power. Thus, thickness is a most important factor in controlling stiffness. As much as a threefold increase in machine direction stiffness can be achieved by increasing the tension on the sheet during drying. Cross-direction stiffness will be decreased by this action, however. Conversely, increasing the moisture content of paper will significantly decrease its stiffness. **Figure 5** illustrates a commonly employed stiffness-testing instrument.

Since stiffness is greatly affected by thickness, it is not surprising that paperboards exhibit by far the highest stiffness values, while tissue and toweling papers are the least stiff. In fact, a prerequisite for soft papers is that they have very low stiffness.

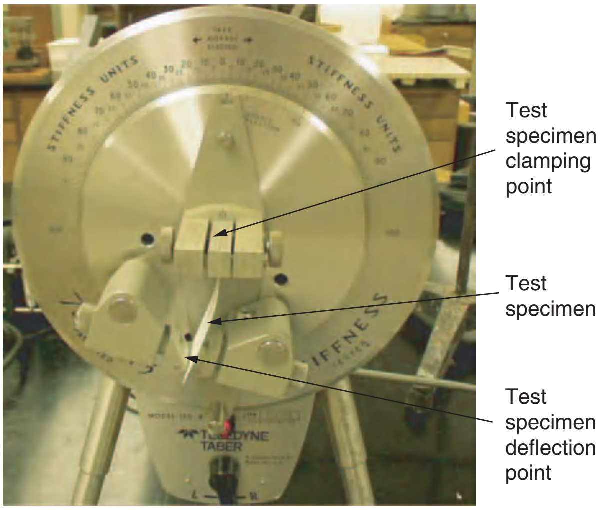

Figure 5 Taber stiffness test. The Taber stiffness test determines the bending moment necessary to deflect the free end of a vertically clamped specimen 15° from its center line when a load is applied 50 mm away from the clamp. This test is most commonly applied to paperboard. (TAPPI test method T489 om-92.)

The Appearance Properties of Paper

In this section, we will consider the appearance properties of paper, called transparency, opacity, brightness, color, and gloss.

A small piece of paper contains several million fibers and millions of small pieces of fibers that were torn away from the pulp fibers during the refining process. When illuminated with a beam of light, the fibers, fines, and filler particles in a sheet of paper cause some of the light rays to be reflected in all directions from the surface of the sheet. Since there are a great number of reflecting particles within the sheet, a great amount of light reflection occurs inside the sheet also. As a result of these multiple reflections, the transmitted light rays that emerge from the other side of the sheet and the reflected rays that emerge back out of the surface of the sheet are not parallel, but travel in all directions. This is indicated schematically in **Figure 6**.

The name given to this type of behavior is diffuse scattering. Hence, most of the light incident on white bond paper is either diffusely reflected or diffusely transmitted since the individual fibers and filler particles are essentially colorless. Materials that diffusely transmit light are said to be translucent. For white papers, the properties opacity, brightness, transparency, and gloss are all functions of the diffuse reflectance and diffuse transmittance of visible light. Colored papers involve light absorption, the topic to be discussed next.

The Color Properties of Paper

Color is used for identification, to attract attention, and to emphasize distinguishing characteristics in commodity papers and packaging. All white papers contain small amounts of dyes called 'tinting dyes.' These colorants produce a slight colored shade, or tinge, that is distinctive of a particular product.

The color of a sheet of paper is determined by the light absorption characteristics of its components. Dyes and colored pigments accomplish nearly all of the light absorption in colored papers. If you plot the diffuse reflectance from a thick pad of colored paper at different wavelengths across the visible spectrum, the resulting curve is called a spectral reflectance curve. Spectral reflectance curves for bleached, uncolored pulp, and the same pulp separately dyed with red, blue, and yellow dyes appear in **Figure 7**.

As is shown in the figure, the principal effect of the dyes is to cause the characteristic spectral reflectance curve of the white pulp to shift, and thus to cause its intrinsic color to change. By selecting industrial dyes having the desired light absorption characteristics, it is possible to create or match a full range of colors for any substrate within the physical limitations of the system involved.

Papermaker's Brightness

Another very important appearance property is called papermaker's brightness. True brightness refers to the lightness or overall spectral reflectance of paper, the energy distribution of the illuminant, viewing conditions and the characteristics of the viewer. Papermaker's brightness, on the other hand, is based on a measurement of the reflectance by white

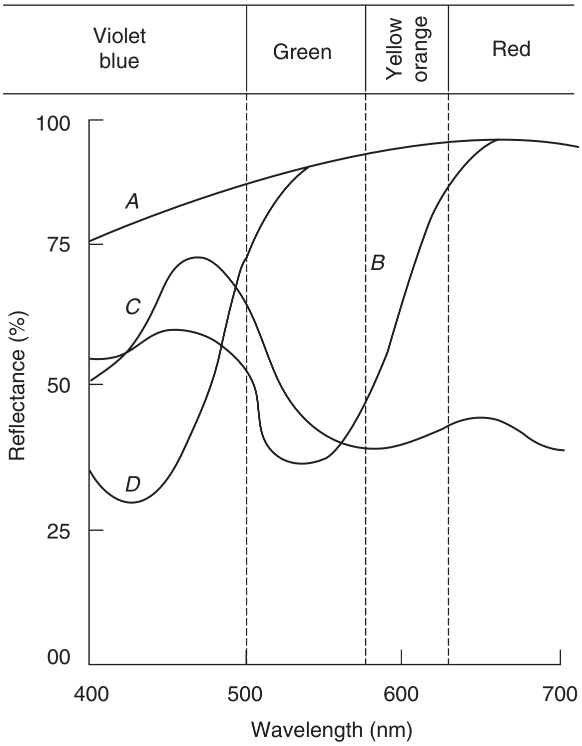

Figure 7 Typical spectral reflectance curves for dyes and undyed pulp. *A*, Bleached, uncolored pulp; *B*, *A* plus red dye; *C*, *A* plus blue dye; *D*, *A* plus yellow dye. Reproduced, with permission, from Scott WE and Abbott JC (1995) *Properties of Paper: An Introduction*, 2nd edn. Atlanta, GA: TAPPI Press.

or near-white papers at a single wavelength, 457 nm. Papermaker's brightness is primarily a measure of freedom from pulp yellowness associated with the presence of lignin and other impurities left by incomplete bleaching.

Unbleached kraft pulp will typically have a papermaker's brightness of 25–30%, while fully bleached kraft pulp will fall in the 80–90% range, depending upon its intended use. Newsprint papers have brightness typically in the 65–75% range.

Gloss

Gloss is the characteristic of a paper surface that causes it to reflect light at a given angle of reflection in excess of the diffuse reflection at that angle. Gloss is the degree to which the surface simulates a perfect mirror in its capacity to reflect incident light. In the case of a mirror, almost all of the light falling on the surface is reflected at an angle equal to the angle of incidence. This is known as specular reflection. Conversely, a completely matte surface will reflect the incident beam in all directions and the surface will appear the same from every angle.

Gloss measurements on paper have been made at many different angles of incidence, but most measurements on paper are made at an angle of 75° from the normal. Highly glossy papers, such as waxed papers, are measured at 20° from the normal. **Table 6** indicates the gloss values measured for a variety of papers.

Table 6 The gloss of different papers compared to polished black gloss as 100

Type of paper	*Gloss*
Lacquer-coated papers	96

Opacity and Transparency

Transparency ratio is the preferred method of evaluating highly transparent materials, while opacity measurements are more suitable for relatively opaque papers.

Transparency

Transparency is important in tracing, reproduction, and packaging papers, to name a few. A completely transparent paper would be one that transmitted, without scattering, all of the light falling on it, and a clear view of an object would be had when the paper was placed between the object and a viewer, regardless of the distance between the paper and any object being viewed through it.

The transparency ratio of a paper, which is a true measure of transparency, is the ratio between the parallel transmittance of light and the total transmittance of light. Glassine, the most transparent paper, exhibits 10–40% parallel transmittance for a total transmittance of 60–85%. On a comparable basis, say 65% total reflectance, a tissue paper would have only 3% parallel transmittance.

Opacity

A perfectly opaque paper is one that is absolutely impervious to the passage of all visible light. The black paper used to wrap photographic films can properly be called 'opaque,' and most paperboards are opaque for all practical purposes. Many papers cannot be classified as opaque, yet opacity is a very important property for them. Printing, bond, and writing papers are good examples where this is true.

Opacity is determined by the amount of light transmitted by a paper. If all of the incident light is transmitted and none is reflected or absorbed, then the opacity will be zero. If no light is transmitted and all of it is reflected or absorbed, the opacity will be 100%. Most papers fall between these two extremes.

The Barrier and Resistance Properties of Paper

Introduction

Papers often come into contact with liquid water while being converted into final products or during their end-use. If it is desired that absolutely no water pass through the web, then the paper is said to exhibit barrier properties. Many packaging products must meet this requirement. Since paper webs are porous, some other material must be combined with it to produce the desired barrier characteristics. Plastic and wax coatings and metal foils are examples of materials that are employed for this purpose.

On the other hand, if it is necessary that a paper only retard or slow down the rate of penetration of liquid water in order to function properly, then the paper is said to exhibit resistance properties. Writing papers, offset printing papers, and coating base stock papers are examples of papers that must resist the penetration of liquid water in order to function effectively. However, if these papers come into contact with water over a long time period, then they will allow its penetration. Hence, they do not have barrier properties.

Another important group of papers must be able to absorb large amounts of water rapidly in use. These are called waterleaf papers. Examples are paper towels, facial tissues, filter paper, and blotting papers.

Table 7 lists the most important factors that affect water penetration rate in paper.

Paper webs are porous, having micron-size pore diameters. Those pores that connect the upper and lower sheet faces provide pathways for liquid penetration. The degree of wetting of fibers by liquids is expressed by the angle between the liquid and solid surface when the two come into contact. **Figure 8** illustrates this phenomenon.

A certain time is required for a liquid to wet paper. This time is called the wetting time. Wetting times ranging from 0.005 s to 0.3 s have been measured for different papers and liquid water.

Paper specimens increase in size (swell) when brought into contact with liquid water. The ratio of such swelling in the different sheet directions has been reported to be 1:2:50 for the machine-direction, cross-direction, and thickness-direction, respectably. This behavior will alter the internal pore structure of paper and affect the interactions that occur between the sheet and water.

It has been hypothesized that the diffusion and subsequent condensation of water molecules contained in the water vapor accompanying the advancing liquid water front aid in the penetration of liquid water through paper. It is expected that this will be a second-order effect that is only important in very dense papers.

Table 7 Factors that influence the rate of penetration of fluids into paper

Diffusion

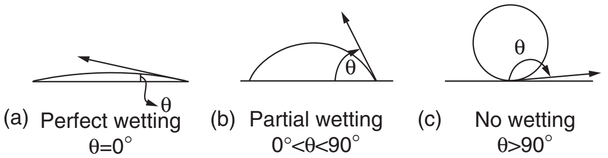

Figure 8 The different contact angles associated with perfect wetting, partial wetting, and no wetting. Reproduced, with permission, from Scott WE and Abbott JC (1995) *Properties of Paper: An Introduction*, 2nd edn. Atlanta, GA: TAPPI Press.

The Influence of Environmental Conditions on Paper Properties

Light, temperature, moisture vapor, and other atmospheric components can all affect paper properties. Of these factors, moisture vapor is by far the most important. Since moisture content can have a significant effect on paper properties, paper testing is usually done under well-defined atmospheric conditions – for example, 23°C and 50% relative humidity in the USA.

The effect of moisture content on mechanical properties is quite complex, as illustrated in **Figure 9**. The figure illustrates that nearly all possible behavior is observed. However, practically all mechanical properties will be adversely affected by relative humidities above 60%.

Changes in moisture content also affect the dimensional characteristics of paper. **Table 8** lists the major effects observed.

Paper expands in all directions when its moisture content increases, with the greatest expansion

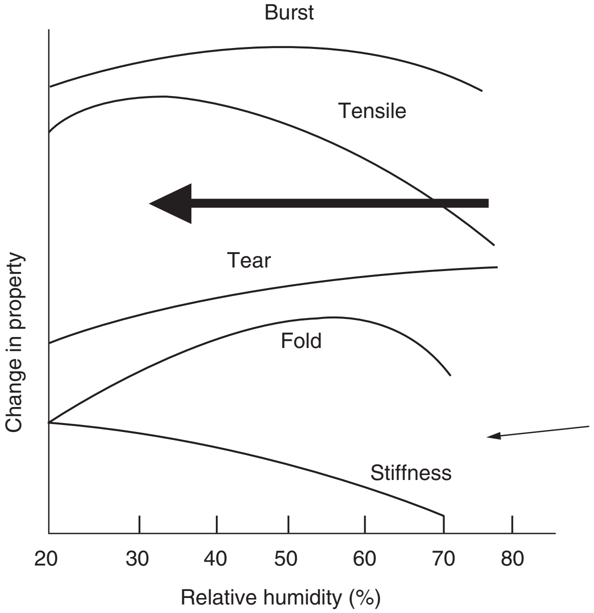

Figure 9 Effects of relative humidity on the mechanical properties of paper. Reproduced, with permission, from Scott WE and Abbott JC (1995) *Properties of Paper: An Introduction*, 2nd edn. Atlanta, GA: TAPPI Press.

Table 8 Influence of moisture content on the dimensional stability of paper

Expansion and contraction
Cockle
Curl
Wavy edges
Tight edges

occurring perpendicular to the plane of the sheet. Cockle refers to the 'puckering' that often accompanies an increase in moisture content. Curl refers to the tendency to 'roll up' into a tube exhibited by many papers as their moisture content increases. Wavy edges and tight edges are ramifications of curl that occur in stacks of paper where moisture content changes occur mostly at the exposed edges of sheets.

The dimensional changes listed in **Table 8** may be reversible or irreversible. In the latter case, they are almost always undesirable and it is necessary to guard against changes in sheet moisture content during conversion or end-use.

Conclusion

This concludes our overview of the most common paper properties important in the manufacture and use of paper. It was pointed out that paper has a highly complex structure and cannot be rigorously treated in fundamental terms. Consequently, papermakers and end-users rely on more empirical and arbitrary ways to characterize the common paper properties employed in manufacturing control and end-use performance. These properties can be grouped into the four categories of structural, mechanical, appearance, and resistance properties that provided a framework for this discussion. Many paper properties are also affected by atmospheric humidity and temperature conditions and the papermaker must take this into account when controlling the final moisture content of manufactured paper. End-users also often control the temperature and relative humidity of their operations because of this.

The intention of this discussion was to provide an introductory overview of the most common physical properties of paper. More detailed treatments can be found in the Further Reading section. In addition, there are other more specialized properties, such as electrical conductivity, that could not be discussed here. You are also referred to the Further Reading section for treatments of these subjects.

Chemical Additives

M A Hubbe, North Carolina State University, Raleigh, NC, USA

Introduction

Chemical additives can be critical to the economic viability of paper machines. Relative to fibers (*see* **Pulping**: Fiber Resources), other materials are present in paper and paperboard at much lower levels. However, additives allow papermakers to differentiate their products to meet the differing needs of customers. They also use additives to make their operations more efficient. This article considers the most widely used papermaking additives, focusing on their composition, their modes of preparation and use, and their impacts on either product attributes or process efficiency. The fact that relatively small amounts of additives can make huge differences makes this a fascinating field of work and study.

Why use Additives During Paper Manufacture?

If you tour a typical papermaking operation you cannot help being struck by the capital-intensive nature of this business. To thrive in a capital-intensive industry it is essential to run the capital equipment as effectively as possible. In contrast, from the viewpoint of the papermaker, chemical additives represent an operating cost, not a capital cost. Those responsible for papermaking operations can decide on a month-to-month basis whether a given additive makes a big enough difference to justify its continued use.

There are two main classes of chemical additives applied in paper machine systems, and each of these involves different motivations concerning its use. The term 'functional additives' will be used here when referring to additives that change paper properties so that they better meet customer needs. A universal customer need is to cut costs; for this reason it makes sense to consider mineral fillers among the other functional additives to be described in this article. Other functional additives include materials to make paper stronger (dry-strength and wet-strength agents), materials to make paper resist water and other fluids (sizing agents), and materials to change the shade or brightness of paper (dyes, pigments, and fluorescent whiteners).

The term 'process additives' will be used here for materials that mainly affect the way the paper machine operates. Factors that determine the overall efficiency of papermaking operations include the speed of the paper machine. Papermaking involves rapid removal of huge amounts of water from fiber slurries (*see* **Papermaking**: Overview). Sometimes removal of water is the production-limiting step. So papermakers treat the furnish with drainage aids, an example of process additives, to allow water to be removed more easily. Another factor governing efficiency is the percentage of time during which the paper machine is successfully making product, i.e., up-time. A key enemy of up-time is the tendency of various materials to deposit on to papermaking equipment. Deposited material often becomes entrained again in the process, leading to spots or holes in the paper, web breaks, and costly downtime. Deposits in press felts, often called 'felt filling,' can cause moisture streaks or just make it necessary to slow down the machine. Chemicals used to fight deposits, as well as the related issues of slime and foam, are further examples of process additives.

Functional Additives for Papermaking

Mineral Fillers

Mineral fillers rank first among papermaking additives in terms of the amounts used. Many paper and paperboard grades contain little or no filler, while printing papers commonly contain up to 25% filler, by mass.

Though the word 'filler' would seem to suggest otherwise, there are numerous reasons to add mineral products to paper. These reasons include cost reduction, enhancement of opacity or brightness (*see* **Pulping**: Physical Properties), and enhanced smoothness of paper after calendering (*see* **Papermaking**: Overview). The minerals do not 'fill' all of the space between fibers in a sheet of paper. In fact, the use of fillers does not necessarily decrease the volumetric proportion of air space. Depending on their detailed locations, filler particles may act as spacers between fibers in the sheet, increasing its thickness or 'caliper' under given processing conditions or at a given target of paper smoothness.

The most widely used mineral products in paper manufacture, including those used in coating of paper (*see* **Papermaking**: Coating), are calcium carbonate, kaolin clay, titanium dioxide, and talc. The most common particle size range of fillers is between about 0.5 and 4.0 μm. An exception is titanium dioxide (TiO_2), the particles of which typically have diameters in the range 0.2–0.3 μm. Because TiO_2 is mainly used to improve paper's opacity, its size is dictated by the need to maximize the scattering of light.

Calcium carbonate Presently in the USA calcium carbonate ($CaCO_3$) is the major mineral additive for papermaking. The main varieties of $CaCO_3$ filler are as shown in **Table 1**.

The process for preparing precipitated $CaCO_3$ (PCC) can be represented by the following formulae:

$$CaCO_3(\text{crude}) + \text{heat} \rightarrow CaO + CO_2\uparrow \quad (\text{calcining}) \qquad (1)$$

$$CaO + H_2O \rightarrow Ca(OH)_2 \quad (\text{slaking}) \qquad (2)$$

$$Ca(OH)_2 + CO_2(\text{gas}) \rightarrow CaCO_3 + H_2O \quad (\text{carbonating}) \qquad (3)$$

Because the mass of CaO (lime) is only 56% of the mass of the corresponding $CaCO_3$, and in order to minimize transportation costs, it is common to carry out reaction (1) near to the mine, and to carry out reactions (2) and (3) adjacent to a paper mill. The precipitation process allows control of the particle sizes and shapes in ways that favor paper grades with differing requirements for brightness, opacity, smoothness, and strength.

The emergence of $CaCO_3$ as the major papermaking filler during the 1980s and 1990s profoundly affected operating conditions in paper mills, including the pH values and the kinds of sizing agents employed. The following reactions take place when $CaCO_3$ is placed in acidic solution, i.e., water with a pH lower than about 6:

$$CaCO_3 + 2H_3O^+ \rightarrow Ca^{2+} + H_2CO_3 + 2H_2O \quad (\text{dissolution}) \qquad (4)$$

$$H_2CO_3 \rightarrow CO_2\uparrow + H_2O \quad (\text{gas evolution}) \qquad (5)$$

Due to these reactions, the use of $CaCO_3$ typically implies neutral or weakly alkaline conditions during the manufacturing process, e.g., $6 < pH < 9$.

Kaolin clay Clay remains the most used mineral product for paper coatings (*see* **Papermaking**: Coating), but by the 1990s it was second to $CaCO_3$ with respect to use as a filler. Kaolinite is a hydrous aluminum silicate, $Al_4Si_4O_{14}(H_2O)_4$. Kaolin deposits in Georgia and South Carolina, having relatively narrow particle size distributions, were laid down by meltwaters from glaciers. The meltwaters slowed down when they entered the prehistoric ocean, allowing the particles to settle. After scooping the clay with a crane, it is commonly mixed with water under severe conditions of agitation in a process called 'blunging.' The clay particles in this initial mixture typically consist of 'bookettes' of clay platelets.

Two processes to modify clay for papermaking use are delamination and calcination. Delamination involves repeated overturning of a mixture of the clay bookettes and porcelain-grinding medium. The resulting shearing separates the clay into platelets. Papermakers favor delaminated clay when they want to decrease paper's air permeability, or when they want to improve brightness and opacity relative to conventional filler clay.

Calcined clay gets its name from the fact that the following reaction is carried out in the same kind of equipment that has been used to convert $CaCO_3$ to lime (see eqn [1]):

$$Al_4Si_4O_{14}(H_2O)_4 + \text{heat} \rightarrow Al_4Si_4O_{14} + 4H_2O\uparrow \qquad (6)$$

Calcination of clay fuses platelets together, and this has been found to be advantageous for bulking and optical properties of paper.

Titanium dioxide Papermakers use TiO_2 when high levels of opacity are needed, or when the market demands lighter-weight paper grades that match opacity levels of higher-weight samples. The major synthetic route for TiO_2 pigment is the so-called 'chloride' process, as follows:

$$2\ FeTiO_3(\text{ore}) + 3C + 7Cl_2 + \text{heat} \rightarrow 2TiCl_4 + 3CO_2 + 2\ FeCl_3 \qquad (7)$$

$$TiCl_4 + O_2 \rightarrow TiO_2 + 2Cl_2 \qquad (8)$$

A so-called 'sulfate' process is also used. By varying the manufacturing conditions it is possible to obtain TiO_2 in two crystal forms, rutile and anatase. Both mineral forms have high refractive indices, 2.7 and 2.5, respectively. By contrast, fibers, calcium carbonate, and kaolin all have refractive indices in the range of 1.5–1.6. The much higher refractive index of TiO_2 helps to explain its much greater ability to scatter light.

Table 1 Calcium carbonate filler types

	Crystal type	*Shape*
Precipitated calcium carbonate (PCC)		
Scalenohedral	Calcite	Rosette
Rhombohedral	Calcite	Blocky
Acicular	Aragonite	Needles
Ground limestone	Calcite	Irregular
Ground chalk	Calcite	Shell-like

Talc The most important characteristics of talc are its oil-loving surface, its platy shape, and its low hardness (1 on the Mohs scale). The low hardness makes it practical for filled paper with talc having large particles, e.g., in the range 3–10 μm. However, a more common application of talc is to control deposits of wood pitch in paper mills using mechanical pulp (*see* **Pulping**: Mechanical Pulping). Such applications require the use of finely divided talc, providing a high surface area of oil-loving material. The fine talc is also used to detackify sticky materials present in many recycled furnishes (*see* **Packaging, Recycling and Printing**: Paper Recycling Science and Technology).

Other fillers Aluminum trihydrate (ATH), having the composition $Al(OH)_3$, has high brightness, and it also acts as a flame-retardant when used at high levels. Gypsum, having a composition of calcium sulfate dihydrate, is also bright and inexpensive. Due to the high solubility of gypsum, some of it is dissolved in the process water during paper manufacture. Precipitated amorphous silicas, silica aluminates, and related products are used for specialty printing applications. These noncrystalline mineral products, having high specific surface areas, can help to hold fluid inks near to the surface of paper.

Dry-Strength Agents

Papermakers add water-loving polymers both at the wet end and at the size press to increase dry strength. Reasons for using a dry-strength additive usually go beyond just meeting specified strength requirements. For instance, a dry-strength agent can compensate for the tendency of fillers to interfere with interfiber bonding. A dry-strength additive can also compensate for low-quality fiber, including recycled kraft fibers that have lost some of their bonding ability. Though it is possible to increase strength by refining (*see* **Papermaking**: Overview), excessive refining hurts drainage of the paper web.

Starch products are by far the most important dry-strength agents presently used in the USA. At the wet end it is most common to use cationic derivatives of corn, waxy maize (a specialty corn variety), or potato starches. Wet-end starches are carefully handled to avoid lowering their molecular mass. The most popular cationic starches contain approximately 0.2–0.3% nitrogen, in the form of quaternary ammonium salt groups. One of the reactions used by suppliers of cationic starch products is shown in **Figure 1**.

Most wet-end starches require cooking (sometimes called 'pasting') at the mill site. In batch operations

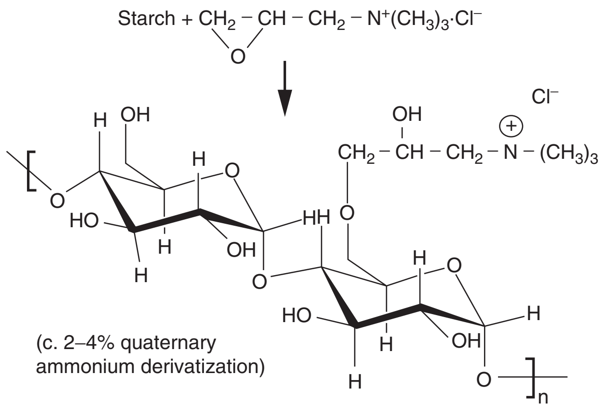

Figure 1 Synthesis of cationic starch.

the dispersed starch granules are heated at ambient pressure to just below the boiling point of water and agitated for about 20 min, at which time the granules have completed their swelling, rupture, and liberation of starch molecules. Starch can also be continuously 'jet-cooked' at higher temperature and elevated pressure. The combination of relatively high molecular mass and weak cationic charge makes it possible to adsorb at least 1% cationic starch, by mass, on to the fiber surfaces before formation of the sheet.

Other dry-strength additives include cationic guar gum, copolymers of acrylamide, and also various anionic polymer products such as carboxymethyl cellulose (CMC). Since fibers used for papermaking typically have a weak negative surface charge, anionic polymers added at the wet end are used in sequence with cationic additives.

Size-press addition of dry-strength agents offers the papermaker some freedom and also some more constraints. Freedom is provided by the fact that nearly 100% of material added to paper's surface becomes part of the product; this means that size press starches do not have to be cationic. But there is an added constraint relative to viscosity. Starch products to be used at the size press typically have to be reduced in molecular mass by treatment with a strong oxidizing agent or with an enzyme. Though the molecular mass reduction renders the starch less effective for strength, it is a necessary compromise to avoid nip rejection and other problems with size-press operations. It is common for the starch to be spread on to the surface of the paper or paperboard as a dilute solution of, say, 10% solids. Starch derivatives commonly used at the size press include unmodified starch, oxidized starch, hydroxyethylated starch, and cationic starch. In addition to starch, papermakers also use polyvinyl alcohol, carboxymethylcellulose (CMC), alginates, and copolymers such as styrenemaleic anhydride (SMA) to enhance the surface strength of paper.

Wet-Strength Agents

Polyamidoamine-epichlorohydrin (PAAE) copolymers are widely used in the USA to help maintain the strength of paper products even after they have become thoroughly wetted. Major applications include currency, paper bags, and paper towels.

Most materials that act as wet-strength agents are polymeric, and they contain some kind of reactive group capable of cross-linking the resin during drying of the paper. PAAE is basically formed as follows:

$$(COOH)(CH_2)_4(COOH) + NH_2(CH_2)_2NH(CH_2)_2NH_2 \rightarrow (COOH)(CH_2)_4(CO)NH(CH_2)_2NH(CH_2)_2NH(CO))(CH_2)_4COOH \quad [A] \qquad (9)$$

$$[A] + \text{epichlorohydrin},\ CH_2Cl(C_2H_3O) \rightarrow \text{PAAE resin} \qquad (10)$$

The PAAE resin has a positive charge in solution due to residual amine groups and cross-linkable azetidinium groups formed by the reaction with epichlorohydrin.

Other important wet-strength resins include gyloxylated polyacrylamide (GlyPAM) and traditional formaldehyde-based resins. GlyPAM is used in cases where a temporary wet-strength effect is desired, e.g., flushable products. Phenol formaldehyde (PF) and melamine formaldehyde (MF) resins offer many advantages, but their usage has decreased due to regulation of formaldehyde levels.

Internal Sizing Agents

The purpose of internal sizing agents, which are added at the wet end of a paper machine, is to inhibit wetting, spreading, or penetration of fluids on to and into the paper. The three major internal sizing agents are alkenylsuccinic anhydride (ASA), alkylketene dimer (AKD), and rosin products.

Alkenylsuccinic anhydride ASA is formed as follows, by the reaction between maleic acid and monounsaturated mineral oil from the distillation and cracking of petroleum:

$$RCH = CH - CH_2 - R' + \text{maleic anhydride},\ C_4H_2O_3 \rightarrow RCH(C_4H_3O_3)CH = CH - R' \qquad (11)$$

where $R = CH_3(CH_2)_n$, $R' = CH_3(CH_2)_m$, and $(n+m) = 13$, 15, 17, or 19. ASA oil needs to be emulsified before its addition at the wet end. Due to ASA's reactivity with water, the emulsification is carried out immediately before use, next to the paper machine. Cationic starch or a moderate-mass acrylamide copolymer can be used to stabilize the droplets of ASA that are formed by application of hydrodynamic shear. Sizing with ASA is generally understood to involve the formation of ester bonds as shown in **Figure 2** during the drying process.

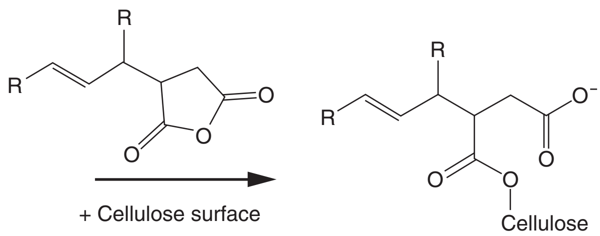

Figure 2 Reaction of alkenylsuccinic anhydride size with a fiber surface.

Alkylketene dimer AKD products are formed by reactions of fatty acids, as follows:

$$RCH_2COOH + SOCl_2 \rightarrow RCH_2COCl \quad \text{(acid chloride)} \qquad (12)$$

$$2RCH_2COCl - HCl \quad \text{(in triethylamine)} \rightarrow 2\ RCH = C = O \ \text{(ketene)} \qquad (13)$$

$$2RCH = C = O \rightarrow \text{alkylketene dimer(four-membered lactone ring)} \qquad (14)$$

where $R = CH_3(CH_2)_n$, and n is an even number between about 14 and 22.

Usually the AKD is emulsified by the chemical supplier and delivered to the papermaker as a ready-to-use dispersion. Stabilizers may include either cationic starch or various synthetic cationic polymers. Though the lower reactivity of AKD relative to ASA can make it easier to apply, it is more difficult to cure. For the curing of AKD it has been proposed by many authors that the ketene dimer's lactone ring opens to form a beta-keto ester with hydroxyl groups on the fiber surface. There has been continued discussion about whether esterification occurs extensively under typical drying conditions. Other factors that may contribute to sizing by AKD include the water-hating nature of the unreacted AKD itself, and its tendency to form insoluble condensation products on heating.

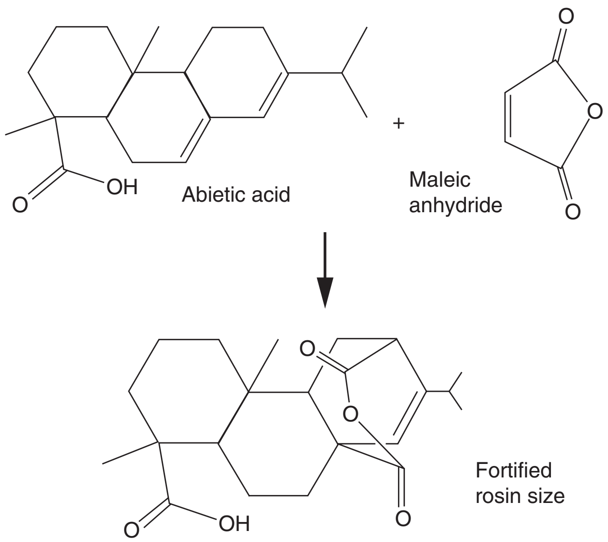

Figure 3 Fortification of rosin size molecule.

Rosin size products Crude rosin is most often obtained as a byproduct of kraft pulping (*see* **Pulping**: Chemical Pulping). The reaction shown in **Figure 3**, called 'fortification,' is carried out before the rosin is used for papermaking. Fortification tends to make rosin formulations easier to handle, less likely to crystallize during storage, and better able to react with aluminum compounds for retention and curing reactions.

Two main types of rosin size formulations are commonly used in the USA. The key difference involves the form of the carboxylic groups. In the case of emulsion-type rosin products, only enough base is added to convert a minor portion of the rosin to its salt form (saponification). The emulsion is stabilized by a cationic polymer or protein, much like the case of ASA, already described. Emulsion-type rosin products benefit from use of a retention aid to attach the particles to fiber surfaces in the wet end. During drying the rosin becomes distributed by vapor transport and a limited degree of spreading of rosin droplets on fiber surfaces. Aluminum byproducts at the paper surface can then bind the rosin. When using rosin emulsion products it is customary to use a reverse order of addition in which the aluminum compound, usually aluminum sulfate or alum, is added first, followed by the size.

Liquid rosin and traditional paste-type rosin soap products have high proportions of saponified, negatively charged carboxylate groups. This fact renders these products dispersible as micelles and monomeric ions in the water. The essential reaction for sizing takes place in the fiber slurry between rosin and a soluble aluminum or iron compound. Though papermakers often use the reverse order of addition when adding rosin soap products in the presence of hard water, the traditional approach is to 'set' the size by adding the alum after the size has been mixed with the furnish.

Colorants and Fluorescent Whitening Agents

With the exception of carbon black, which is polymeric, most colorants used for paper are monomeric organic chemicals. They derive their ability to adsorb light from multiple conjugation, i.e., extensive alternation of single and double covalent bonds.

The most widely used class of papermaking dye has the color index designation of 'direct.' Direct dye molecules contain negatively charged sulfonate groups. The molecules are relatively big and planar, attributes that help them to be retained on fiber surfaces even without the use of a fixative chemical. When papermakers want even higher retention of dye it is possible to use another class of dye, the cationic direct dyes. However, very high affinity is not always an advantage. To avoid an unintentional speckled appearance of the paper, cationic direct dyes need to be diluted and added at a point where there is good agitation. A class of dyes called basic dyes is widely used for yellow pages and other dyed products made from mechanical pulps. Pigment colorants, usually formed by precipitation or 'laking' of organic dye molecules, require the use of a retention aid, as in the case of the mineral fillers. Papermakers favor pigment colorants for products that have to resist fading on exposure to light.

Fluorescent whitening agents, often called 'optical brighteners,' are chemically very similar to certain direct dyes. However, they have the special ability to absorb light energy in the ultraviolet range and reemit some of that energy in the visible, blue part of the spectrum.

Process Additives for Papermaking

Retention and Drainage Additives

Papermaking involves separation between a solids-rich phase, the paper web, and a liquid-rich phase, the white water (*see* **Papermaking**: Overview). Chemicals that make this separation occur more completely or more quickly are called 'retention aids' and 'drainage aids.' There is so much overlap between the chemicals that perform these two functions that it makes sense to discuss them together. In colloidal chemical terms most of these additives can be grouped within the categories of coagulants, flocculants, and colloidal particles.

Coagulants

During papermaking one function of a chemical coagulant is to neutralize the surface charge of suspended materials and remove electrostatic barriers, preventing them from colliding with each other and sticking together. Because the fibers and many other materials used for papermaking typically have weak negative charges at their surfaces, coagulants usually consist of multivalent cationic materials, which can be either soluble inorganic products or organic polymers.

Among inorganic coagulants, the most widely used is aluminum sulfate, or 'papermakers' alum.' Alum derives its coagulating ability from the trivalent character of aluminum, plus a tendency to form oligomeric species. The system pH, contact times, and temperature profoundly affect alum's performance, with best results often obtained in the so-called 'acidic' range of papermaking, between pH values of 4 and 6. Polyaluminum chloride (PAC) and related products have extended the range of efficient coagulation to somewhat higher pH values.

The most important polymeric coagulants are the polyamines, including polydimethylamine-epichlorohydrin, as well as polyethylenimine (PEI) products and poly-diallyldimethylammonium chloride (DADMAC). The common feature of these polymeric coagulants is their high positive charge density, often with 100% of the monomeric groups bearing a charge. Molecular masses typically range from hundreds of thousands to about two million grams per mole.

Flocculants

The function of a flocculant is to cause suspended particles to stick together very strongly after coming into contact. The effect is achieved by use of very-high-mass polymers, which are capable of forming molecular bridges between the adjacent surfaces. When papermakers use the term 'retention aids,' they most often mean linear copolymers of acrylamide. Molecular masses of these retention aids range from about 4 million to upwards of 20 million $g\,mol^{-1}$. Retention aids with a wide range of charge density, either positive or negative, are widely used. Retention aids are most commonly delivered to the paper mill in the form of a water-in-oil emulsion, which needs to be inverted at high levels of dilution and agitation before it can be used. It is common to add a retention aid flocculant near the end of the wet-end process, after furnish has been conditioned by the addition of a lower-mass coagulant.

Colloidal Particulates

Since the 1980s there has been a trend toward the use of colloidal 'microparticles' or 'nanoparticles,' including colloidal silica and montmorillonite clay products. Under the right conditions, these have the ability to interact with the flocculants just discussed, producing a pronounced increase in drainage rates during paper formation.

Deposit Control

Papermaking operations are vulnerable to problems resulting from the deposition of tacky and pitch-like materials on to the equipment. In addition to talc, as already mentioned, deposit-control additives include organic detackifying agents, dispersing agents, and barrier chemicals. Effective use of a retention aid program, as just discussed, also helps to avoid deposition of fine materials on to chests, pipe walls, headbox surfaces, and in press felts and related equipment. Organic detackifiers include soluble polymers, such as polyvinyl alcohol products, designed to adsorb on to oil-loving surfaces and make them less tacky. Dispersing agents, including nonionic surfactants composed of short ethylene oxide chains attached to oil-loving groups, can be used to overcome deposition of tacky materials at specific locations in a papermaking process. The term 'barrier chemicals' describes materials sprayed directly on to the surface of a forming fabric or press felt to overcome deposit problems. Highly cationic polymers, i.e., organic coagulants, are used alone or in combination with surfactants to achieve this effect.

Biological Control

Papermaking systems, with their warm temperatures and content of starch and other biodegradable materials, can provide a wonderful medium for the growth of bacterial and fungal slime. Slime can become entrained and cause holes and breaks in the paper web, in addition to spots and bad smells. The two main categories of chemicals that papermakers use for slime control are oxidants and toxic organic chemicals. Chlorine dioxide has become a favored oxidant, especially for paper grades that use bleached kraft pulp. The selection of slimacides depends on factors such as temperature, the kind of slime in the system, and issues of effectiveness and biodegradability of the added material.

Foam Control

Due to the presence of air, water, high degrees of agitation, and various substances that can stabilize bubbles, there is the potential for severe foam problems during papermaking. Some of the problems can be minimized by avoiding overuse of surface-active materials and water-soluble polymers such as starches and wet-strength agents. Chemical defoamer formulations typically contain water-insoluble surfactants. They can also contain hydrophobic particles that help to rupture bubble surfaces when the surfactant molecules spread across those surfaces.

Environmental Control

D Peterson, Western Michigan University, Kalamazoo, MI, USA

Introduction

The basic operations of the paper industry involve the conversion of renewable resources using chemicals, energy, water, and human ingenuity to produce a universal consumer product. Wastewater, air emissions, and both dry and waterborne solids are generated during the process. Heat and noise also are generated and disbursed into the environment. The objectives of this article are to identify the sources of these emissions and the processes by which they can be managed.

An overview of the paper manufacturing process suggests that the sequence of events can be divided into distinct phases. The first phase involves the recovery of papermaking fiber from either wood or recycled fiber resources. The second phase involves the purification of the liberated fiber and preparation of that fiber for the papermaking process. The final phase includes formation of the paper mat and modification of its surface to meet specific moisture resistance, strength, and optical properties for designated paper or paperboard applications.

The pulping operation and papermaking operations often run at separate locations, while integrated operations combine both pulping and papermaking facilities at one manufacturing site. The pulping phase is accomplished using several different processes ranging from full chemical pulping to thermal and mechanical defibering with a large variety of sequential treatment combinations involving chemical, thermal and/or mechanical processes in between. The chemical pulping operations often are accompanied by a variety of complex chemical recovery processes depending on the chemicals involved.

The fiber purification processes involve both mechanical and chemical processes to remove unacceptable components and to brighten the fiber for specific applications.

The papermaking phase commonly involves the dispersion of the fiber in large quantities of water and other additives to modify optical, chemical, and physical properties. The thin slurry is distributed on a continuous moving forming fabric allowing the water to separate from the wet fiber mat. The wet mat is then pressed against an absorbent fabric to dewater the wet mat. The partially dewatered mat is dried by evaporating most of the remaining moisture to form a paper or paperboard sheet.

Depending on the use of the paper it may also have been surface treated with sizing to minimize moisture penetration and to prevent ink from feathering on a printed page or coated with additional material and/or treated mechanically to modify its surface and optical properties. Coating followed by calendaring are common treatments to obtain papers with excellent printing quality characteristics.

Before dealing with the treatment of some specific waste streams, it is important to recognize some of the waste streams that are characteristic of the production phases. Characterizing each of these by-product streams and assessing their reuse alternatives will enable the diversion of some of the waste streams to reuse elsewhere in the manufacturing sequence.

The following figures (**Figures 1** to **5**) depict several of the steps in the production of paper and identify some of the major emissions from the various stages. The process schemes describe the liberation of fiber from wood or the recovery of fiber from recycled paper sources (post consumer) through

	Process stage	By-products
	Roundwood	
Chip preparation	Wood handling	Dust, dirt, bark
	Debarking	Bark and shower water with wood extractives, suspended solids
	Chipping	Noise
	Chip screening	Undersize and oversize chip
	Wood chips	
Chemical pulping	Pre-steam	Vent volatile wood extractives
	Cook chips	Vent odorous digester gases
	Wash cooked chips	Discharge spent liquor (weak black liquor)
	Blow chips to blow tank	Vent odorous blow vent gases
	Brown stock washing	Vent washer hood gases
	Screen brown stock	Collect uncooked chips and knots
	Liberated chemical fiber

Air Emissions and Control Processes

Sources

Air emissions from the manufacturing process include: dust from wood handling, chemical recovery operations, the recovery furnace and the calcining operation, and the drying processes associated with moisture removal from paper and applied coatings. Odorous gases are generated during the chemical pulping and chemical recovery operations. Odorous gases characteristic of the Kraft process include: sulfides (mercaptans) and total reducible sulfides (TRS) that are detectable in the 1–20 ppb concentration range. Small quantities of noxious gases are generated from the bleaching process that volatilize as fugitive emissions. Fugitive emissions including chlorinated organic compounds, such as chloroform, originate in small quantities from the chlorine bleaching process. In addition to the emissions from the manufacturing process the generation of power and steam needed to operate the manufacturing facility also generate air emissions. Energy generated from fossil fuels, biomass, and the incineration of wastes all involve the combustion of hydrocarbon material. The possible byproducts from the combustion include: CO_2, CO, H_2O, NO_x, SO_x, particulate matter, and waste energy (heat). The amount of each of these by-products depends on the fuel used in the process and the energy requirements of the facility.

Control

Particulates can be recovered by filtration (bag house operations), scrubbing (absorption), or settling induced by gravity or by electrostatic mechanisms. Gases are recovered either by collection in another media or by chemical conversion to a more benign compound. Media alternatives include the adsorption of the gases material on to a solid substrate or the absorption into a liquid media. The media selected may include chemicals that will ultimately react with the compounds sorbing the gaseous constituent.

Particulates

Treatments for particulates suspended in air are of three types: one is dependent on their density, the second is dependent on their physical size, and the third is dependent on generating a unique force that can be applied to the particle as it passes through a control device.

The density dependent control processes are based on the particle's inertia. Because of its inertia, the particle will tend to continue moving in a straight line as the carrier fluid (air) is forced to change direction. The resulting path of the particle is to impact (and be collected) on a collecting surface. The most common inertial control device, effective on relatively large particles (greater than 30 μm diameter), is a cyclone collector. Since the centrifugal force depends on the rate of directional change that takes place in the fluid stream, cyclones with small diameters are more effective but require larger pressure drops. A number of cyclones can be configured into a single body to save space. Scrubbers can be used to improve particle collection efficiency by first collecting the particles in a liquid droplet followed by the separation of the droplet from the gas stream. The liquid can be introduced in a number of ways including:

- a venturi device preceding the cyclone
- a liquid spray inside the cyclone
- directing the particle laden gas into a liquid before going into the cyclone.

The inertial phenomena also can be used effectively by impinging the gas flow through open structure forcing the gas to make many directional changes causing the particles to impact onto wetted surfaces within the erratic structure. One advantage with these control devices is that they can operate continuously. As the collected particles are continuously flushed from the collecting surfaces, the operation of the control device does not need to interrupt its operation to be cleaned.

The collection methods based on physical size are essentially screening processes. Particles that are larger than the openings in the filter media are trapped in the media, thus separating the particles from the fluid stream. Fabric filters are commonly configured with a number of cylindrical collection surfaces bunched in a common housing. The 'bag house' filter is limited to dry conditions and requires some interruption of the collection process to dislodge the collected material. The filter tends to plug as the surface becomes clogged with particulates and needs to be cleaned periodically. The cleaning cycle involves taking a portion of the filter off-line and cleaning it by back flushing with a burst of air or shaking it to dislodge the collected material. Collection efficiency and pressure drop depend on the size of the openings in the filter media.

The third type of collector functions by charging the particles electrically and exposing the charged particle to a surface with the opposite charge. The electrostatic forces cause the particle to migrate to the collecting plate where they accumulate. In this collection device the accumulated particulates are dislodged by shaking the plate, causing the accumulated layers of particles to slough off and fall to the bottom of the precipitator. Since the particles come off as a conglomerate, they are not re-entrained in the gas stream and thus are separated from the gas. This process is effective for very small particles but is limited by the dielectric property of the gas, which is heavily influenced by high temperature and the presence of moisture.

Gases

The controls for gases (sulfur oxides, sulfides, nitrogen oxides, volatile organics) might include or incorporate collection, destruction, or prevention. Collection can be accomplished by either absorption or adsorption while destruction can be accomplished by chemical reaction induced by either thermal destruction or imposed reactions. Prevention is the first choice where this alternative is feasible.

Absorption involves the transfer of the gas from the carrier gas to a liquid stream. The transfer is accomplished by contacting the carrier gas with an appropriate liquid in which the contaminant is soluble or with which it will react to form a soluble compound or precipitate.

Adsorption is used to transfer the contaminant to a surface. A highly porous surface is particularly effective. A good example is the use of activated carbon to adsorb volatile organic compounds.

Thermal processes utilize high temperature with or without a catalyst to convert the contaminant into benign compounds, or compounds that have less effect on the environment. Chemical reactions include specific reactions to convert contaminants into more agreeable compounds. Typical examples include oxidation of hydrocarbons to carbon dioxide and water or reactions that produce passive materials that do not have any impact on the environment.

One example of a prevention effort is the oxidation of odorous sulfides to sulfur oxides to reduce the foul odor associated with the spent cooking liquor generated in the Kraft pulping process.

Wastewater Emissions and Treatment Processes

Sources

Wastewater sources probably are the must numerous of all of the emissions sources from the paper manufacturing industry. Some mills use water to wash logs before treating the logs in a drum debarker, while others use high-pressure water to hydraulically debark the logs. In either case the wastewater generated contains both soluble and suspended solids.

The fiber liberation and purification processes also generate significant wastewater discharges. Except for accidental releases and leakage, all of the waterborne wastes from the chemical pulping process goes to chemical recovery. Chemical recovery releases foul condensate, and sludge from the slaking and smelting processes. Waterborne wastes from mechanical and thermal pulping processes, however, generate significant amounts of both dissolved and suspended solids.

Wastewater Treatment

To minimize maintenance concerns in the wastewater treatment train and to stabilize flow rates and loads many treatment systems include barrier screens and equalization basins. Barrier screens prevent oversize pieces of suspended solids from getting into the inlet flow stream that might interfere with the process equipment. Equalization basins serve to mix intermittent high concentration and large flows in a storage basin to provide a consistent feed rate to conventional primary and secondary treatment operations.

The primary clarifier is intended to remove the suspended solid portion of the wastewater. The primary treatment process is usually dependent on gravity settling to separate the suspended material from the liquid suspension. Because the settling rate is proportional to the square of the diameter of the particle, the raw wastewater is sometimes treated with coagulants that encourage individual particles to agglomerate forming large flocs. A typical primary clarifier is designed to handle between 500 and 1000 gpd/ft^2 of surface area removing 80–90% of the suspended material. Because some of the oxygen-demanding material is the suspended material itself or is attached to the suspended material, the removal of suspended material can also remove a significant fraction of the oxygen-demanding waste load. Another method of removing suspended material involves the use of a flotation clarifier. The flotation clarifier also used additives to agglomerate the suspended material with an air bubble, thus creating a particle that is less dense than the fluid causing the coagulated particle to float to the surface. The floating material can be skimmed from the surface and thus separated from the bulk of the liquid.

Biological treatment is intended to reduce the oxygen demanding components (biochemical oxygen demand, BOD) in the wastewater entering the secondary treatment system. The removal of the BOD components is accomplished by allowing bacteria to consume the BOD, usually in the presence of excess oxygen. The treatment occurs in aerated stabilization basins, activated sludge systems, large oxidation basins, or other biological contact processes. The key components in the process are aerobic bacteria, dissolved oxygen in water, and the oxygen-demanding material. The required residence time depends on the temperature, concentration of bacteria, concentration of oxygen, the BOD_5 load and nitrogen and phosphorus nutrients. The optimum temperature range is 20–30°C, the ideal BOD_5/N/P ratio is approximately 100/5/1, and the desired pH range is from 6.5 to 7.5, while residence times range from 3 h to more than 60 days. The residence times are 3–24 h for the activated sludge process, 5–10 days for the aerated basin process, and from 20 to 60 days for a storage aeration pond. The activated sludge process achieves BOD reductions in a short residence time by concentrating the bacteria in a highly oxygenated basin and recycling the bacteria by settling them in a clarifier and immediately returning them to the aeration chamber where they are combined with the flow of fresh wastewater. Another way to shorten the residence time is to inject oxygen-enriched air in the aeration chamber. The aerated stabilization basin process supplements the oxygen concentration by introducing oxygen by aerating the basin using surface mixers or subsurface aeration. The storage aeration process uses natural aeration of the basin's contents as the wind provides a natural wave action. The lower oxygen and bacteria concentrations require a longer retention time. This process generally follows one of the other aerobic processes. All of the above processes suspend the bacteria in the wastewater to accomplish the BOD reduction. The 'trickling filter' and 'rotating biological contactor' arrange to have the bacteria fixed on a structural media and provide for alternate contact between the bacteria and the BOD in the water and oxygen in air. The trickling filter requires a larger footprint than the activated sludge process but requires less energy to operate the system. These fixed media biological treatment processes are not widely used in the industry.

Another alternative for the treatment of mill wastewater is anaerobic treatment. As the name implies the process operates in the absence of oxygen. The carbon components are oxidized to CO_2 and reduced to CH_4. The methane gas is recoverable and can be used to provide heating to maintain reactor temperature or other combustion applications. The optimum temperature is approximately 35°C. One advantage of this process is that the amount of sludge produced per unit reduction of BOD is reduced to between 20% and 35% of that produced from the aerobic process. The anaerobic process is most effective for high BOD loads. This alternative is currently used at only a few pulp and paper installations and most of these are large covered-basin systems.

Effluent waters typically are treated by conventional means; primary treatment is followed by secondary treatment as needed. Mills in urban settings are likely to provide only primary treatment of their effluent before it goes to a municipal wastewater treatment facility. Mills in a more isolated setting would need to provide both primary and secondary treatment before discharge to a natural estuary or receiving water.

Solid Waste Sources and Management Alternatives

Sources

The solid waste components that accumulate around a manufacturing facility are the most diverse of all of the waste categories. Waste sources include: process wastes, raw material wastes, production wastes, spills, housekeeping, maintenance and remodeling wastes plus the residues that are generated by the treatment processes to manage air and water emissions. Solid wastes are generated from wood processing, chip preparation, pulping residuals, screening and cleaning rejects, and from nonpulpable components from secondary fiber sources. Sludges from wastewater treatment activities and recovered bottom ash and fly ash from power generation and incineration of other solids, fly ash from the recovery furnace, and fly ash from the calcining kiln are the result of environmental controls. Shipping containers, packaging materials, surplus and worn-out equipment, combined with numerous cleaning, housekeeping, maintenance and manufacturing remnants also contribute to the solid waste stream.

Wood pulping Process wastes generated by the industry are mostly derived from either organic sources (biomes or sludges containing biomes) or inorganic chemicals derived from inorganic minerals. Typically the largest source of organic waste comes from the log preparation, debarking, and chip screening operations. Some additional organic residual comes from the washing stages following the digester containing incompletely digested wood chives and knots. These mechanically separated materials can be dried and burned in the energy and power generation facilities associated with the mill. The resulting ash (both bottom ash and fly ash) plus the ash from the auxiliary fuel are additional waste components that need to be handled. Small quantities of solids are recovered from the purification and stock preparation processes that precedes the paper making operation.

Chemical recovery Chemical recovery operations generate a couple of inorganic wastes in the form of smelt dissolving dregs, green liquor clarifier and lime slaking dregs and fly ash from both the recovery furnace and the lime kiln. The fly ash components recovered from both of these sources are reintroduced back into the chemical recovery cycle.

Secondary fiber The recover of papermaking fiber from post consumer waste paper and paperboard generate a large variety of solid wastes. Nonpulpable material, dirt, sand and grit, staples, adhesives, sealing tape, labels, plastics, and packing materials are all separated from the reusable fiber. These materials each contribute to the wastes that are generated from the secondary pulping process. In the event that deinking and chemical purification of the secondary fiber is warranted, additional sludge containing ink, coating, and filler materials and soluble by-products are generated.

Treatment

Because of the diversity of materials that constitute the solid waste fraction, the treatment options are more diverse. Some of the materials are recyclable, some combustible, some can be land applied or composted while other fractions seem to have so little value that the most common option is to secure them in a well-designed landfill.

A major share of the solid waste stream is recovered because of its intrinsic value. Scrap metals, worn parts, and surplus equipment are notable examples. Components that are routinely replaced, shipping containers, and remodeling wastes are encouraged to be recycled by the supplier. Items of little intrinsic value generated by maintenance and housekeeping are commonly transferred to a waste disposal agent.

Organic wastes have a significant heating value; however, only those materials that can be effectively dewatered are viable candidates for energy recovery. Bark and wood wastes that are easier to dewater and dry are more likely to contribute to the energy needs of the mill. Most organic sludge materials are difficult to dewater though it is not unusual for these materials to be burned. Because of the moisture content of these wastes the remaining alternatives for treatment include biological treatment, land application/composting, or storage in a landfill.

Wastewater treatment sludges originate from either primary treatment or secondary (biological) treatment. Sludges from primary treatment will have either a high fiber content or a mix of fiber and filler material. Secondary treatment sludge is characterized as having a large amount of microbiological residue that is very effective at retaining moisture. The particular characteristics of each of these sludges prescribes how these sludges can be handled.

Secondary sludges have a large microbial cell content and are extremely difficult to dewater or stabilize. These sludges are difficult even to landfill because of their water content and unstable flow characteristics. One solution used often is to combine primary and secondary sludges to facilitate dewatering of the secondary portion. Alternatives for treatment include additional biological treatment, composting and anaerobic digestion. These additional processes reduce the quantity of the waste, which generally is easier to dispose.

Beneficial Use

Recycling is the most likely alternative for handling the largest share of solid wastes generated by a mill. Undersized and oversized chips are either burned for energy generation or the oversized are processed in a rechipping operation. Some operations focus on incompletely digested wood which can be treated in two different ways. One is to use the undigested wood as fuel and the second is to return it to the digester for another pass through the system.

Other beneficial uses for materials such as wastewater treatment solids include land application/composting, burning for energy, or use in by-products such as animal bedding, absorbent materials, concrete, fuel pellets, etc. Ash can also be used as a construction material or in by-products such as concrete.

Thermal Sources and Discharge

Thermal releases are associated with steam and power generation, pulping, chemical recovery, and drying process emissions. Manufacturing facilities recover and recycle as much of the thermal energy from these processes as practical. The lowest temperature energy residuals are discharged to the atmosphere as hot air or moisture generated by cooling tower operations or building vents. Some thermal energy is typically also released in wastewater discharges.

Noise Sources and Control

Noise is generated by the vibrations of rotation machinery and pumps, and by the flow of fluids through throttling valves. Treatment generally is accomplished by redesign and isolating rotating machines. Many pieces of equipment are mounted on vibration isolating pads and often are contained with noise insulated enclosures. Personal hearing protection is often used to protect personnel from the noise associated with some parts of the manufacturing process.

Summary

It is important to recognize that the various treatments of wastes (air, water, solids, heat, and noise) are often interdependent. The treatment of one type of waste can impact another type of waste. Management of any one of these environmental concerns can in turn affect other areas. Wastewater treatment commonly generates some sludge solids. Incineration of solids commonly generates some emissions to the air. Treatment of air pollutants generates either solid or liquid wastes. It is also important to recognize that most processes produce some by-products along with the desired product.

With these facts in mind, it makes sense to minimize the production of pollutants by modifying the manufacturing processes rather than treating pollutants after they are formed. The definitive solution to the environmental issues is to eliminate pollution sources where technically and economically feasible, minimize their production as much as practical, recycle by products as much as possible, and safely manage the remainder. The hope is that we can minimize waste streams and make them nontoxic and benign to our environment and us.

RECREATION

Contents

User Needs and Preferences

W E Hammitt, Clemson University, Clemson, SC, USA

Definitions

'Forest recreation' is defined as 'recreational activities and experiences conducted in forest and associated wildland environments that are dependent on the natural resources of these areas.' I include associated wildland environments along with forests in the definition, for forest recreation activities can occur above treeline at high attitudes and/or extreme latitudes, on streams and lakes in forested areas, and in old fields. The key point is that forest recreation is dependent upon the natural resources of the areas. Moreover, the resources and conditions of these forest/wildland settings are largely natural, and management strives to maintain a natural appearance.

'User needs' refer to physiological or psychological requirements for the well-being of an individual. Needs are the primary influences on an individual's behavior. When a particular need (physiological–emotional state) emerges in a recreationist, it determines the recreationist's behavior in terms of motivations, priorities, and actions taken. The unmet needs of recreationists are the basis for psychological and physiological forces, motives, and drives, which cause recreationists to pursue forest environments, recreational engagements, and desired recreational experiences. Driver and Tocher postulate that recreation is an experience that exists to the extent to which the needs or desires to recreate are gratified.

'Preferences' are related to needs gratification and refer to desired conditions and favored situations that recreationists expect will facilitate or satisfy their unmet needs during recreation engagements. Recreation managers need to know user preferences toward site facilities, services, programs, and management policies in order to design and manage conditions and situations to meet the recreation needs of users. They also must know users' psychological needs and preferences toward recreational experiences expected and desired, in order to provide opportunities for users to realize those needs and preferences.

User Need and Preference Relationships

User needs and preferences are essential components of forest recreation science and management, for the ultimate aim and product of forest recreation planning and management are quality recreation experiences. The relationships among user needs, preferences, quality experiences, and recreational benefits must be understood in the field of forest recreation (**Figures 1–3**).

Figure 1 A preferred campsite where the recreation user is offered the opportunity of naturalness and solitude in a nonimpacted site.

Figure 2 An unpreferred campsite where the natural conditions of the forest environment have been greatly impacted by heavy recreation use.

Figure 3 Nearness to water or in view of it is a major preference of forest recreation users. However, riparian sites can be sensitive to recreation use impacts.

Quality Experiences

Forest recreation, like any aspect of natural resource management, be it timber management, wildlife management, or water management, is ultimately concerned with enhancing the quality of the existing resource and the products and benefits derived from management. Long before professional forestry and forest sciences existed, forests were capable of producing timber, wildlife, water, and recreational benefits. However, because societal pressures and use of these resources can decrease the quality of products and benefits derived from them, professional management has aimed to maintain and enhance the quality of derived products and benefits, when possible. In the specific area of forest recreation, science and management have aimed to enhance the quality of resource conditions upon which various forest recreation engagements depend, the quality of visitor use of these dependent resources, and the interactions between the two. In order for forest recreation to enhance the quality of desired recreation resource conditions, and opportunities for quality recreation experiences, the recreational needs and preferences of users need to be identified. Once identified, managers can attempt to provide the resource and social conditions, and recreational opportunities, for users potentially to realize the quality experiences desired.

Diverse Opportunities

Many different types of users come to forest environments to engage in many diverse activities and resource settings, in order to realize quality and fulfilling recreation engagements. Associated with this diversity of user activities and resource settings is a diversity of user needs and preferences. In an attempt to meet these needs and preferences, scientists have researched the spectrum of needs and preferences, and management has developed recreation opportunity systems. Dr. Driver, long-time researcher at the University of Michigan and US Forest

Service, worked with colleagues to develop the recreation opportunity spectrum (ROS) as a system of diverse recreation opportunities to meet the many needs and preferences of forest recreationists in North America.

ROS has been formally adopted by the US Department of Agriculture Forest Service and the Department of Interior's Bureau of Land Management to manage forest recreation on their lands. The spectrum of recreation opportunities approach to forest recreation is based on understanding the recreation experience needs and preferences of users, and providing opportunities necessary to enhance the quality of recreation engagements, experiences, and outcome benefits.

Conceptual Models

Researchers have conceptualized the relationships among forest recreation, user needs, preferences, recreation opportunities, quality/experiences, satisfaction, and benefits (**Figure 4**). Driver *et al*. provide expanded discussions of the models and their theoretical/research foundations.

In **Figure 4**, it is proposed that unmet psychological and physiological needs result in internal drives and motivations to seek desired opportunities in order to fulfill need states and preferences, thus leading to satisfying experience outcomes and personal benefits. The model is based on Lawler's work with expectance theory. Lawler's approach is backed by the unmet-needs hypothesis of behavior, suggesting that the attractiveness of recreation experiences is determined by the extent to which it satisfies a human need. For example, the attractiveness to hike in a wilderness area is determined by the expectation that it will satisfy the human need for solitude and privacy in a natural outdoor setting. The focus of the Fishbein and Ajzen theory is upon salient beliefs regarding the outcomes of making a specific recreation choice.

In more practical terms of forest recreation science and management, the behavioral model of **Figure 4** can be restated to say that forest recreation users have needs, preferences, and expectations concerning resource settings, services, programs, and social setting use conditions. These user needs, preferences, and expectations toward recreation resource conditions and desired outcomes must be understood in order for managers to provide quality recreation opportunities and recreation experiences to gratify user needs and preferences and thus provide personal–social benefits. It must be realized that forest recreation cannot manage personal, psychological needs, preferences, and experiences; it can only attempt to understand user needs, preferences, and desired experiences so that diverse opportunities can be managed to meet the potential needs and preferences of users.

Figure 5 provides a more applied conceptual model of forest recreation-based needs-preference behavior. In the application, recreation visitors interact with forest environments because they have certain recreation needs. The needs are the determining factor behind their preferences and expectations concerning recreation opportunities and engagements. Management has the ability to enhance or diminish the quality (i.e., the plus and negative signs in the model) of recreation opportunities – experiences, and thus satisfaction – benefits of forest recreation to society.

User Need Determination

The determination of forest recreation needs has been influenced by Maslow's theory of hierarchy of needs. Maslow theorized that humans have five classes of needs and that various need states could be classified into these five categories in a hierarchical structure. The need hierarchy can be visualized as a climbing ladder where the individual must have

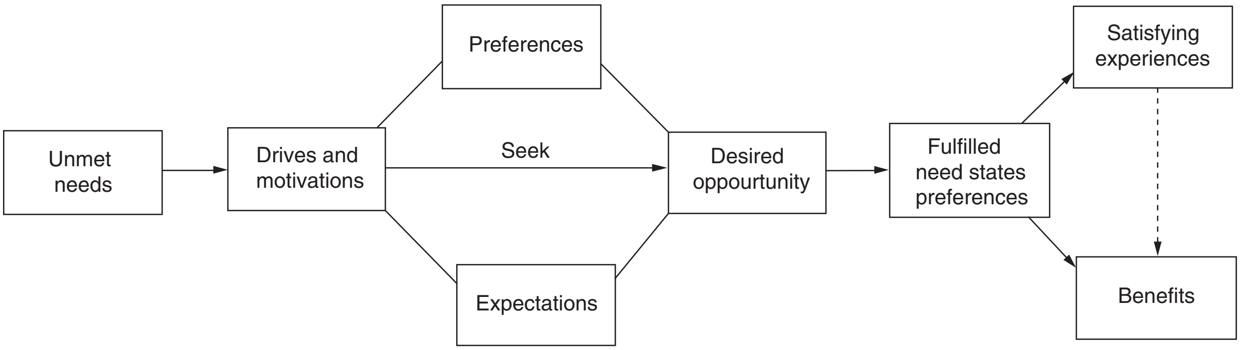

Figure 4 Conceptual model of relationships between user needs, preferences, desired opportunities, and satisfying recreational experiences.

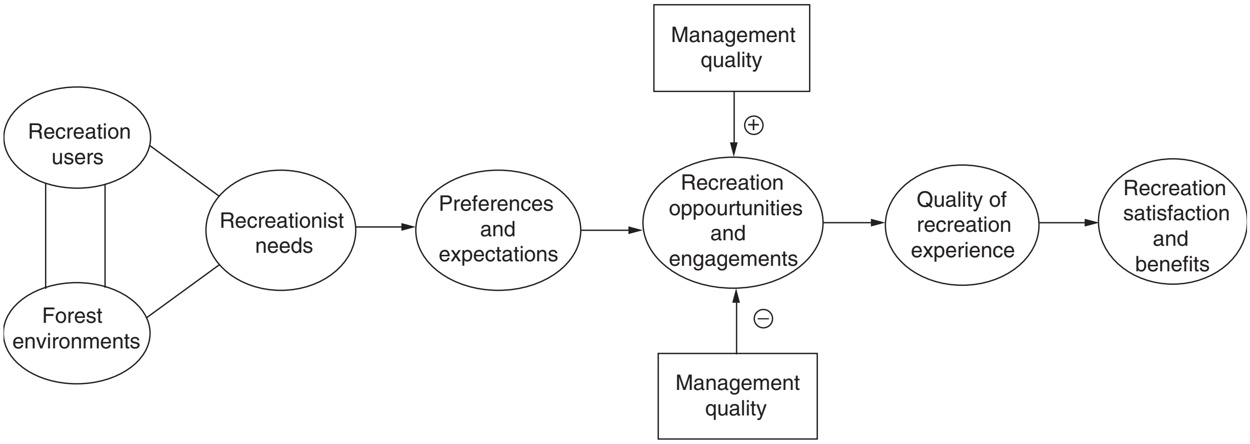

Figure 5 Conceptual model of forest recreation needs, preferences, and quality recreation opportunities – experiences.

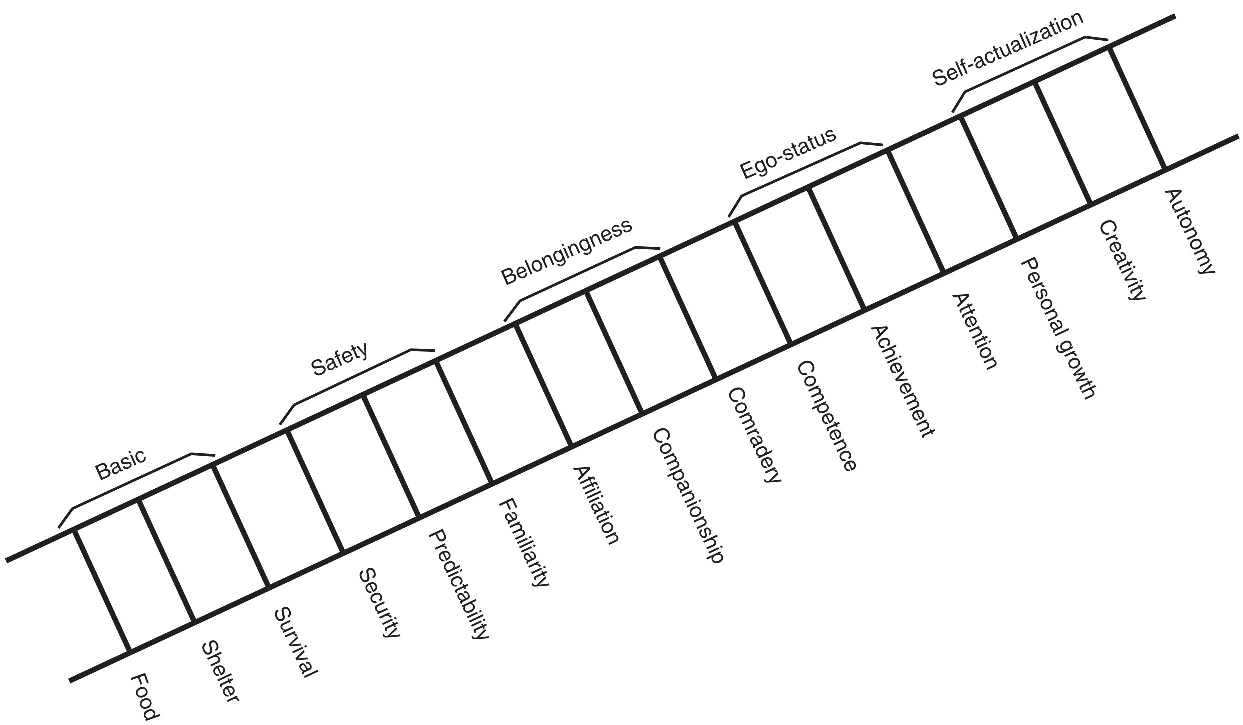

Figure 6 Maslow's ladder of human needs applied to forest recreation.

experienced a secure footing on the first rung in order to experience the need to step up to the next higher rung (**Figure 6**). He believed that there is a natural process whereby individuals fulfill needs in ascending order from the basic needs of food, shelter, survival, and other physiological needs, to the higher-order needs of self-actualization and personal creative growth.

Maslow's needs categories are related to needs-preference research in forest recreation. For example, survival skills and survival forms of wilderness recreation where self-reliance is necessary to participate successfully could be linked to basic-level needs. Safety and security needs are often at play when recreation planners, managers, and back country rangers design facilities, regulate visitor use, and rescue individuals from dangerous situations. The needs for affiliation, companionship, and comradery are commonly associated with many group activities and address the need level of belongingness. Ego-status is relevant to forest recreationists in terms of the need for competence and achievement that accompanies advanced skills necessary to participate in many risk-oriented and adventure activities. Self-actualization includes needs for personal growth, creativity, autonomy, and freedom to act, assets of many forms of remote-area recreation.

Tinsley and associates developed an inventory of psychological needs concerning leisure, using the paragraphs about leisure (PAL) inventory. The PAL inventory of recreation needs is based on the premise that leisure experiences result in the satisfaction of some of the psychological needs of recreation participants. The needs gratification helps to maintain and enhance the physical health, mental health, and life satisfaction of individuals which, in turn, stimulates personal psychological growth and increased self-actualization.

The PAL methodology consists of a series of single paragraphs which describe the gratification of a particular psychological need. Respondents are instructed to indicate the extent to which each paragraph is an accurate statement about the leisure activity being described. Ratings are done on a five-point rating scale with response alternatives ranging from 1 = not true to 5 = definitely true. This research resulted in the identification of 44 psychological needs that may be gratified by participation in leisure activities. Tinsley and associates also identified 27 of the 44 need-gratifying dimensions that varied the most across leisure activities. These two groups of leisure needs are shown in **Table 1**.

User Preference Determination

User needs are the psychophysiological antecedents that lead to the desired conditions and preferred situations (i.e preferences) that recreationists expect will facilitate and/or satisfy unmet needs. Driver's research, though similar in many respects to that of Tinsley's on leisure needs, concentrated on determining the recreation experience preferences (REP) of recreationists in natural environments. In particular, the research identified and assessed the relative importance of individual reasons or feelings of motivational implying reasons why recreationists selected certain activities and environments. A primary objective of this research was to enhance forest recreation managers' ability to specify management objectives and prescriptions that would provide quality recreation experience opportunities (i.e., the plus and minus aspects in **Figure 2**) identified by research on recreationists' motivations.

Like the PAL, the development of the REP scales was backed by the unmet-needs hypothesis that forest recreation was beneficial to helping people gratify needs not satisfied by their nonleisure behavior. Identification and evaluation of people's 'recreation experience preferences' was seen as a means to address the more difficult determination of human need states and as a managerial guide to provide the necessary recreational opportunities for quality recreation experiences. This research orientation later led to the practice of experience-based management of recreation settings, plus the development of the ROS.

The REP scales to measure recreationists' preferences were developed by means of survey questionnaires and interviews of individuals engaged in many activities in many environments. Each item in the REP inventory was assessed as to its 'importance' as

Table 1 Psychological needs of leisure

Leisure activity general: 17 needs which are satisfied to approximately the same degree by all leisure activities		
Abasement	Infavoidance	Relaxation
Autonomy	Justice	Self-control
Counteraction	Moral values	Succorance
Defendence	Order	Task generalization
Deference	Recognition	Tolerance
Harm-avoidance	Rejection	
Leisure activity specific: 27 needs which can be satisfied to a significantly greater degree through participation in some leisure activities than by participation in other leisure activities		
Ability utilization	Creativity	Security
Achievement	Dominance	Self-esteem
Activity	Exhibition	Sentience
Advancement	Getting along with others	Sex
Affiliation	Independence	Social service
Aggression	Nurturance	Social status
Authority	Play	Supervision
Catharsis	Responsibility	Understanding
Compensation	Reward	Variety

Reproduced, with permission, from Tinsley HEA, Barrett TC, and Kass RA (1977) Leisure activities and need satisfaction. *Journal of Leisure Research* 9: 110–120.

a reason for deciding to recreate in a particular activity at a certain place. Recreationists rated the reasons on a five-point importance basis, ranging from not at all important to extremely important. Years of research by Driver and colleagues resulted in 43 reliable and valid REP scales to measure the extent to which specific experiences are preferred and expected from recreational activities. **Table 2** demonstrates 19 general recreation experience preference domains into which the 43 REP scales are grouped empirically (i.e., factor analysis). Note the degree of similarity and difference between the human needs of Maslow, the leisure needs of Tinsley, and the REP of Driver.

The REP scales have dominated the determination of user needs and preferences in forest/wildland recreation, involving over 30 years of research by many different scientists. This research has yielded REP profiles for many recreational activities in an array of natural environments. **Table 3** summarizes the overall mean scores and rank order of 16 REP domains (i.e., groups of REP scales) of users of 15 different areas ranging from low-use designated wilderness to highly used outdoor areas. Note the patterns of commonality across areas in those REPs ranked the highest (i.e., enjoy nature, reduce tensions in wilderness). In areas offering a more diverse array of undeveloped and developed facilities and activities than wilderness, more variation in preference profiles, specific to activity and place, have been produced.

Site Needs and Preferences Application

While recreation scientists, planners, and managers have been interested in the physiological–psychological needs and preferences underlying why people recreate and the experiences preferred, they have also been interested in user needs and preference about on-site facilities, services, and other amenities desired. The behavioral needs and preferences of users are directly, and indirectly, related to the amenity needs and preferences of forest recreationists, for the amenity-site facilities and services can influence the type of experience derived by users. For example, the many amenities of a developed campground can provide for the needs of affiliation and family cohesion while an undeveloped wilderness area is better suited for solitude and self-reliance.

There have been many management-oriented studies on the site needs and preferences of users in many activities in many environments. Manning provides a major review and synthesis of this research, which will be summarized here.

Table 2 Recreation experience preference (REP) scales making up the recreation experience preference domains[a]

1. Enjoy nature
   A Scenery
   B General nature experience
2. Physical fitness
3. Reduce tension
   A Tension release
   B Slow down mentally
   C Escape role overloads
   D Escape daily routines
4. Escape physical stressors
   A Tranquility/solitude
   B Privacy
   C Escape crowds
   D Escape noise
5. Outdoor learning
   A General learning
   B Exploration
   C Learn geography of area
   D Learn about nature
6. Share similar values
   A Be with friends
   B Be with people having similar values
7. Independence
   A Independence
   B Autonomy
   C Being in control
8. Family relations
   A Family kinship
   B Escape family
9. Introspection
   A Spiritual
   B Personal values
10. Be with considerate people (social security)
11. Achievement/stimulation
   A Reinforcing self-confidence
   B Social recognition
   C Skill development
   D Competence testing
   E Seeking excitement
   F Endurance
   G Telling others
12. Physical rest
13. Teach/lead others
   A Teaching/sharing skills
   B Leading others
14. Risk-taking
15. Risk reduction
   A Risk moderation
   B Risk prevention
16. Meet new people
   A Meet new people
   B Observe other people
17. Creativity
18. Nostalgia
19. Agreeable temperatures

[a] Individual REP scales are designated by the capital letters if there is more than one scale per domain and by the name given the domain when there is only one scale per domain.

Reproduced, with permission, from Driver BL, Tinsley HEA, and Manfredo MJ (1991) The paragraph about leisure and recreation experience preference scales: results from the two inventories designed to assess the breadth of the perceived psychological benefits of leisure. In: Driver BL, Brown PJ, and Peterson GL (eds) *Benefits of Leisure*, pp. 263–286. Pennsylvania: Venture Publishing.

Table 3 Mean scores and ranks (in parentheses) of 16 recreation experience preference domain by users of 15 recreation areas[a]

	Experience preference domains	Designated wilderness							
		Weminuche (CO) (n = 313)	Maroon Bells (CO) (n = 268)	Flattops (CO) (n = 135)	Eagles Nest (CO) (n = 271)	Rawah (CO) (n = 212)	Linville Gorge (NC) (n = 249)	Shining Rock (NC) (n = 297)	Joyce Kilmer (NC) (n = 80)
1.	Enjoy nature	1.5 (1)	1.5 (1)	1.5 (1)	1.5 (1)	1.7 (1)	1.5 (1)	1.6 (1)	1.4 (1)
2.	Physical fitness	2.4 (4)	2.0 (2)	2.5 (5)	2.3 (2)	2.3 (3)	2.1 (2)	2.2 (2)	1.8 (2)

Ogden, UT: USDA Forest Service, Intermountain Forest and Range Experiment Station.

Environmental Preferences

Recreation experiences are seldom derived from a single on-site recreation activity (i.e., camping), but rather, result from a package of amenity-related events. For example, trail hiking and/or driving to sightsee the surrounding forest environs are popular and rewarding outdoor recreation activities while camping. Trail preferences among North American forest recreation users indicate they prefer trails of less than 10% slope, that have many bends to create an element of mystery in terms of what lies around the corner, a natural but somewhat open understory so they can see into the forest, views of large and otherwise unique features, including wildlife, and the most important preference, nearness to water.

Sightseeing involves larger-scale environmental forest preferences. Sightseers in North America prefer vistas and corridors that offer views into the forest, large trees and mature forests that have open, park-like understories that offer visual penetration into the forest, viewsheds that include water (i.e., rivers, lakes, falls), mountains offering multiridge and valley views, and unique features and landmarks. These sightseeing needs and preferences of forest recreationists are essential to understand and manage, for driving-for-pleasure remains one of the most popular forest recreation activities. Scenic byway, parkways, and natural-roaded areas are the preference of 'windshield visitors' to forested areas.

Developed Recreation Areas

Campsites and campgrounds have been researched the most and offer insight as to what campers prefer, and what planners need to consider when designing camping-related recreation opportunities.

Most campers find partial-to-full shade desirable, strongly prefer vegetative screening between adjacent campsites, and prefer spacing between campsites in the 50–100 ft (15–30 m) range, to be located between 100 and 200 ft (30 and 60 m) from both comfort station and drinking water, strongly prefer flush toilets, and favor fireplaces constructed of metal. Nearness to lakes, rivers, and other water, as well as major tourist attractions, are universally desired amenities of developed camping. However, it should be noted that there are several types of developed campgrounds and a diversity of camper preferences, meaning that management for the average preferences of the average camper may not meet the diverse preferences of many campers.

Undeveloped Recreation Areas

Several studies have researched the preferences of backcountry and wilderness users toward management policies, and facilities and services. Preferences toward management policies suggest that:

1. Most users prefer restrictions on the number of users in crowded areas.
2. There is no consensus on the preferred method of use rationing, although queuing seems most favored and lottery the least favored procedures.
3. Opinions are mixed on the desirability of fixed-travel routes or itineraries (via, permits).
4. A majority of users support self-registration permits.
5. Degree of preference is mixed on spatial zoning by method of travel (i.e., horse versus hiking), lowering trail standards, and restricting or downgrading access routes.
6. Most users prefer limits on group size.
7. Most users do not favor prohibition of campfires, although this may change as more areas restrict campfire use.
8. Most wilderness users do not prefer policies requiring use of designated campsites.

Studies of backcountry–wilderness user preferences for facilities and services (**Table 4**) suggest:

1. Relatively low-standard trails are preferred to high-standard trails.
2. Most users prefer bridges at large streams difficult or dangerous to ford.
3. Information signs along trails (i.e., trail names, directions, and distances) are preferred, while campsite and interpretive signs are less favored.
4. Fireplaces and picnic tables are not preferred at campsites, while fire rings are.
5. Degree of preference is mixed on pit toilets and other types of sanitary facilities at campsites.
6. Degree of preference is mixed on trail shelters.
7. Special equestrian facilities (i.e., corrals and hitching racks) are generally not preferred.
8. Emergency telephones are generally not favored, although cell phones are more commonly being carried into wilderness areas.
9. Maps and informational pamphlets about areas are preferred by the majority of areas.
10. The majority of users favor the presence of wilderness rangers.

In both developed and undeveloped areas, there is considerable evidence that users tend to prefer or respond favorably to the facilities and services they find on-site when recreating; in other words, site supply determines preference demand. Manning suggests this finding might be explained by the fact that visitors may sort themselves, or self-select,

Table 4 Percentage of users preferring selected backcountry facilities and services

Location	*Facility*	*%*
Mt. Marcy, NY	Pit toilets, sanitary facilities	70

among areas and facilities according to their preferences. Preferences may also be based on the types of areas and facilities previously encountered, and familiarity. For example, field observation research shows that users tend to camp at previously used and familiar sites rather than seek out and establish new sites.

Use Impact Preference

User perceptions and preferences regarding various types and levels of recreation-caused impacts to environmental and experiential conditions are of interest to recreation researchers and managers, for impacts can degrade the quality of recreation places and experiences. However, forest recreationists seem to have few reactions to impacted site conditions, and are often not perceptive of existing impacts. Some exceptions are severe disturbances to site conditions (i.e., deep trail erosion) and experience conditions (i.e., crowded users); both examples of impacts that can be managed to improve the quality of forest recreation. In addition, forest recreationists are very sensitive about litter in natural areas. Litter is not only a site impact; it is also an experience impact. Litter decreases the naturalness of a site, can indicate that an area is overused and/or misused, and detracts from the preferred conditions and, thus, quality of recreation experience received by users.

While forest recreation users exhibit preferences against some major impacts as listed above, they are not perceptive of and/or demonstrate preferences toward the majority of recreation resource impacts. For example, worn-out campsites and trails, as well as water pollution and wildlife disturbance, are not perceived by the majority of users as impacts or unpreferred conditions. A study of camper perceptions of site impacts at three Indiana state park campgrounds indicated that the majority of campers rated ground cover conditions as satisfactory to excellent, even in areas where over 75% of the campsites were 100% bare-ground and severely compacted. Two-thirds of the campers did not notice damage to trees or shrubs, despite the fact that damage was extensive in several areas. In addition, even the minority of users who rated the campsite conditions as poor reported that these conditions did not detract from their enjoyment of the area.

The lack of perception and reaction of recreationists toward recreation resource impacts has been troublesome to recreation resource managers, whose responsibilities include maintaining and enhancing the quality of the recreation resource. It seems the perceptions and preferences of users do not always match those of recreation scientists and managers. Managers tend to be more perceptive of site and experience conditions, and prefer higher standards of conditions than the majority of users. This is true for developed campgrounds, backcountry campsites, wilderness areas, roaded forest lands, and state parks. Impacts and problems studied in these areas have included litter, vandalism, theft, human waste, environmental impacts at campsites and along trails, water pollution, wildlife disturbance, excessive noise, rule violations, and conflicts among recreationists. Managers also tend to rate such issues as greater problems than do site users. Similar differences between managers and users have been found to occur concerning motivations and reasons for area and activity participations, and preferences/attitudes toward recreation management policies and practices. Thus, forest recreation scientists and managers not only need to understand the needs and preferences of recreation users, they must also understand the differences that exist between scientists, managers, and users of resources.

Inventory, Monitoring and Management

T Sievänen, Finnish Forest Research Institute, Helsinki, Finland

Introduction

Outdoor recreation in forested settings is a use of forest resources which has become more and more important for urbanized societies. It plays a prominent role in people's leisure time. Forests together with other natural areas offer an environment where people can participate in many kinds of recreation activities, and where they can feel close to nature and natural resources. This article offers an overview of the key issues and research regarding the evaluation and management of forest recreation.

This article includes a brief history of recreation research, a description of methods and types of data gathered for recreation information concerning both demand of recreation and supply of recreation resources, and an overview of management methods of recreation resources and visitors.

History of Recreation Research

Research on forest recreation started to develop in the USA and European countries such as Germany in the late 1950s and 1960s. One of the first authors to discuss the information needs and provide a theoretical basis for producing information on outdoor recreation was Dr. Marion Clawson. The Outdoor Recreation Review Commission (ORRRC) was established in 1958 in the USA, and that started the process of producing regular nationwide recreation participation surveys. The ORRRC report was first published in 1962, with recreation participation surveys taking place at 5–12-year intervals up to that of 2000, led by Dr. H. Ken Cordell. Canada also has a long tradition of recreation participation surveys since the early 1980s. In Europe, some countries have done long-term monitoring for decades. Sweden was one of the first to produce outdoor recreation information on a population basis in 1964 and 1974, and repeated a population study in the 1990s. In Denmark, the first nationwide recreation participation survey was done in 1976–1977 by Niels Elers Koch, and repeated in 1993–1994. The Netherlands has also monitored outdoor recreation since the 1970s. In countries such as Finland and Italy, the first nationwide recreation participation surveys were done in the 1990s and early 2000.

In addition to nationwide surveys, development work for producing visitor information on recreation areas was needed. Visitor surveys and visitor-counting methods have been studied since the 1960s. Dr. George A. James in the USA and Dr. Lars Kardell in Sweden were the most prominent pioneers of this work. In the 1990s, a number of handbooks were produced to help park personnel to monitor visitation.

Science-based visitor management in recreation areas, national parks, and wilderness areas has demanded growing attention. Research related to concepts of ecological and social carrying capacity and conflict management, done by Dr. David Lime and others, have been important in improving management methods in the 1970s–1980s. That line of research was adopted into a planning system or framework, e.g., limits of acceptable change (LAC) in the 1980s, developed by Dr. George Stankey and others. The LAC approach has been adopted in many countries as a tool for planning the sustainable recreational use of natural resources. Studies on recreation experiences and benefits gained from recreation have produced systematic development frameworks for visitor management, i.e., benefit-based management or outcomes approach to leisure, developed by Dr. Bev Driver and his colleagues in the 1980s and 1990s.

Beside the recreation participation surveys, research on recreation resource inventories has developed over the years. In the USA, the ORRRC report included a recreation resource classification. Next, the theoretical framework for classifying recreation environment, i.e., recreation opportunity spectrum (ROS), was developed by Dr. Bev Driver and Dr. Perry Brown and their colleagues in the late 1970s. The nationwide application of broad-scale resource inventories in the USA was led by that country's Forest Service in the late 1970s and 1980s. Methods to implement these scientific-based approaches into resources management were also developed, such as the early visual management system developed in the 1970s by the US Forest Service (*see* **Landscape and Planning:** Visual Resource Management Approaches). Recently, geographic information system (GIS)-based planning methods and participatory planning processes have advanced recreation planning and management in many countries.

Methods and Data for Recreation Information Gathering

Studies on recreation inventory and monitoring fall into two basic types – studies of user needs and activities (demand), and studies of the recreation facilities and land-based resources (supply).

Recreation Demand Surveys

Nationwide population surveys Recreation demand refers here to the actual or potential participation in recreation activities. There is a need to know how many people, and how many times, or how many days per year they walk for pleasure, hike, ride a bicycle, and do other recration activities. The need for nationwide information on recreation demand was recognized 40 years ago, when the first National Recreation Survey (NRS) was conducted in 1960 in the USA. Monitoring of recreation demand will help forest managers in allocation and planning of the use of forest resources in the future. The continuity of a core set of participation and demographic questions has ensured that trend construction and comparisons of recreation have been possible at the national level over the years. Similar efforts have been made in other countries like Canada, Denmark, and Sweden but the contents and extent of the nationwide recreation surveys vary considerably.

The latest National Survey of Recreation and Environment 2000 (NSRE) includes several themes of recreation research. In particular, information concerning recreation participation and recreation trips serves to monitor recreation demand. The survey covers 50 different outdoor activities. The survey had about 75 000 responses.

Denmark has conducted a series of recreation surveys, which offer the possibility of comparing forest recreation participation over time: Danish surveys covered overall visitation into the forestland, and included a remarkable set of data on forest and landscape preferences. The survey in 1993–1994 as well as the 1993–1994 survey reached a response rate of over 80%, from samples of almost 3000 persons. In Finland, only one nationwide recreation survey has been conducted but the study is planned to be repeated in 2008–2010. The Finnish survey data included about 10 000 respondents. The main issues measured were participation in outdoor activities, recreation trips close to home, and nature trips including an overnight stay. In southern Europe, Italy has conducted its first nationwide recreation survey. Even though there are still many discrepancies in use of concepts, terms, and units of measurement, some international comparisons can be made. **Table 1** shows participation rates of some of the most typical recreation activities in six countries, expressing the diversity, similarity, and differences in recreation behavior among different nations. The issue of harmonizing policy and procedures for recreation information monitoring internationally has been discussed in the research community and may provide more comparable data in the future.

On-site user inventories: monitoring visitor flows and gathering visitor information On-site recreation inventories, i.e., visitation monitoring systems, are an important part of the management policy of recreational and protected areas in many countries.

Table 1 Participation rates in some recreation activities in six countries in the 1990s. Participation rate means the portion of population which recreate doing the activity at least one time during one year

Recreation activity	*Participation rate (%)*

Recreation monitoring as applied is most often a science-based system for data collection, data management and reporting, which supplies managers with baseline, updated visitor information on a continuous basis. Monitoring systems differ between countries, but often standardization of methods and harmonization of information content have taken place within one country or at least within one public land agency.

The most common visitation information measured includes number of visits, duration of visit, and distribution in the area. Information gathered from visitors often consists of socioeconomic factors such as sex, age, income, and municipality/region/country of residence, length and means of travel, and money used. Visitor behavior pattern describes recreation activities participated in, length of stay in the area, and company of visit. Visitor satisfaction, motives, and expectations of visit and experiences are also studied in most cases.

In the USA, the National Park Service implements a mail-back customer satisfaction card (referred to as the visitor survey card or VSC), which is similar to surveys used by other agencies. All National Park Service units systematically measure and report annually on visitor satisfaction. The customer satisfaction card enables parks, clusters, regions, and national program offices to measure their progress toward meeting annual and long-term goals of park management. The US Forest Service has implemented a sophisticated on-site visitor monitoring system called the National Visitor Use Monitoring (NVUM) system. With this system, one-fourth of the 160 national forests in the country are sampled each year through a system of site-day sampling. Activities, duration of visit, satisfaction, trip spending profiles, and sites visited are collected and geographic information systems (GIS) referenced to provide location-specific, regional, and national estimates to guide policy, management, maintenance, budgeting, and customer responsiveness.
