Pines

P W Rundel, University of California, Los Angeles, CA, USA
D M Richardson, University of Cape Town, Cape Town, South Africa

Introduction

Pines clearly form the most ecologically and economically significant tree group in the world. The genus *Pinus* contains 110 species (**Table 1**), comprising more than half the species in the Pinaceae and almost 20% of all gymnosperm species. Ecologically, pines also influence the structure and function of many forest ecosystems. They affect biogeochemical processes, hydrological and fire regimes, and provide food and create habitats for animals. Pines are important, and very often dominant, components of the vegetation over large parts of the northern hemisphere (**Figure 1**). Economically, pines play a major role as sources of timber, pulp, resin, nuts, and other products. Pines have also been cultivated in many parts of the world, both within and well outside their natural range, and they form the foundation of exotic forestry enterprises in many southern hemisphere countries. Moreover, pines have featured in ancient myths and rituals throughout human history, and have been celebrated in visual art, prose, poetry, and music.

Pines are found in a remarkably wide range of environments, from above the arctic circle where winters are very cold and growing seasons are short, to the tropics where frost never occurs and growth continues through the year. Pines are the dominant trees over large parts of the boreal forest, or taiga, which covers about 12 million km^2 of the northern hemisphere. In temperate latitudes of the northern hemisphere they occur abundantly in high mountains, in Mediterranean-climate regions, and mixed with junipers over extensive semi-arid woodlands. Some pine species form virtually monospecific forests over very large areas whereas others form mixed forests with other conifers (notably spruce and fir species) and broadleaved trees (notably oak, poplar, birch, and alder species), or form subtropical savannas or open woodlands. In temperate regions, and even more so in the tropics, pines are usually associated with acidic, nutrient-poor soils. Pines possess a range of specialized mechanisms that enable them to thrive (and usually attain dominance) in these harsh environments. That pines are not restricted to such sites is clearly shown by their ability to spread into more productive sites, both within and outside their natural ranges, following disturbance that reduces the competitive superiority of vigorous angiosperms. The disturbance regime is thus an important determinant of pine distribution and abundance in the landscape. Fire is the driving force in succession in nearly all pine habitats.

The Origin and Evolution of Pines

The expansion of angiosperms and the concurrent decline of gymnosperms in the late Mesozoic had a significant impact on the phytogeographic history of the earth. The earliest-known angiosperms arose in the Early Cretaceous (130–90 million years ago), and there are now between 250 000 and 300 000 extant species. The first gymnosperms arose in the Middle Devonian (365 million years ago), much earlier than the angiosperms, but the group never achieved a high diversity of species. Evidence from fossilized cones shows that ancestors of the Pinaceae had evolved by the mid-Jurassic, and that pines themselves had evolved by the Early Cretaceous. Most of the other modern genera of the pine family appeared only in the Early Tertiary or later.

By the end of the Mesozoic (65 million years ago), pines had diversified into two major groups, or subgenera (**Table 2**); the subgenus *Pinus* (diploxylon or hard pines, with two fibrovascular bundles in each needle) and subgenus *Strobus* (haploxylon or soft pines, with one fibrovascular bundle in each needle). At this stage, pines had migrated throughout the middle latitudes of the supercontinent Laurasia. However, as major environmental changes occurred in the Early Cretaceous (between 130 and 90 million years ago), the diversification and rapid spread of angiosperms throughout middle latitudes pushed most conifers to small, cool or dry refugia in polar latitudes and scattered upland refugia at middle latitudes.

Intensive mountain-building events in the Tertiary created the environmental heterogeneity that drove the radiation of pine taxa in secondary centers of diversification, notably Mexico and northeastern Asia. Angiosperms that were best adapted at that time to tropical and subtropical conditions declined dramatically throughout middle latitudes following climatic deterioration at the end of the Eocene, allowing pines to expand their ranges.

Like the Eocene, the Pleistocene was also characterized by profound environmental changes that influenced the evolution of pines. However, whereas events in the Eocene completely reshuffled elements of the genus, Pleistocene changes caused pine species and populations to shift first toward the equator, then poleward (and to lower, then higher elevations), following the cycle of glacial and interglacial periods. Such migrations had important influences on the genetic diversity of pines. In some areas, such as the Pacific Northwest of North America, pine distributions were not so much split into distinct ranges by glaciations, as fragmented into small, semidisjunct populations. Such migrations served to promote intraspecific diversity while not necessarily promoting speciation. Although geographic conditions prevented pines from migrating south of the Sahara Desert, Nicaragua in Central America, or Java and Sumatra in Asia, the success of planted pines in the southern hemisphere shows that large parts of this hemisphere are highly suitable for pine growth.

Many significant changes in the abundance and geographic ranges of pines have occurred since the end of the last glacial period as pines rapidly expanded their ranges into deglaciated regions of North American and Europe. Wood rat middens preserved over the past 40 000 years at many sites in the Great Basin and other parts of the southwestern United States show a replacement of pinyon–juniper woodland by desert scrub in the Great Basin with warming at the end of Pleistocene.

Why Are Pines so Successful?

It is in the role of aggressive postdisturbance colonizers that pines are most clearly differentiated

Table 1 List of *Pinus* taxa, with common names, selected morphological features, and biogeographic region and habitat; figures relate to conditions regularly observed in the field (figures in brackets indicate exceptional dimensions)

Pinus *taxon*	*Common name*	*Needle number*	*Needle length (cm)*	*Needle longevity (years)*	*Cone length (cm)*	*Height (m)*	*Biogeographic region*	*Habitat*
P. albicaulis	Whitebark pine	5	3–7	5–8	4–8	5–10(30)	Western North America	Subalpine
P. aristata	Colorado or Rocky Mountain bristlecone pine	5	3–4	10–20	5–6(11)	5–15(30)	Rocky Mts, North America	Subalpine
P. armandii	Chinese white, Armand('s), or David's pine	5	8–15(18)	2–3	8–14	20–30	West and central China, Taiwan	Temperate montane
P. attenuata	Knobcone pine	3	9–15	4–5	8–15	10–20	Baja California, California, southwest Oregon	Mediterranean coastal
P. ayacahuite	Mexican white pine	5	8–15(22)	3	25–45	35–50	Mexico, Central America, Arizona, New Mexico	Tropical montane
P. balfouriana	Foxtail pine	5	(1.5)3–4	10–30	6–9(12)	10–22	California	Subalpine
P. banksiana	Jack pine	2	2–5	2–4	3–3.5	10–18(20)	Canada, northern USA	Boreal forest
P. bhutanica	Bhutan white pine	5	12–28	2–3	12–20	25	Himalayas	Temperate montane
P. brutia	Eastern Mediterranean or Calabrian pine	2	8–15	?	6–9	10–25	Eastern Mediterranean Basin	Mediterranean coastal
P. bungeana	Lacebark pine	3	6–8	3–4	5–6	15(30)	Central and north China	Temperate montane
P. canariensis	Canary Island pine	3	20–30	2–3	10–20(25)	30	Canary Islands	Mediterranean
P. caribaea	Caribbean pine	(2)3(4–5)	15–25	2	5–12	20–30	Caribbean area, Central America	Tropical/savanna
P. cembra	Swiss stone or Arolla pine	5	7–9	3–12	4–10	8–20(25)	Central Europe	Subalpine
P. cembroides	Mexican pinyon	(2)3(4)	2–6(7)	3–4	1–3.5	5–10(15)	Northwest Mexico, southwest USA	Arid/montane
P. chiapensis	Chiapas white pine	5	10–12	?	7–16	40	South-central to south Mexico, Guatemala	Tropical
P. clausa	Sand pine	2	6–9	2–3	3(4–8)	6(10)	Southeastern USA	Subtropical
P. contorta	Lodgepole pine	2	2–8	3–8	2–6	3–46(50)	Western USA	Temperate montane/subalpine
P. c. subsp. *bolanderi*	Bolander pine	2	2–5	?	?	6–15	California	Temperate
P. c. subsp. *contorta*	Shore or beach pine	2	2–7	?	2–5	3–10(16)	Coastal north California to British Columbia	Temperate
P. c. subsp. *latifolia*	(Rocky Mountain) lodgepole pine	2	(4)5–8	5–18	?	40–46	Rocky Mts, North America	Temperate montane
P. c. subsp. *murrayana*	Sierra (Nevada) lodgepole pine	2	(5–8)	?	2–5	15–40(50)	Sierra Nevada to Baja California	Temperate montane/subalpine
P. cooperi	Cooper pine	5(6–8)	8–10	?	6–10	30–35	Western Mexico	Tropical montane
P. coulteri	Coulter or bigcone pine	3	16–30	3–4	20–35	15–25	California, Baja California	Mediterranean coastal
P. cubensis	Cuban pine	3	10–14	?	4.5	?	Cuba	Tropical/savanna

P. culminicola	Potosí pinyon	(3–4)5(6)	5–6	?	3–5	1–5	Northeast Mexico	Tropical
P. dabeshenensis	Dabie Shan white pine	5	5–14	?	11–14	20–30	Eastern China	Temperate
P. dalatensis	Dalat or Vietnamese white pine	5	4–10	?	5–10	?	Vietnam	Tropical
P. densata	Sikang or Gaoshan pine	2(3)	8–14	3	4–6	30	China	Temperate montane
P. densiflora	Japanese red pine	2	(6)9–12	2–3	3–5	20–30 (36)	Japan, Korea, China	Temperate
P. devoniana	Michoacán pine	5	20–35	?	20–30	20–30	Mexico, Guatemala	Tropical
P. discolor	Border pinyon	3	2–6	?	2–3	5–10	Southwest USA, central and northwest Mexico	Arid/montane
P. donnell-smithii	Donnell Smith pine	5–6(7–8)	5–22	?	10–13	25	Guatemala	Tropical/subalpine
P. douglasiana	Douglas pine	5	20–35	?	7–10	20–35	West Mexico	Tropical
P. durangensis	Durango pine	6(7–8)	12–20	?	7–10	30–40	Northern and central Mexico	Tropical
P. echinata	Shortleaf pine	2	7–11	3–5	4–7	15–30(35)	Southeastern USA	Subtropical
P. edulis	Colorado pinyon	2	2–4	4–6	3–6	5–15	Western USA	Arid
P. elliottii	Slash pine	2–3	15(–30)	2	8–18	25–30	Southeastern USA	Subtropical
P. engelmannii	Apache pine	(2)3(4–5)	25–35	?	(10)–15	25(– 30)	West Mexico, Arizona, New Mexico	Temperate/montane
P. fenzeliana	Fenzel pine	5	4–18	?	6–10	13–50	South China to central Vietnam	Temperate
P. flexilis	Limber or Rocky Mountain white pine	5	3–8	5–6	7–15	7–15 (24?)	Western North America	Subalpine
P. gerardiana	Chilgoza or Gerard's pine	3	6–10	?	12–20	10–20(25)	Punjab, Afghanistan, Pakistan	Temperate montane
P. glabra	Spruce pine	2	(4)6–8	2–3	4–9	22–35	Southeastern USA	Temperate
P. greggii	Gregg's pine	3	8–15	2–3	8–14	10 – 15(25)	East Mexico	Tropical
P. halepensis	Aleppo pine	2(3)	6–12(15)	2	5–12	10–20(25)	Mediterranean Basin	Mediterranean coastal
P. hartwegii	Hartweg pine	3	8–16	?	8–14	20–30	Mexico, Guatemala	Tropical/subalpine
P. heldreichii	Heldreich whitebark or Bosnian pine	2	6–10	2–3(6?)	7–8	20(30)	Balkan peninsula, Greece	Temperate montane/subalpine
P. herrerai	Herrera pine	3	10(10–25)	?	2–3(4)	20–25(35)	West Mexico	Tropical
P. hwangshanensis	Hwangshan (Huangshan) pine	2	5–9	?	4–6	25	Central and eastern China	Temperate
P. jaliscana	Jalisco pine	4–5	12–16	?	4–8	20–30	West Mexico	Tropical
P. jeffreyi	Jeffrey pine	3	12–15(23)	4–6	15–30	25–50(60)	California, Baja California	Temperate montane
P. johannis	Zacatecas pinyon (pine)	3	3–5	?	3–4	2–4	Northeast Mexico	Arid/montane
P. kesiya	Khasi or Khasya pine	3	12–20(22)	2	5–7(10)	20–35(45)	Southeast Asia	Tropical
P. koraiensis	Korean stone pine	5	(6)8–13	2	9–20	20–35	Korea, Japan, northeast China, Siberia	Temperate montane
P. krempfii	Krempf pine	2	3–7	?	7–9	12–30	Vietnam	Tropical
P. lambertiana	Sugar pine	5	(5)8–10	2–4	25–50(60)	75	Baja California, California, Oregon	Temperate montane
P. lawsonii	Lawson's pine	3–5	15–20	?	6–8	25–30	South Mexico	Tropical

from firs, spruces, other conifers, and from angiosperm trees. An idealized 'pine prototype' would conform with the following profile: a light-demanding, fast-growing tree that regenerates as even-aged cohorts following landscape-scale disturbance, and retains its position in the landscape by exploiting aspects of its regeneration biology. This is an oversimplification, however, when one considers the wide range of habitats in which pines occur, and the range of life history syndromes evident in the genus.

Among the factors that have contributed to the ecological success of pines are their abundant output of seeds from an early age, their effective mechanisms for long-distance seed dispersal, their ability to colonize nutrient-poor and disturbed sites, and their mating system that permits inbreeding and selfing in isolated trees and confers resilience at

the population level under a wide range of disturbance regimes.

Morphological Traits of Pines

Pines, like many other conifers, typically have a main trunk which can grow to a large size. The largest species of pines in the world are found in California and the Pacific Northwest of the USA. Growth conditions in these regions favor immense size in many conifer genera, including *Abies*, *Picea*, *Pseudotsuga*, *Thuja*, *Tsuga*, *Sequoia*, and *Sequoiadendron*. The largest species of pine in both height and girth is *Pinus lambertiana* which reaches over 75 m in height and more than 5 m in diameter in the Sierra Nevada of California. Three other pines from the western USA, *P. jeffreyi*, *P. monticola*, and *P. ponderosa*, all reach heights of 60 m or more.

Pines can, however, be quite short in stature in more extreme habitats. The pinyon pines usually attain heights of no more than 5–10 m when mature. Timberline pines also may be low growing, particularly when they occur as multistemmed krummholz shrubs at the upper limits of tree distribution. Most of these timberline species have the genetic potential for taller growth, and may reach 10–20 m in height under more favorable conditions.

Many pines are very long-lived, and the two bristlecone pines, *Pinus aristata* and *P. longaeva*, are the oldest living organisms in the world, with the latter reaching documented ages of nearly 5000 years. *Pinus albicaulis*, *P. balfouriana*, and *P. flexilis* may live for more than 2000 years, while others such as *P. jeffreyi*, *P. monticola*, and *P. ponderosa* can reach ages beyond 1000 years. All of these are montane or timberline species from western North America.

Because of their great ages, pines have played a fundamental role in the development of the modern science of dendrochronology, beginning with the pioneering work of Andrew Douglas in the American Southwest. Douglas developed the concept of cross-dating to compare and extend tree ring measures over broad regional areas to identify year-to-year variation in climate. It was this research that led to the establishment of the Laboratory of Tree Ring Research at the University of Arizona in 1906. Collaborative work with anthropologists soon led to what were then revolutionary approaches to dating the construction of Indian dwellings in Chaco Canyon and Mesa Verde in the Southwest. These studies allowed the earliest measurement and linkages of floating chronologies to develop long-term records over more than 2000 years, and had profound impacts in the field of anthropology.

The field of dendrochronology has expanded greatly in scope and depth in recent decades. Chronologies of living *P. longaeva* tied to floating records in logs show promise of developing a 10 000-year record across the Holocene. Tree ring chronologies are also proving to be valuable records of alteration of typical forest growth regimes resulting from fires and from atmospheric pollution or other causes.

Although all pines share the defining morphological trait of possessing pine needles, there is a wide variation in the size and manner of needle display. Needles are arranged in bundles (generally termed fascicles or needle clusters), with the number of needles per fascicle being a reasonably constant and species-specific characteristic in many taxa. Most pine species have two, three, or five needles per fascicle, but other numbers are also present. Only one species has one needle per fascicle: *P. monophylla*, the singleleaf pinyon of the southwestern USA. At the other extreme, four species of typically five-needled Mexican pines (*P. cooperi*, *P. donnell-smithii*, *P. durangensis*, and *P. pseudostrobus*) frequently have six needles per fascicle, and sometimes up to eight.

Needle number does not have any established ecological correlation. Adaptive radiation within specific subsections of the genus *Pinus* has taken place, both with and without modifications of needle number per fascicle. For example, almost all of the 24 Old World pines of the subsections *Pinus* and *Pinaster* have two needles per fascicle (**Table 2**) – this despite the wide range of habitats occupied by taxa in this group (e.g., *P. resinosa* and *P. sylvestris* in boreal-type forest; *P. nigra* and *P. pinaster* in lower-elevation sites in the Mediterranean Basin; *P. heldreichii*, *P. mugo*, and *P. uncinata* at high-elevation sites in the Mediterranean Basin; *P. kesiya* and *P. merkusii* in tropical savannas; and a set of eastern Asian species that occupy a wide range of habitats). The white pines occupying varied montane and subalpine habitats all typically have five needles per fascicle. At the other extreme are the pinyon species of North America which include taxa with one to five needles per fascicle, despite the arid environments in which all these species occur.

The length and form of pine needles varies greatly among pine species. The longest needles of any pine species are those of the appropriately named longleaf pine, *P. palustris*, in the southeastern USA (up to 45 cm), and *P. nubicola* in Mexico which also reach lengths of over 40 cm. At the other extreme are many pines with very short needles in the 2–8 cm range of maximum lengths. These short-needled species are almost entirely confined to the arid-adapted pinyon pines, high-elevation, or timberline pines, and pines on low nutrient sites, suggesting a relationship with environmental stress.

There are other interesting needle traits in pines that have not been studied to assess ecological significance. Several Mexican pine species have drooping, or ‘weeping’, needles that hang downward, and there are intermediate morphologies in other species with relatively flexible needles. Such long, fine needles may aid the condensation and drip of fog moisture in tropical mountain areas or in coastal fog zones, as with *P. lumholtzii*, *P. nubicola* and *P. patula* in Mexico, *P. radiata* on Cedros Island and the coast of California, and *P. canariensis* in the Canary Islands. Such hypotheses remain conjectural, however. Another unusual needle morphology in pine is that of flattened needles which are characteristic of the rare *P. krempfii* from the central highlands of Vietnam.

One strong environmental correlate of needle traits in pines does exist. Needle longevity is strongly correlated with habitat water availability and nutrient relations and/or stress. Tropical pines such as *P. caribaea* and the southern USA species *P. palustris* keep needles for no more than 2–3 years, and the Indian species *P. roxburghii* usually sheds its needles every year. Temperate forest pines commonly retain their needles for intermediate periods of 4–6 years. Pinyon pine leaves have relatively greater longevities of up to 10 years. Subalpine pines such as *P. longaeva* retain their leaves for up to 30 years or more, and even 45 years in extreme circumstances at the timberline in the White Mountains of California. This is the greatest needle longevity recorded for any conifer.

The form and morphology of pine cones is highly variable, with obvious relationships to the reproductive biology of individual species. The greatest length of cone in any pine occurs in *P. lambertiana*, where cones reach up to 50 cm in length. In terms of fresh cone weight, *P. coulteri* from California holds the record, with large globular cones 20–35 cm in diameter weighing as much as 2.3 kg. Large cones are also present in the Mexican taxa *P. ayacahuite*, *P. devoniana*, and *P. maximartinezii*. About one-third of pine species typically bear cones that are less than 5 cm long. As a broad generalization, it appears that taxa associated with stressful environments have smaller cones. *Pinus* is far more diverse in the morphology of its seeds than all other Pinaceae combined, a fact that certainly contributes to the wide range of habitats in which pines flourish. While most pines have wind-dispersed seed, the pinyon pines and many subalpine pines have large seeds dispersed by birds. It is intuitive to expect the largest seeds in species with the largest cones, but correlations between cone size and seed size is poor.

Ecophysiological Traits of Pines

Coniferous forest trees characteristically utilize a very different strategy of canopy carbon gain than do hardwood trees. Compared to deciduous hardwoods, conifers generally show a relatively low level of carbon gain per unit of leaf area, but a far higher leaf area index (LAI). Needles are retained for several to many years, and a clustered arrangement of foliage and regular canopy architecture has evolved to allow maximum irradiance of older foliage. Thus, the net primary productivity of conifer forests with high LAI is typically as great or greater than that of deciduous hardwood forests in the same climatic regime despite the lower photosynthetic rates. However, most conifers are inherently slow in becoming established in successional sequences where environmental stress is not extreme because it takes them multiple years to attain a full canopy. Under these conditions, deciduous hardwood saplings which can attain a full canopy in a single year are much more competitive.

Pines differ from the typical conifer strategy in several respects. Typical ranges of LAI in field populations of pines are only 2–4 $m^2 m^{-2}$, compared with values of 9–11 $m^2 m^{-2}$ in the more shade-tolerant genera *Abies*, *Picea*, and *Pseudotsuga*. The low LAI in pines largely results from the fact that many species carry relatively few years of needles compared to other conifers. Except in pines characteristic of environments of extreme cold or drought stress, 2–5 years of needles in the canopy at any time is typical. Thus, despite their relatively low LAI, pines are inherently more effective colonizers than many other conifers because they can attain a full canopy of foliage more rapidly early in succession. Many pines, however, can be selected for a higher LAI under plantation conditions where resources are not limiting. Highly productive plantations of commercial pine species such as *P. radiata* owe much of their productivity to LAIs two or three times those found under natural conditions.

It is interesting to speculate on the potential similarities of the rapid growth and colonizing abilities of many pines and the traits of early successional hardwood trees. The relatively low LAI of pines and their generally poor shade-tolerance are shared by such hardwoods as temperate *Eucalyptus* and many tropical pioneer trees. Shade-tolerant conifers such as *Abies*, *Picea*, *Pseudotsuga*, and *Sequoia* not only have high LAIs, but share a typical architectural form characterized by growth cycles that produce regular whorls of branches at levels determined by the height of the trunk meristem. In contrast to this pattern, most pines and many tropical colonizers (e.g., *Cecropia*, *Macaranga*, and *Musanga* spp.) are shade-intolerant and possess a canopy architecture with the cyclical addition of tiers of branches which are structurally identical to the trunk.

Considering the wide range of ecological habitats in which pines occur, it is noteworthy that there is relatively little variation in their photosynthetic characteristics. Maximum rates of photosynthetic capacity under field conditions within ecologically plastic species such as *P. contorta* and *P. sylvestris* appear to vary as much as within pines as a group. When grown under common garden conditions under nonlimiting conditions, pines from very different environments exhibit quite similar photosynthetic responses to irradiance, suggesting a considerable degree of phenotypic plasticity. This is equally true both for ecotypes of the same species and different species. Thus, variation in net primary production rates of pines in different environments is less a function of differences in photosynthetic capacity than of climatic factors of cold or drought that limit the period of positive net carbon gain throughout the year.

Seasonal patterns of low temperatures in autumn and winter are clearly important components of the potential net primary production of pine species. Thus pines in cold-temperate environments or timberline habitats have high levels of positive canopy photosynthesis limited to relatively few months of the year. Subtropical and tropical species grow throughout the year, with light, LAI, and nutrient availability as the primary factors controlling net primary production. Although pine species may tolerate habitats over a wide range of annual precipitation, the response of individual species to limited water availability is surprisingly consistent, as with almost all conifers. Net photosynthesis in pines typically falls to zero at relatively modest tissue water stress, thereby limiting the growth potential of pines in semi-arid environments.

Other aspects of the ecophysiology of pines show highly adapted traits between species that adapt them to specific climatic or environmental conditions. As logic would suggest, pines of cold habitats commonly have much lower temperature optima for photosynthesis than do species of warm climates. A stomatal response to environmental water vapour deficit is another trait showing adaptive selection. Species of semi-arid environments are highly sensitive to small changes in vapor pressure, thereby regulating summer water loss, while subtropical species are quite insensitive to such changes. Clear differences in tolerance of low nutrient conditions are also apparent in pine species whose ranges overlap.

Human Impacts on Pines and Pine Forests

Human-induced changes to pine forests have had significant impacts on the structure, dynamics, and biodiversity of these ecosystems for centuries. The consequences of human activities likely extend back thousands of years in the Mediterranean Basin where marked changes in human population numbers and far-reaching changes in land use practices have exerted major influences. Human impacts have come from logging and deforestation, land use practices that increase or decrease natural frequencies of fire, grazing, and plantation establishment outside of normal species ranges.

There is a massive literature on the history, policies, politics, and practices of logging in different parts of the range of pines. Logging takes place in natural pine forests around the world for construction-grade lumber, with varying levels of sustainability. Additionally, the need for fuelwood in many parts of the natural range of pines in the developing world still accounts for a large part of the total area of pine forest cleared every year. While pines are important lumber sources, logging of hardwood forests has often led to a stimulation of pine establishment and dominance. For example, past clearing of broadleaved forests in the southeastern USA and areas of Asia has created suitable conditions for pines. Human-induced changes to natural fire regimes have had a particularly dramatic effect on pine ecosystems. This impact has been seen most strongly where human activities have led to increased fire frequency. In Central America, Mexico, and Southeast Asia this has often arisen through the agency of slash-and-burn agriculture. However, the opposite condition of reduced fire frequencies has also been widespread and has affected pine establishment. Heavy grazing of rangelands has reduced fire frequency in many parts of the American West by reducing fuel loads, and this has had a major impact on vegetation dynamics. Fire exclusion has allowed pines to spread into some areas where the natural fire regime excluded them, and has changed the forest composition in areas where the natural fire regime allowed pines to grow, but where changed fire characteristics have altered processes affecting vegetation dynamics. Some impacts of fire suppression in pine forests through the disruption of the relationships between pines, fire, pathogens and insects are complex.

Changes in grazing pressure have triggered changes in pine distribution in many regions, but the phenomenon has been best studied in North America. Grazing facilitates pine establishment in abandoned fields by reducing the cover of vigorous grasses and thus competition with pine seedlings. Areas subjected to heavy grazing often remain susceptible to colonization by pines long after grazing pressure has been greatly reduced or eliminated. Such effects have been documented for pine forests adjoining mesic subalpine meadows and mixed grass and brush in more arid regions.

Humans have harvested pines and their products for thousands of years. There are 29 pine species whose seeds are harvested for human consumption. In some societies, pine seeds harvested from natural forests are still important economic resources, as in Pakistan, India, China, and Mexico.

Pines have been widely planted in the Mediterranean Basin since prehistoric times, and more recently throughout the world. Some pines have proved highly successful for use in plantations outside their natural ranges where there is a shortage of coniferous species to produce fibers and solid wood products. This is particularly true of temperate areas in the southern hemisphere where there are massive plantations of *Pinus radiata* and other pine species. Reasons for the widespread use of pines in exotic forestry plantations include their simple design with straight trunks and geometrical branching habitat that makes them ideal for timber production. Moreover, pines grow faster than many other potential species, are easy to manage in plantations, have easily collected seeds, and are ideally suited for planting in marginal forest lands where most plantations are desired. Many pine species – *P. caribaea*, *P. elliottii*, *P. kesiya*, *P. oocarpa*, *P. patula*, *P. radiata* and *P. taeda* – are widely grown in plantations in the tropics and subtropics.

Threats to Pine Species

One-third of all pine species are either threatened in their entirety, or have subspecies or varieties that are threatened. This includes species with naturally restricted ranges and small population sizes as well as others that owe their threatened status to human activities. Even among pine taxa that occupy large ranges, large portions of their genetic diversity have been lost; this may have reduced their ability to respond to changing environmental conditions.

Poplars

B Stanton, GreenWood Resources, Clatskanie, OR, USA

Introduction

The genus *Populus* (family Salicaceae) comprises 29 diverse species found almost exclusively in forests of the northern hemisphere. Considered as a whole, *Populus* covers an impressive ecological amplitude from the tropics to the boreal forests. In China alone, an extraordinary number of species are found in the cold northeast, the arid northwest, and the subtropical Qinghai–Tibetan plateau. No less impressive is the close association between *Populus* forests and the development of humankind that has included their cultivation for shelterbelts, fuel, animal feed and forage, pulp, veneer, lumber, and more lately, engineered wood products. Moreover, this group of trees has lately assumed a vital ecological role in forestalling desertification in Asia and in restoring and maintaining many of the world's degraded rivers and floodplains (**Figure 1**). In the latter regard, conserving the genetic resources embodied in the natural stands of many *Populus* species is critically important. These genetic resources are also an indispensable foundation for many breeding programs that support ongoing *Populus* domestication efforts. As the global forest plantation industry becomes inexorably associated with high-yield plantations of the tropical and subtropical regions, such applied genetics programs will help to sustain *Populus* plantations as the only temperate-zone tree that can be managed for near-comparable yields.

This article is an overview of the genus *Populus* and its members, where they occur, examples of how

Figure 1 *Populus* frequently grows in riparian habitats that are also the base for much of society's agricultural and industrial sectors. The conservation of *Populus* stands in the riparian zone is an integral component of the restoration of such ecologically important habitats.

they have adapted to their environment, the particulars of their genetic recombination systems that allow for future adaptive changes, the needs inherent in their conservation, and the current genetic improvement strategies being used to domesticate *Populus* to meet the demands of a growing world population.

The *Populus* Genus

Populus is mainly found in the northern hemisphere's boreal and temperate forests but is also an inhabitant of the world's tropical and subtropical forests. The genus is divided into six sections. Three sections contain nearly all of the commercial species: section *Populus*, the aspens and white poplars (formerly known as section *Leuce*), section *Aigeiros*, the cottonwoods, and section *Tacamahaca*, the balsam poplars. Section *Populus* is distributed throughout North America, Europe, and Asia. Section *Aigeiros* is best known in North America and Europe, while section *Tacamahaca* has a North American and Asian distribution. Three less economically important sections (*Abaso*, *Leucoides*, and *Turanga*) have less extensive botanical ranges, but include species that greatly extend the class of sites occupied by *Populus* (**Table 1**).

Populus has a pioneering habit, colonizing sites after disturbances; fire and floods are often a prerequisite for good establishment. They are fairly unique among forest trees in their capacity for impressive reproduction by both sexual and asexual means. Very rapid growth rates during the juvenile phase are often exhibited. However, lifespans do not extend much beyond 100 years. In some cases, succession to ensuing seral stages may be postponed by fire or other disturbances; spruce budworm outbreaks in eastern Canada maintain the presence of *P. tremuloides*, preventing its replacement by *Abies* and *Picea*.

Table 1 Sections and species of the genus *Populus* according to Eckenwalder (1996)

Section	*Species*
Abaso	*P. mexicana*
Aigeiros	*P. deltoides*
	P. fremontii
	P. nigra
Leucoides	*P. glauca*
	P. heterophylla
	P. lasiocarpa
Populus	*P. adenopoda*
	P. alba
	P. gamblei
	P. grandidentata
	P. guzmanantlensis
	P. monticola
	P. sieboldii
	P. simaroa
	P. tremula[a]
	P. tremuloides
Tacamahaca	*P. angustifolia*
	P. balsamifera
	P. ciliata
	P. laurifolia
	P. simonii
	P. suaveolens[b]
	P. szechuanica
	P. trichocarpa
	P. yunnanensis
Turanga	*P. euphratica*
	P. ilicifolia
	P. pruinosa

[a] *Populus. tremula* includes *P. davidiana*.
[b] *Populus suaveolens* includes *P. cathayna, P. korena, P. maximowiczii*.
Source: Eckenwalder JE (1996) Systematics and evolution of *Populus*. In: Stettler RF, Bradshaw HD Jr, Heilman PE, and Hinckley TM (eds) *Biology of Populus and its Implications for Management and Conservation*, pp. 7–32. Ottawa, Canada: NRC Research Press.

The species are deciduous in all but a few cases. Their growth habit is indeterminate with the production of neo-formed leaves occurring until growth cessation occurs, triggered in many species by diminishing day length. They are largely shade-intolerant, although there are noticeable differences within the genus ranging from the intolerant (*P. balsamifera, P. trichocarpa*) to the very intolerant (*P. tremuloides, P. deltoides*). The white wood is diffuse–porous with indistinct annual growth rings and comparatively soft and light quality.

The major sections of the genus can also be broadly characterized according to the general class of sites on which they are commonly found. Sections *Aigeiros* and *Tacamahaca* are prominently adapted to lowland riparian zones along major river systems with broad floodplains, but not exclusively; *P. balsamifera* (section *Tacamahaca*) and *P. deltoides* (section *Aigeiros*) have been found respectively, on grasslands and abandoned farm fields and *P. ciliata* (section *Tacamahaca*) is found at higher elevations in the Himalayan foothills. By comparison, the aspens of section *Populus* are more frequently found on drier, less fertile, upland and montane sites; *P. tremuloides* is found at elevations of 3000 m in western North America and *P. tremula* at 3300 m in Mongolia. *Populus euphratica* (section *Turanga*) is typically found in the arid, desertlike environments of Asia, often growing on saline soils, while *P. heterophylla* (section *Leucoides*) is well adapted to prolonged inundation in swamps along the southeastern seaboard of North America.

Botanical ranges in *Populus* typically cover exceedingly wide geographic areas. For example, in section *Populus*, the range of *P. tremuloides* spans approximately 110° of longitude and over 50° of latitude in North America. Even more outstanding is *P. tremula* which grows throughout Europe and Asia, from the Atlantic to the Pacific Oceans, ranging from 70° N latitude in Norway and the tundra in Russia, south to the Mediterranean basin. Similarly, *P. alba* is distributed throughout central and southern Europe and extends southward into Afghanistan, Iran, Iraq, and Syria. In section *Tacamahaca*, *P. balsamifera* has a transcontinental range covering much of Canada, Alaska, and the Great Lakes Region of the United States. *Populus trichocarpa* spans approximately 30° of latitude from southeastern Alaska south to Baja California. The Asian *Tacamahaca* species of widest distribution, *P. suaveolens*, is found from central Asia eastward to the Japanese islands. In section *Aigeiros*, *P. nigra* spans all of Europe, northwestern Africa, western Asia, the Caucasus, and western Siberia. *Populus deltoides* ranges from the Canadian prairie southward to the coast of the Gulf of Mexico and east to the Atlantic seaboard. *Populus euphratica* (section *Turanga*) occurs over an area from North Africa and the Mediterranean through central Asia and northwestern China.

Other species have more limited or disjunct ranges. *Populus ilicifolia* (section *Turanga*) is found growing along four rivers in Kenya between 1° N and 3° S latitudes. *Populus heterophylla* (section *Leucoides*) is endemic to the coastal plain of the southeastern USA and then further inland in the Mississippi and Ohio River valleys. Separate populations of the tropical species *P. mexicana* (section *Abaso*) are located along the Pacific and Gulf coasts of Mexico.

Adaptation

The genus *Populus* has successfully adapted to the world's climatic variations. This adaptation may be expressed in a differentiation among populations and its expression is critical to the ecological and evolutionary functioning of individual species and the genus as a whole. One example, adaptive variation in phenology, is of primary importance and is often associated with a population's geographic source. The association is keyed to environmental stimuli, including temperature, photoperiod, and precipitation. In species of the temperate and boreal forests, spring growth takes place only after sufficient winter chilling has occurred which allows a response to warming temperatures, while a reduction in day length towards the end of the growing season cues the process of winter dormancy. Similarly, above-freezing cold temperatures bring about leaf abscission. Populations of *P. balsamifera*, *P. deltoides*, *P. tremuloides*, and *P. trichocarpa* from different latitudes differ in the timing of these spring and autumnal events. Northern populations typically have a lower temperature threshold required for spring growth initiation than their more southerly counterparts. Northern populations also enter the dormant phase under the influence of a longer day length than southern sources of the same species. The synchronization of these growth cycles with the change of seasons has allowed *Populus* species to achieve their characteristically wide geographic distributions.

Other examples of adaptive population variation include:

1. *Populus trichocarpa* from coastal and inland regions of the North American Pacific Northwest are differentiated in their tolerance of winter temperatures. *Populus trichocarpa* populations sampled from contrasting elevations within the same river drainage are differentially adapted to growing season length.
2. *Populus deltoides* from the lower Mississippi River valley has greater chilling requirements for flowering than more northerly populations.
3. *Populus deltoides* populations in southwest North America exhibit differences in drought tolerance that are associated with local precipitation.
4. Differences in crown architecture of Italian *P. alba* populations are correlated with latitude, from which an adaptive strategy for light interception has been inferred.

Adaptations to temperature, photoperiod, light intensity, and precipitation are sufficiently precise that populations of the same species originating from contrasting environments can be differentiated in their response to these environmental cues when tested in a single locale. In nearly all cases, the pattern of adaptive variation in studies sampling populations from latitudinal ranges has been continuous, suggesting the existence of clines. Population differences notwithstanding, genetic systems are such that the larger source of variation in most studies has been found within populations among the individual members; appreciable gene flow between populations partially counters the effects of natural selection. This reservoir of variation allows populations to accommodate yearly variations in climate as well as long-term climatic changes that alter the future adaptive landscape (**Figure 2**).

Next to the importance of climatic adaptations, the resistance to foliar, shoot, and stem diseases also plays a major role in the adaptive strategies of *Populus*. The pathogens of most significant ecological and commercial impact include *Melampsora* leaf rust, *Marssonina* leaf spot, *Venturia* shoot blight, *Septoria* canker, *Hypoxylon* canker, *Dothiciza* canker, and *Xanthomonous* bacterial canker. Pathogenic variation encompasses a range in both virulence and aggressiveness. *Populus* genetic systems have coevolved mechanisms of resistance to both as their pathogens undergo mutation and sexual recombination.

Figure 2 The timing of spring growth initiation in *Populus trichocarpa* is of critical importance to the adaptation of populations to their environment. The adaptive strategy includes differences in the earliness with which individuals of a population initiate growth, perhaps in response to yearly variation in warming spring temperature patterns.

Host–pathogen interactions of *Melampsora* leaf rust have been extensively studied in *Populus*. Resistance involves both major and minor gene systems. Qualitative resistance is expressed in the isolation of the infection by the host's hypersensitive response. If qualitative resistance is lacking and the infection moves throughout the leaf tissue, the rate at which the pathogen spreads and sporulates is controlled by the host's rate-limiting quantitative resistance mechanism. Pathogen interspecific hybridization has been observed and may progress to advanced generations with the formation of hybrid swarms potentially adding a new dimension to the range of variability and virulence; in *Melampsora* leaf rusts, there have been two occurrences of interspecific hybridization.

The strategy of disease adaptation in *Populus* is oftentimes tied to environmental conditions that determine selection pressure. *Populus trichocarpa* populations from mesic, low-elevation environments typically exhibit significantly higher overall levels of *Melampsora* resistance, compared with populations native to arid regions that lack rust populations that act as a force of natural selection to heighten host resistance levels. A similar pattern has been observed in *P. deltoides*; populations from the drier portion of the range show lower levels of rust resistance in comparison with populations sampled from more humid, wetter environments.

Recombination System

The *Populus* recombination system is efficient in both the creation of new phenotypes in succeeding generations to allow for adaptation to changing environments, and in preserving the standing adaptability of the parental generation. The recombination system is characterized by mostly dioecious species and is thus outcrossing. Staminate and pistillate flowers are grouped in unisexual inflorescences (hermaphroditism is rare but has been reported in sections *Aigeiros*, *Populus*, and *Tacamahaca*). Sex ratios are balanced in most cases, thereby maximizing the effective population breeding number (sex ratios may shift in favor of females on higher-quality sites). A higher proportion of recombinant progeny is promoted by outcrossing and a large effective breeding number. The following characteristics of *Populus* reproductive biology further promote open recombination (**Figure 3**):

1. Full reproductive maturity is achieved after 10–15 years, ensuring wide participation in the breeding population before individuals are eliminated by stand competition.
2. Periodicity seems to be an unknown in sections *Aigeiros* and *Tacamahaca* with fruiting occurring every year (production of sizable seed crops in section *Populus* occurs on 4- or 5-year intervals).
3. Pollination is anemophilous, achieving wide distribution of male gametes.
4. Each pistillate inflorescence may contain 30–40 flowers, each of which develops into a two- to four-carpelary capsule that can contain upwards of 30 ovules leading to impressive seed production by individual female trees.
5. Seeds are capable of long-distance transport by virtue of their small size and attached cotton fibers that facilitate movement by air and water. Germination is epigenous; stand establishment is prompt and fairly complete when seeds germinate on a moist mineral soil (dormancy is incomplete and stratification is not required).
6. The basic chromosome number of 19 is high in comparison to other dicotyledonous forest trees. Triploids are known in section *Populus* and probably occur in *Tacamahaca* although polyploidy is the exception rather than the rule throughout the genus. The relatively high basic number and the distinctiveness of a diploid chromosome set allows for a higher rate of recombinant gametes during reduction division.

Figure 3 Whilst *Populus* is normally dioecious and outcrossing, departures occur in many species. Shown here is *Populus trichocarpa* cv. PS-53-97 bearing pistillate (center), staminate (upper) and two hermaphroditic inflorescences (left and right) along one long and one short shoot.

7. The F_2 *P. trichocarpa* × *P. deltoides* generation typically displays large segregation variation for growth and phenology with a relatively high frequency of intermediate types as well as transgressive segregants. This may indicate a loose linkage system that furthers open recombination. Conversely, a physical clustering of genes controlling *Melampsora* leaf rust resistance may lead to an increase in parental phenotypes.

Vegetative reproduction is also highly developed in *Populus* which along with stabilizing selection counterbalances the open recombination system of *Populus* preserving the parent generation's refined adaptations. Clonal propagation from roots, stumps, and twigs commonly occurs. Extensive clonal stands of *P. tremuloides* have been established by suckering from root sprouts on upland sites. Similarly, grasslands have been colonized by *P. balsamifera* by suckering from roots of trees growing in surrounding forests. *Populus trichocarpa* reproduces clonally along riparian corridors by a process of cladoptosis. *Populus nigra* establishes along river courses by sprouting from limbs and stems buried in alluvium. Apomixis is also known to occur in the genus, although the frequency of apomictic offspring is probably low and does not significantly restrict the recombination system.

Introgression and the Recombination System

Introgression can alter the genetic composition of populations of the participating parental species. Although phenological barriers to the cross-pollination of distinct *Populus* species appear to be insubstantial in most instances, the reproduction of interspecific crosses usually functions at a lower level than their intraspecific counterparts owing to problems with either prezygotic (pollen–stigma interactions) or postzygotic (embryo abortion, low seed germination, seedling mortality) effects. Nevertheless, interspecific hybridization is known to occur in the wild between members of the same section. *Populus* × *canescens*, the hybrid offspring of *P. alba* and *P. tremula*, is widely distributed throughout Europe. *Populus grandidentata* hybridizes with *P. tremuloides* (*P.* × *smithii*) in the upper Midwest of North America. Furthermore, intersectional hybridization between *Aigeiros* and *Tacamahaca* has been observed; in California and Nevada, hybridization between *P. fremontii* and *P. trichocarpa* (*P.* × *parryi*) occurs, whilst *P. deltoides* reproduces with *P. trichocarpa* (*P.* × *generosa*) at the western limit of its range in Washington and Idaho where the two species come into contact. Hybrids of *P. deltoides* and *P. balsamifera* (*P.* × *jackii*) are found in Ontario and Alberta.

A quite large hybrid swarm involving *P. trichocarpa, P. balsamifera, P. angustifolia*, and *P. deltoides* is being studied along several rivers in southern Alberta.

Although interspecific hybrids have largely formed the foundation of commercial *Populus* plantations with vigorous growth rates and substantial disease and insect resistances, they are often less disease-resistant, less tolerant of herbaceous competition, and more palatable as herbivore browse when grown in the wild without benefit of cultivation, a phenomenon known as hybrid breakdown. But despite their reduced fitness, barriers to continuous backcrossing and introgression are not absolute. Persistent hybrid swarms are a force that opens the recombination system of the participating species, especially at the fringes of their ranges, where the pressure to adapt may be greatest. Natural hybrid zones are also of ecological significance to the degree that they foster an extensive diversity of associated plant and animal species.

Conservation

Sections *Aigeiros* and *Tacamahaca* are commonly found occupying floodplain and riparian habitats, at times growing in large contiguous, pure stands. The construction of dams, revetments, levees, and channelization projects along many of the world's rivers has reduced the frequency with which their banks are scoured and gravel bars created, both of which are essential to the establishment of a next generation of *Populus* stands. Construction of levees along the Mississippi River has eliminated much of the natural cycle of flooding and meandrous flow and, consequently, a noticeable decline in the regeneration of *P. deltoides*. The same can be said of many river systems in Europe and Asia.

The conservation of the genetic resource contained in riparian *Populus* species include *ex situ* preservation of wild *Populus* collections in cultivated arboretums. Some arboretums may incorporate a multiple population breeding system to direct and enhance within-species genetic variation. The European Forest Genetic Resources (EUFORGEN) Program to conserve *P. nigra* is perhaps the most advanced *ex situ* effort today with a collection of nearly 2800 clones from 19 countries. Similarly, an *ex situ* collection of *P. trichocarpa* from 100 stands has been assembled in the Pacific Northwest of the USA by GreenWood Resources in response to the loss of riparian forests along the Columbia and Willamette Rivers and their tributaries. Alternatively, *in situ* conservation efforts secure native *Populus* populations in large nature reserves and, in some cases, may include efforts to restore degraded habitats. A major *in situ* effort has been initiated in China's Xinjiang Autonomous Region with the establishment of the Tarim River nature reserve; a critical component is the conservation of *P. euphratica* riparian forests that have shrunk in area by nearly two-thirds.

Other conservation examples include a long-standing effort to preserve *P. nigra* in the Netherlands where it has been replaced *Populus* hybrid plantations. Similarly, the conservation of Italian *P. alba* populations has been proposed in view of the loss of native germplasm in the wake of expanding agriculture. Finally, the Indian government with support from the International Poplar Commission and the United Nations Development Program has surveyed *P. ciliata* populations in the Himalayan foothills as the first step in implementation of its conservation.

Relatively recent changes in air quality are now known to have impacted *Populus* genetic resources. A well-documented example is *P. tremuloides* in North America; populations sampled from regions with a history of chronic exposure to polluted air show significantly higher tolerances to ozone, as natural selection has eliminated sensitive individual phenotypes. The long-term effect of this narrowing of the *P. tremuloides* genetic resource is not known but no less an important concern. Natural selection and loss of diversity is likely to be occurring in polluted areas of Europe and Asia. Conservation efforts here are worthwhile to the extent that populations undergoing selection may also be losing potentially valuable alleles.

The Conservation Role of Commercial *Populus* Plantations

Production plantations established with highly selected interspecific hybrid varieties and intensive agronomic-style tending practices, are among the highest-yielding crop trees in the temperate zone. For example, growth rates of 21–33 $m^3 ha^{-1}$ have been achieved at age 7 in *P.* × *generosa* plantations in the Pacific Northwest. High-yield plantations allow for the preservation of natural forested lands while meeting the fiber and fuel needs of a growing world population.

Beyond North American *P.* × *generosa* plantations, other worldwide plantations programs include cultivation of *P.* × *canadensis* (*P. deltoides* × *P. nigra)* in France's Loire River Valley and the Po Valley of Italy, *P. simonii* × *P. nigra* in northeastern China, *P.* × *tomentosa* (*P. alba* × *P. adenopoda*) in the northern plains of China, and *P. tremuloides* × *P. tremula* in western boreal Canada. Plantations of *P. deltoides* have been established in the southeastern USA, southern Brazil, Argentina, northern India, and southern China. These plantations are managed for a range of products including fuelwood, chips for paper, and logs for veneer and sawnwood products. Intercropping with soya, ryegrass, and corn during the first several years of a *Populus* rotation is practiced in agroforestry programs in China, India, and elsewhere where labor costs are low and arable land is scarce.

A reduction in soil erosion and an increase in water quality are often claimed as environmental benefits of *Populus* cultivation. *Populus* plantations have also been used extensively in various afforestation projects in India and China to address wood shortages while also slowing desertification. Over 1 million ha of *Populus* plantings were established during the 1970s as part of China's 'Green Great Wall' project to slow the spread of the northern deserts (**Figure 4**).

Their environmental benefit notwithstanding, the degree of gene flow between plantations of exotic species or interspecific hybrids and neighboring wild *Populus* populations is an important question in the context of native species conservation. Low levels of gene flow between *P.* × *generosa* plantations and native *P. trichocarpa* stands in the Pacific Northwest have been observed. The level of gene flow between *P.* × *canadensis* plantations and *P. nigra* stands in France may be higher, however.

Domestication

As high-yield plantations become ever more important in meeting the world demand for wood and fiber, novel genetic improvement strategies become an integral component of intensive plantation management practices. A unique combination of classical plant breeding methods and contemporary molecular approaches is used in *Populus*.

Classical *Populus* breeding strategies

Breeding and selection of *Populus* has a lengthy and distinguished history among trees, beginning with a large-scale commercial improvement program conducted in North America in the late 1920s. Successful breeding programs have since been initiated in Europe, Asia, and North America in many cases relying upon nonrecurrent, first-generation (F_1) interspecific hybridization. Hybridization brings the variation encompassed by separate species into a single generation that often exhibits heterosis for yield. Although controlled reproduction may be difficult when some species are hybridized, the ease with which superior individual selections can be vegetatively propagated promotes F_1 hybridization as a popular breeding method (**Table 2**). Advanced generation breeding into the second generation (F_2) is sometimes accompanied by diminished vigor most likely due to the disruption of coadapted linkage groups that occurs during F_1 gametogenesis or to a reduction in overdominant gene action, although transgressive segregants are occasionally found. Backcross breeding is used to introduce a single, highly heritable trait from a donor species to improve an otherwise suitable recurrent parent. For example, in the North Central region of the USA, *P. deltoides* × *P. suaveolens* F_1 hybrids are crossed (back) to unrelated *P. deltoides* selections in an attempt to introduce the strong adventitious rooting ability of *P. suaveolens* into the recurrent *P. deltoides* parent that shows superior resistance to *Septoria* canker (F_1 *P. deltoides* × *P. suaveolens* hybrids are themselves highly canker susceptible).

Given that the entire range of genetic variation can be exploited by clonal selection, a very significant advantage compared to other species that rely upon seedling-based family selection programs, *Populus* programs have frequently focused solely on the selection of superior individuals as opposed to efforts to improve the average performance of whole populations. A complete strategy incorporates recurrent breeding of parental populations so as to improve their hybridizing quality thereby more fully guaranteeing future genetic gains. The ideal is a reciprocal recurrent breeding program. But this has often proved too expensive to implement. Moreover, a lack of full reproductive compatibility between species can greatly complicate the estimation of parental hybrid breeding values required by a reciprocal recurrent

breeding. Consequently, many *Populus* programs substitute intraspecific breeding values as a guide for the manner in which parental populations are refined for interspecific hybridization.

The traits targeted for *Populus* improvement are usually the agronomic ones of yield, stem form, pest resistance, tolerance of cold and drought, wind firmness, and adventitious rooting. All have exhibited pronounced rates of genetic variation and have responded well to clonal selection programs. Field evaluations typically involve a multistage process to sequentially refine large populations until a group of elite selections has been identified. Other selection criteria may include wood and fiber properties for the veneer and sawnwood industries and the calorific quality of biomass for the heat- and power-conversion industries.

An imperative for production programs that incorporate clonal stands is a diverse pool of operational selections to help minimize the risk of plantation failures due to unforeseen climatic and biotic events. Most plantation programs are therefore allied with an ongoing hybridization program that continuously feeds new selections into production use. Continuous turnover of the commercial pool of clones is a safeguard against catastrophic failures due to coevolution of associated pests.

Application of Molecular Tools to Tree Improvement

Populus, by virtue of its relatively small genome, ease of cloning, and use of interspecific hybridization, has emerged as the model species for the application of molecular tools (genomic mapping and genetic engineering) to more traditional tree improvement approaches. Genomic markers associated with quantitative trait loci could lead to new approaches to the evaluation of full-sib seedling populations for superior selections that normally would not be revealed until conventional field tests are conducted for a half rotation or longer. Genomics could eventually lead to map-based cloning of important genes that are then used in transformation projects. The Joint Poplar Genome project is scheduled to complete sequencing of the *Populus* genome by the end of 2003.

Genetic transformation methodologies are well developed in *Populus*. Transformation can improve existing varieties for desired traits that otherwise are unavailable to conventional hybridization programs using recombinant DNA. *Populus* varieties have been modified for herbicide resistance, altered lignin content, and leaf beetle resistance. Currently field trials of genetically modified varieties have been conducted in North America with *P. deltoides* and *P. trichocarpa* × *P. deltoides* hybrids. In Europe, more than 20 field trials have been established using genetically modified *P. tremula*, *P. tremuloides, P. deltoides*, and *P. alba* × *P. tremula* selected varieties. The use of genetically modified plants has raised concerns over the risk posed to the fitness or future adaptability of wild relatives with whom transgenic plantations might reproduce. Consequently, a major ongoing effort has been sterility transformation that would prevent completely the sexual reproduction of transgenic plantations.

Spruces, Firs and Larches

H Wolf, State Board for Forestry (Saxony), Pirna, Germany

Introduction

Together with the genera *Pinus* (subfamily Pinoideae), *Cathaya*, *Pseudotsuga* (subfamily Laricoideae), and *Cedrus, Keteleeria, Nothotsuga, Pseudolarix, Tsuga* (subfamily Abietoideae), the genera *Picea* (subfamily Piceoideae), *Abies* (subfamily Abietoideae), and *Larix* (subfamily Laricoideae) belong to the family Pinaceae. The subfamilies are distinguished by cone and seed characters like the existence of an umbo or the existence of resin vesicles on the seed.

Species of the genera *Picea* (spruce), *Abies* (fir), and *Larix* (larch) are exclusively distributed in the northern hemisphere from 22° N in the south to 73° N forming the polar borderline of trees. Several species of these genera cover wide areas in boreal Eurasia and North America. They contribute to a major extent to the northern coniferous forests which stretch from coast to coast across these latitudes and form the greatest expanses of continuous forests. Many species of these genera are also found in mountainous regions of the more temperate zones often forming the alpine tree border line.

Picea, Abies, and *Larix* species occur in a wide range of habitats with very different soil and climate conditions. They are associated with various tree species depending on certain site conditions but they can also be found in pure stands under extreme site conditions. Mainly reproducing sexually by wind pollination, vegetative reproduction is the dominant mode of propagation if sexual reproduction is limited due to climatic limitations.

The lifetime of *Picea, Abies*, and *Larix* species ranges variously from 150 to 900 years. Under favorable conditions they grow to tall trees often forming dense forests with considerable growing stocks. Among populations of most species genetic differences can be observed in various traits. Due to their wood characteristics, the timber of spruces, firs, and larches can be used for a wide variety of purposes and is therefore of high economical importance.

Spruces

The genus *Picea* (subfamily Piceoideae) is related most closely to the genus *Pinus* (subfamily Pinoideae), but differs significantly by, e.g., cone and seed characteristics, the absence of short shoots, or the period of cone maturing. *Picea* is a very uniform genus, showing no significant differences within the genus allowing the delineation of subgenera. The genus *Picea* includes 34 species of cone-bearing, tall evergreen trees with straight stems and regularly constructed crowns with columnar or pyramidal habit. The horizontally arranged and usually rather short branches are whorled. On young trees, the bark is rather thin, on old trees scaly. The buds are conical or ovate, resinous or without resin. The spirally arranged needles are either four-sided or flat on a short petiole which remains on the shoot after needle fall. Stomatal bands can be found on all four sides or in the case of flat needles on the lower surface.

Natural Distribution

Out of the 34 species of *Picea*, eight species occur naturally in North and Central America, and 26 species are distributed in Eurasia (**Table 1**). The greatest species diversity is found in China and the Himalayas often in single species stands.

Picea species are mainly distributed in the boreal and subboreal zones of the northern hemisphere as well as to a minor extent in the mountainous regions of the more southerly zones where *Picea* can be found up to the subalpine range forming the treeline (**Figure 1**). The species of the genus *Picea* can be divided in a northern and a southern group, the differences between the groups are important from the ecological and genetical point of view. *Picea* species of the northern group occur mainly in large, often overlapping natural distribution areas either from east to west only interrupted by the Atlantic Ocean and the Bering Sea like *Picea abies, P. glauca,* and *P. obovata* or from north to south like *P. engelmannii* (**Figure 1**). In contrast, the species of the southern group grow in small, often isolated natural occurrences, for example *P. omorika*.

The northern limit of distribution of *Picea* is reached at about 69° N in Norway (*P. abies*) and the Northwest Territory of Canada (*P. glauca, P. mariana*). In the south, *Picea* stands can be found up to 23° to 27° N at the eastern (*P. morrisonicola*) and up to 23° to 25° N at the western hemisphere (*P. chihuahuana*) (**Figure 1**). In warmer regions, the water supply is the limiting factor of distribution.

In the northern part of the distribution area, the vertical occurrence of *Picea* reaches from sea level in North America and Eurasia to 2250 m above sea level in the Central Alps (*P. abies*) and about 3700 m in the southern Rocky Mountains (*P. engelmannii*). In the southern part, *Picea* species with upright growth can be found in altitudes up to 4700 m in the Himalayas forming the most upper limit of closed forests in the world (*P. asperata*).

Climate and Soils

Picea species can withstand extremely cold temperatures down to −60°C. The amplitude of temperature varies from −60°C to 35°C. The mean annual precipitation ranges from 230 to 4000 mm with the maximum falling outside the vegetation period. The vegetation period ranges from 26 to 175 days, the shorter growing season in the north counterbalanced by longer periods of daylight and the ability of spruces to assimilate down to temperatures of −6 to −7°C.

Picea species are not very demanding of soil conditions with the exception of the water supply.

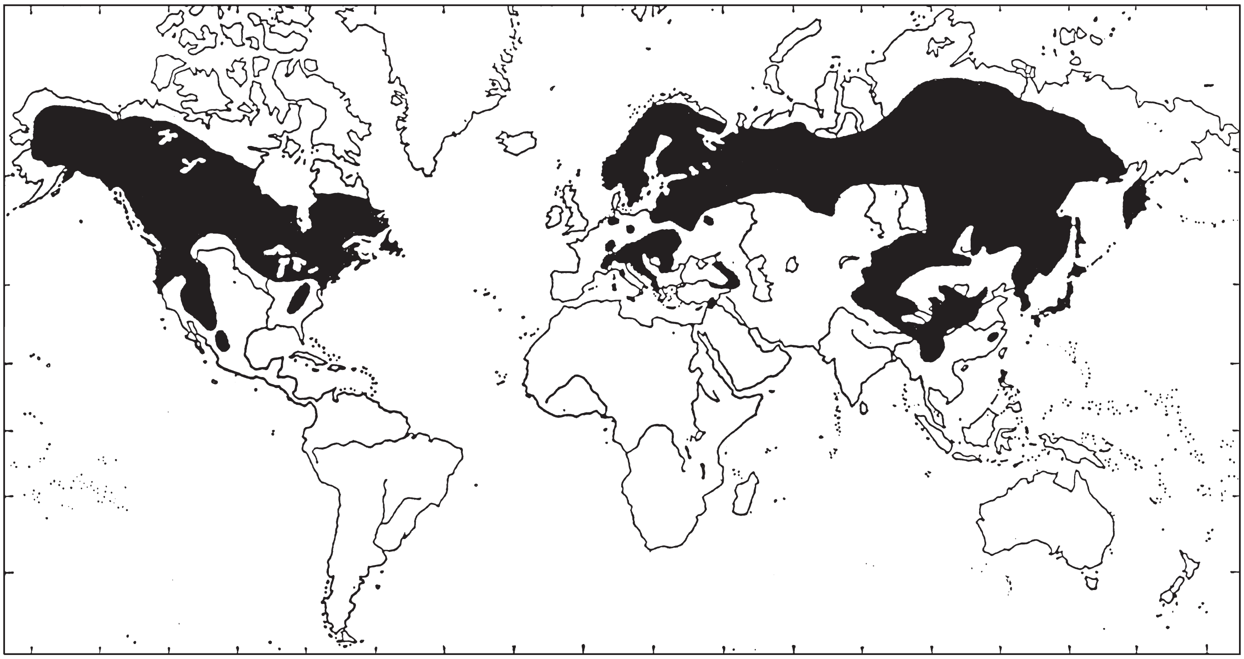

Figure 1 Natural distribution area of spruces (*Picea* spp.) Adapted with permission from Kruessmann G (1983) *Handbuch der Nadelgehoelze*. Berlin: Parey-Verlag.

In the northern part of the distribution area, *Picea* species occur on all soils showing the best growth on well-aerated, deep, acidic to slight alkaline soils with an intermediate nutrient supply and water supply over average. In the southern part, they are restricted to wet, cold or shallow soils of bogs.

Associated Forest Cover

Growing at extreme site conditions, *Picea* species can be found in pure, often uneven-aged stands. Under more favorable conditions, however, *Picea* species are associated with species of the genera *Abies, Chamaecyparis, Larix, Pinus, Pseudotsuga, Thuja,* and *Tsuga* as well as *Acer, Alnus, Betula, Populus, Prunus, Quercus,* and *Salix* in North America. In Eurasia, the species admixed to *Picea* belong to the genera *Abies, Juniperus, Larix, Pinus, Taxus, Thuja,* and *Tsuga* as well as *Betula, Fagus, Quercus, Populus,* and other deciduous broadleaved species.

Reproduction and Growth

Flowering starts between the age of 10–50 years. Male and female flowers are inserted in axils of needles of the previous year's shoots on different branches of the same tree, the female flowers inserted upright in the upper part of the crown. The flowering period varies from April to July. Peak flowering can be observed from every second year to every 13th year, in average from the third to the sixth year. Pollination is by wind over long distances due to the light weight and the low falling speed of the pollen grains which contain air vesicles. The yellowish green, crimson, or purple-colored cones ripen in the same year turning color during ripening. A ripe cone consists of brownish, woody scales, each bearing two brown to black seeds at the base. The ovate seeds are winged and mainly dispersed by wind during autumn and winter. The empty cones do not disintegrate and remain on the trees for about 1 year. Germination capacity varies from 75% to 95%. The weight of spruce seeds shows a big variation and ranges from 60 000 (*Picea torano*) to 890 000 (*P. mariana*) cleaned seeds kg^{-1}.

Seeds of most *Picea* species show no dormancy and germinate promptly without stratification. However, seeds of some species may require light for germination but prechilling will usually overcome the light requirement. Under natural conditions, seeds germinate on almost any seedbeds including rotten wood, but survival may be low. The germination is most successful on a mineral or mixed mineral and organic soil seedbed, especially under light shade, as long as drainage is adequate and the soil provides sufficient nutrients. The germination is epigeal, the four to 15 cotyledons rising above the ground.

If sexual reproduction is limited or nonexistent due to climatic limitations at the arctic or alpine tree line, vegetative reproduction of *Picea* species by layering is apparently the dominant mode of propagation.

Roots are also known to produce shoots. Artificially, vegetative propagation is easily possible by rooting of softwood cuttings from juvenile material or grafting.

Similar to that of *Abies* and *Pseudotsuga*, the root growth of *Picea* species starts before the shoot growth. The development of the root system is generally influenced by the existing soil conditions of which the oxygen supply may play an important role. Growing at sites with unfavorable soil conditions (e.g., near surface water table, clay-containing or compacted soil), *Picea* species develop an extremely shallow lateral root system near to the surface. On deep, porous, and well-drained soils, the lateral root system penetrates the soil by layer roots to a depth of 2.5 m and more.

The average age of *Picea* species varies from 250 to 800 years (*P. sitchensis*). Under favorable conditions, the average height of mature trees ranges from 25 to 40 m, some species reaching heights between 50 and 60 m (*P. sitchensis*). The mean diameter at breast height (dbh) of mature spruces ranges from 50 to 150 cm. Under favorable conditions, *Picea* forests produce timber volumes between 190 and 690 $m^3 ha^{-1}$, and at exceptionally good sites between 870 and 1200 $m^3 ha^{-1}$ (*P. abies, P. sitchensis*).

Species of the genus *Picea* have intermediate tolerance of shade, the tolerance decreasing with increasing age. Height growth is slow in the first few years but increases rapidly thereafter. When mixed with other species, *Picea* species can also survive and grow in the understory using occasional stand disturbances to rise up in the overstory.

Silviculture

Depending on the site conditions, even-aged as well as uneven-aged silvicultural systems are appropriate for the regeneration of *Picea* forests. The even-aged methods include clear-cutting and shelterwood cutting. Seed tree cuttings are not suitable for the regeneration of spruce due to its susceptibility to windthrow. Appropriate uneven-aged cutting methods are individual tree and group selection cuttings and their modifications. Thinning in young *Picea* stands enhances the growth of diameter and the crown development improving the stability of spruces.

In deep shade, lower branches soon die, decay, and break off, the resinous stubs remaining for many years. *Picea* species only exceptionally develop sprouts from adventitious buds along the stem related to light intensity, e.g., after thinning.

Pests and Diseases

Picea species are subject to damage from abiotic agents, pathogens, insects, and animals. Among abiotic agents windthrow is the most serious especially after initial or partial cuttings in old-growth stands. Species of the genus *Picea* are also sensitive to air pollution. However, most common diseases of spruces are caused by wood-rotting fungi resulting in loss of volume and predisposition of trees to windthrow and wind break. In pure stands, the mass propagation of bark beetles can cause serious damage. Due to their thin bark, *Picea* species can also be damaged by game animals that peel the bark.

Genetics

Compared to *Picea* species growing in the northern part of the distribution area, the species from the southern part show a greater systematic uniformity. Most of the *Picea* species of the northern part can be separated into geographical races or systematic varieties indicating genetic differences. The differences can be seen in phenological, morphological, quantitative, and qualitative characters as well as in resistance against pest and diseases influencing the suitability of the provenance in question for cultivation out of its natural distribution area. In North America and Asia, spontaneous hybridization between *Picea* species can be observed in common growing zones of the species in question. In Germany, the UK, and Scandinavia, *P. abies* and *P. sitchensis* in particular are the subjects of intense breeding programmes for commercial plantation forestry.

Uses

The strong, lightweight, light-colored, fine-grained, even-textured, and long-fibered wood makes most spruce species useful timber trees. The timber can be used as lumber, construction wood, rotary-cut veneer, furniture timber, posts, poles, and mine timber as well as plywood, pulpwood, and fuelwood. The high strength-to-weight ratio and the resonant qualities make the wood suitable for the construction of aircraft parts and musical instruments. Due to its wood qualities and yield, *Picea* is one of the most important commercial genus in the boreal forest. Several species like *P. abies, P. glauca, P. sitchensis,* or *P. omorika* are planted commercially outside their natural distribution area. Most *Picea* species are also important watershed protectors because of their occurrence at high elevations and on steep slopes.

Firs

Compared to the genus *Picea*, the genus *Abies* (subfamily Abietoideae) is a very heterogenous genus allowing the delineation of 10 sections with several subsections. The genus *Abies* includes 49 species of cone-bearing, tall evergreen trees with straight stems and regularly built-up crowns with pyramidal habit (**Table 2**). The horizontally arranged branches are distinctly whorled. On young trees, the bark is thin and smooth, often with resin blisters, in old trees often thick and fissured. The buds are usually resinous, globose, or ovate to fusiform. The linear–lanceolate, flat, singly borne needles are dark green above with two bluish or silvery-white stomatal bands on the lower surface. The needles which are widened like a shield at the base are inserted on long shoots usually in two ranks leaving a rounded scar after fall or removal.

Natural Distribution

Out of the 49 species of *Abies*, 15 species occur naturally in North and Central America, and 33 species are distributed in Eurasia (**Figure 2**). In contrast to *Picea* and *Larix*, one *Abies* species is found exclusively in northern Africa (**Table 2**). Similar to *Picea*, the greatest species diversity in *Abies* can be observed in China and the Himalayas.

Abies species occur from sea level to the timberline but the majority are found at middle to high elevations in mountainous areas. However, in North America as well as in North Asia, *Abies* species are found as components of boreal forests. Few species of the genus *Abies* grow as components of low-elevation, temperate forests. In North America, *Abies* species can be found from 64°30′ N in Yukon Territory, Canada (*Abies lasiocarpa*) to 14°49′ N in Central America (*A. guatemalensis*) and from 53° W in Newfoundland (*A. balsamea*) to 140° W parallel to the borderline between Alaska and Canada (*A. lasiocarpa*). The vertical distribution ranges from sea level to about 3600 m. In Eurasia and Africa, the distribution area extends from 67° 40′ N in the north (*A. sibirica*) to about 22° N in the south (*A. kawakamii*) and from 6° W in the west (*A. alba*) to 160° E in the east (*A. sachalinensis*). Vertically, firs grow at elevations from about 300 m to 4700 m in the Himalayas (*A. squamata*).

Climate and Soils

Since *Abies* species occur in very different regions of the northern hemisphere, the requirements of the climate also vary accordingly. The mean annual temperature ranges from −4°C to 11°C within the distribution area with an amplitude of temperature from –45°C to 41°C. The mean annual precipitation varies from 510 to 2540 mm with extremes between 390 and 6650 mm. In mountainous regions, between 50% and over 80% of the annual precipitation is snow and sleet. Snow packs between 3 and 12.7 m are

reported. The vegetation period ranges from 40 to 250 days, the shorter growing season in higher elevations being compensated by the ability of some fir species to assimilate down to a temperature of $-5°C$.

Due to its large distribution area with very different geological bedrocks, *Abies* species grow on a wide variety of soils developed from almost every kind of parent material. *Abies* species are tolerant of a wide range of soil conditions, nutrient content and availability as well as pH values. Species of the genus *Abies* are more dependent on moisture availability and temperature. However, the best growth of *Abies* species can be expected on deep, nutrient rich, fine to medium textured and well-drained soils.

Associated Forest Cover

Abies species seldom grow in pure, uneven-aged stands. Mainly, they can be found in mixed forests also under extreme site conditions. In North America, *Abies* species are associated more or less with the same species as *Picea* species. In Eurasia and Africa, the species mixed with *Abies* belong to the genera *Cedrus, Chamaecyparis, Juniperus, Larix, Picea, Pinus, Taxus, Thuja,* and *Tsuga* as well as *Acer, Betula, Fagus, Fraxinus, Quercus, Populus,* and other deciduous broadleaved species.

Reproduction and Growth

Flowering starts between the ages of 20 to 50 years. Male and female flowers occur separately on the same tree. The female flowers are typically inserted highly in the crown on the upper side of the previous year's shoot, the male flowers generally lower in the crown than female flowers densely along the undersides of 1-year-old twigs. The flowering period varies from April to July. Peak flowering can be observed from every second to every eighth year, on average from the second to the fourth year. Pollination by wind takes place mostly among neighboring trees due to the heavy weight and the fast sinking speed of the pollen despite the existence of air vesicles. The red or greenish conspicuous cones ripen the first year; a ripe cone consists of brownish, woody scales, each bearing two winged and typically ovate to irregularly triangular seeds at the base. The seeds with conspicuous resin blisters are mainly dispersed by wind from August to November. In contrast to other conifers, the erect cones disintegrate leaving only the spikelike cone axis on the tree. Germination capacity varies from 25% to 70% but it is very often low, around 30%. The weight of the comparatively heavy fir seeds ranges from 10 000 (*Abies cilicica*) to 200 000 (*A. koreana*) cleaned seeds kg^{-1}.

Since *Abies* seeds are disseminated in autumn under conditions which may allow an early germination, the germination is hampered by resins stored in the seed coat. Under forest conditions the dormancy is broken by evaporation of the resins during the winter after seed fall. The germination is most successful on a warm seedbed with moist mineral soil. The germination is epigeal, the three to 14 well-differentiated cotyledons rising above the ground.

Under natural conditions, most *Abies* species do not reproduce vegetatively either by sprouting or layering. Layering can be observed in few species growing in extreme conditions of the more northern and mountainous regions, e.g., *A. balsamea* or *A. lasiocarpa*. Artificially, vegetative propagation is possible by grafting or rooting of cuttings from juvenile material.

The root systems of *Abies* vary from shallow and widespread where the effective soil depth is limited by rocks or seasonable water tables, through relatively deep lateral root systems under more favorable conditions, to a deep and intensive taproot system which also develops under less favorable soil conditions.

The average age of *Abies* species varies from 150 to 500 years, exceptionally to 700 years (*A. procera*). Under favorable conditions, the average height of mature trees ranges from 20 to 50 m, several species reaching heights between 60 and 90 m (e.g., *A. alba, A. amabilis, A. grandis, A. procera, A. spectabilis*). The mean dbh of mature *Abies* trees ranges from 30 to 300 cm (*A. spectabilis*). Due to their capacity to maintain a high level of stand density and due to the generally low taper of *Abies* trees, a considerable growing stock can be observed between 450 and 600 $m^3 ha^{-1}$ on average sites. Under favorable conditions, *Abies* forests produce timber volumes between 1000 and 1600 $m^3 ha^{-1}$ (e.g., *A. alba, A. amabilis, A. concolor, A. grandis, A. procera*), and in exceptional cases up to 2300 $m^3 ha^{-1}$ (*A. magnifica*).

Although *Abies* species grow well in full sunlight, most species can survive and grow for long periods in relatively dense shade and therefore they are classified as shade tolerant. However, some species are not too tolerant of shade especially if regeneration under a closed forest canopy is considered. Due to their shade tolerance over average compared to other tree species, *Abies* species can be found in mixed coniferous and conifer–broadleaved forests as well as in pure stands.

Silviculture

For most *Abies* species, uneven-aged silvicultural systems are the most appropriate way for regeneration. Appropriate uneven-aged cutting methods are individual tree and group selection cuttings and their modifications providing the necessary growth advantage several species need in front of competing species due to their slow growth in the juvenile stage.

Pests and Diseases

Abies species are subject to damage from abiotic agents, pathogens, insects, and animals. *Abies* species are very sensitive to air pollution. Due to their thin bark, *Abies* species are susceptible to severe damages and fire. Among pathogens, mistletoe causes major damage. In old-growth trees, wood rotting fungi cause major losses. Species of the genus *Abies* are also very sensitive to browsing and bark peeling by game.

Genetics

Several *Abies* species show a high self-fertility, up to 70% and more of sound seeds being produced by outcross pollination. Since the range in elevation and latitude is large in various *Abies* species and due to different evolutionary processes, differences among populations of several species can be observed in morphology, phenology, growth rate, monoterpenes, or isozyme patterns. In North America and Eurasia, spontaneous hybridization between *Abies* species is reported in common growing zones of the species in question. In the USA, selective breeding programs are practiced, particularly for the improvement of shape, size, and color of Christmas trees.

Uses

With the exception of the absence of primary resin canals, the characteristics and uses of fir wood are similar to them of spruce wood. Young trees of most *Abies* species are preferred Christmas trees. *Abies* species growing at high elevations and on steep slopes are also important for the protection of watersheds. Only few species of the genus *Abies* are planted commercially outside their natural distribution area, for example *A. grandis* or *A. nordmanniana*.

Larches

The genus *Larix* (subfamily Laricoideae) is the type genus of the subfamily mentioned before. The genus is divided into two groups separated by the position of the bracts (exserted or nonexserted). The genus *Larix* includes 11 species of cone-bearing, tall deciduous trees with straight stems and narrow, sometimes broad, mostly regularly built-up crowns. The horizontally arranged branches are not whorled. The bark is fissured, reddish-brown to gray-brown in color. The buds are small and ovate with a little number of short and imbricate scales. The soft and thin needles are inserted in bunches on short shoots and spirally on long shoots.

Natural Distribution

Out of the 11 species of the larches, three species occur naturally in North America, and eight species are distributed in Eurasia (**Table 3**). The conifer forests around the Arctic Circle are mainly formed by

Table 3 Intrageneric classification and distribution of species of the genus *Larix*

Distribution	*Botanical name*	*Common name*
North America	*L. laricina*	Tamarack
	L. lyallii	Alpine larch
	L. occidentalis	Western larch
Central Europe	*L. decidua*	European larch
North Eurasia	*L. czekanowskii*	—
	L. gmelinii	Dahurian larch
	L. sibirica	Siberian larch
China and Himalayas	*L. griffithii*	Sikkim larch
	L. mastersiana	—
	L. potaninii	Chinese larch
Japan	*L. kaempferi*	Japanese larch

Larix laricina, L. sibirica, and *L. gmelinii* with largely extended distribution areas. Other larches occur in the mountainous regions of more temperate latitudes, distributed in smaller and more scattered areas with extreme vertically extension.

In North America, species like *L. laricina* extend from 53° W in Newfoundland to 140° W parallel to the border of Alaska and Canada and from 40° N in the south to 67° N forming the northern treeline. The vertical distribution reaches from sea level to 1220 m above sea level in eastern North America (*L. laricina*) and from 180 to 3020 m (*L. lyallii*) in the west of North America.

In Eurasia, the distribution area of *Larix* species reaches from 68° N to 73° N (*L. gmelinii*), its northern limit forming the polar treeline. The southern limit can be found at about 22° N in the Himalayas and China (*L. griffithii, L. potaninii*). The west–east distribution reaches from 5° E in the western Alps (*L. decidua*) to about 170° E in East Siberia (*L. gmelinii*) (**Figure 3**). The vertical extent varies among the different parts of the natural distribution area. In Europe and North Asia, the genus ranges from the riverine lowlands of the north (*L. sibirica, L. gmelinii*) to elevations of 2400 m forming the alpine treeline in the western Alps (*L. decidua*) or in the Manchurian Mountains (*L. gmelinii*). *Larix* species grow in altitudes between 1000 and 2700 m on the island of Hondo in Japan (*L. kaempferi*), and they can be found between 2500 and 4000 m in the Himalayas and China (*L. griffithii, L. potaninii*).

Climate and Soils

Larix species can withstand extremely cold temperatures down to −70°C as well as a large range of temperatures from −70°C to 35°C. The mean annual precipitation varies from 180 to 2500 mm. In mountainous regions, about 75–80% of the annual precipitation is snow and sleet. The vegetation period ranges from 50 to 230 days, the shorter growing season in the north being counterbalanced by longer periods of daylight.

Species of the genus *Larix* can tolerate a wide range of soil conditions. Species forming the forests at the Arctic Circle grow most commonly on wet to moist organic, boggy, and acidic sites with a shallow layer of peat or soil over permafrost. The best growth of *Larix* species can be observed on moist and deep soils rich in nutrients with high water storage capacity.

Associated Forest Cover

Growing in extreme site conditions, species of the genus *Larix* can be found mainly in pure, often even-aged stands. Under more favorable conditions, however, *Larix* species are associated with species of the genera *Abies, Picea, Pinus, Pseudotsuga, Thuja,* and *Tsuga* as well as *Acer, Betula, Fraxinus, Populus,* and *Ulmus* in North America. In Eurasia, the species associated with larch belong to the genera *Abies, Picea,* and *Pinus* as well as *Betula, Fagus,* and *Populus.*

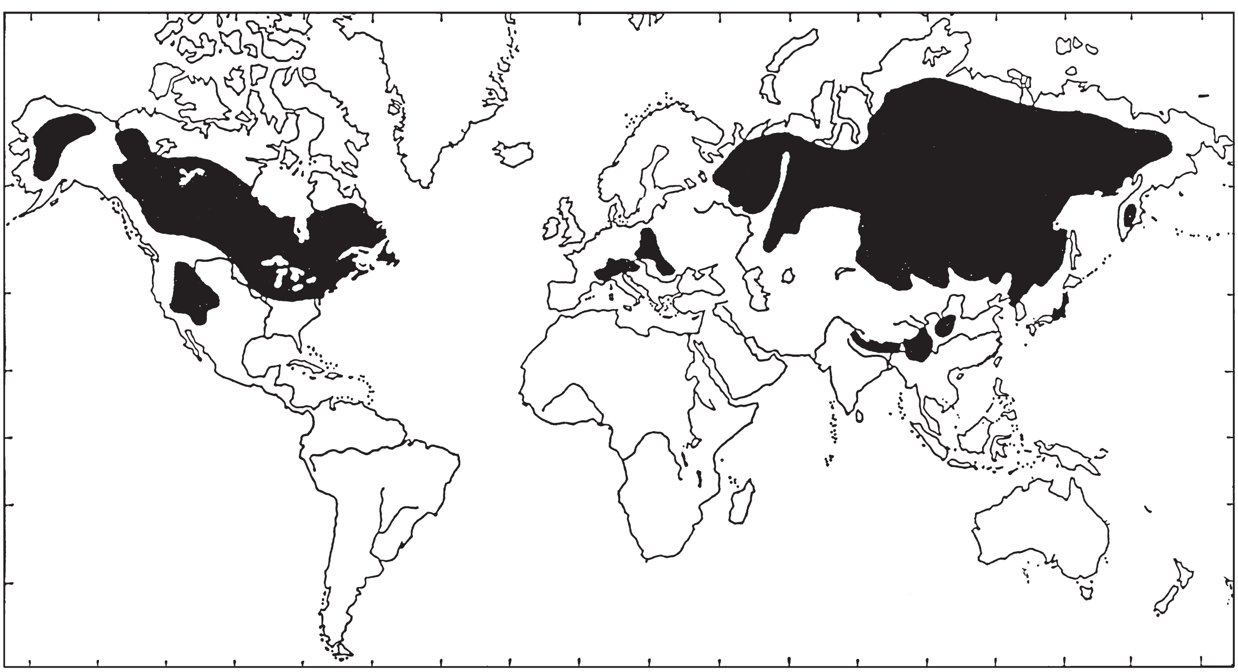

Figure 3 Natural distribution area of larches (*Larix* spp.) Adapted with permission from Kruessmann G (1983) *Handbuch der Nadelgehoelze*. Berlin: Parey-Verlag.

Reproduction and Growth

Flowering starts between the ages of 10 and 40 years. Male and female flowers occurring separately on the same tree open a few days before needle elongation or appear with the needles. The flowering period varies from March to June. Peak flowering can be observed from every year to every 10th year, on average from the third to the sixth year. Pollination by wind takes place mostly among neighboring trees due to the heavy weight and the fast falling speed of the pollen grains which lack air vesicles. The red or greenish cones ripen the first year; a ripe cone consists of brownish, woody scales, each bearing two seeds at the base. The winged and nearly triangular seeds are mainly dispersed by wind from September to spring. The empty cones do not disintegrate and remain on the trees for an indefinite period. Germination capacity varies from 15% to 50%. The small and lightweight *Larix* seeds range from 100 000 (*L. sibirica*) to 700 000 (*L. laricina*) cleaned seeds kg^{-1}.

With few exceptions internal seed dormancy ranges from none to mild. Under forest conditions any existing dormancy is broken during the winter after seed fall. The germination is most successful on a warm seedbed with moist mineral soil. Germination is epigeal, the five to seven cotyledons rising above the ground.

If sexual reproduction is limited or nonexistent due to climatic conditions along the northern limit of *Larix* species, e.g., in Canada and Alaska, layering is apparently the dominant mode of propagation. Roots are also known to produce shoots. Artificially, vegetative propagation is easily possible by rooting of softwood cuttings of juvenile material or grafting.

Species of the genus *Larix* have a very adaptable root system, coping with permafrost soil, rocky substrate, or deep and well-drained soils. Under favorable conditions, most *Larix* species develop a deep taproot with extensive and large lateral roots.

The average age of *Larix* species varies from 150 to 900 years (*L. occidentalis*). Under favorable conditions, the average height of mature trees ranges from 15 to 55 m, occasionally exceeding 60 m (*L. occidentalis*). The mean dbh of mature *Larix* trees ranges from 35 to 230 cm. In the most northern parts of the distribution area, a growing stock can be observed from 30 to 50 $m^3 ha^{-1}$. Under favorable conditions, larch forests produce timber volumes between 300 and 550 $m^3 ha^{-1}$ (*L. occidentalis*).

Larix species are highly intolerant of shade. Compared to other conifers, most *Larix* species show rapid juvenile growth, giving larches the height advantage they need to survive. When mixed with other species, *Larix* must be in the overstory and they are practically never found in the understory.

Silviculture

The requirements of *Larix* forests are best met by even-aged silvicultural systems of shelterwoods, seed tree cuttings, and clear-cuts. Thinning in young *Larix* stands enhances the growth of diameter and height during the juvenile years when response potential is greatest.

Compared to other conifers, *Larix* trees are good self-pruners, and boles of 25–30-year-old trees may be clear of branches for one-half or two-thirds their length. Older *Larix* sometimes produce sprouts from adventitious buds after thinning, the amount of sprouting increasing with the severity of thinning.

In natural forest stands located in the boreal zone, fire is essential for the maintenance of *Larix* forests. Fires thin stands, reduce fuels, regenerate the undergrowth, and prepare seed beds.

Pests and Diseases

Larix species are more resistant than other conifers to air pollution, mechanical damage or soil compaction. Some species with thin bark have low resistance to surface fire. In mountainous areas, snow avalanches and snow slides can cause serious damages. Outside the natural distribution area, *Larix* trees are very often subject to damage from pathogens and insects.

Genetics

Within *Larix* species growing over a wide range of sites as well as within species with a distribution area divided into different parts, significant differences of traits can be observed among provenances. The traits include morphological, quantitative, and qualitative characters as well as resistance against pests and diseases, influencing the suitability of the provenance in question for cultivation out of the natural distribution area. In North America and Asia, spontaneous hybridization between *Larix* species is reported in common growing zones of the species in question. In Europe, hybrids between *L. decidua* and *L. kaempferi* are planted commercially providing exceptional growth and resistance to canker.

Uses

Larix timber consists of a narrow, bright yellow sapwood and a reddish-brown heartwood which is hard, heavy, durable, and tough as well as fungi and acid resistant. The timber can be used as lumber, construction wood, fine veneer, furniture timber, posts, poles, and mine timber as well as pulpwood and fuel wood. Several species including

L. decidua, *L. kaempferi*, *L. laricina*, and *L. sibirica* are planted commercially outside their natural distribution areas.

TREE BREEDING, PRACTICES

Contents

Biological Improvement of Wood Properties

B Zobel, North Carolina State University, Raleigh, NC, USA

Introduction

The objective of this article is to discuss how wood can be changed either naturally or by manipulation and how these changes might affect the final product. All wood characteristics are the result of physiological effects (controls) on growth. When the physiological controls are determined by genetic or other within-plant influences, they are referred as internal. These are difficult to manipulate and require activities such as breeding to obtain the desired kind of wood. When the physiological controls are primarily influenced by forces outside the tree, such as weather, nutrient availability or other, one refers to them as external controls.

A good example of a wood property strongly controlled internally is wood density or wood specific gravity. This makes possible the development of high or low wood density races of trees within a species, when selective breeding is used. When the wood of the tree is primarily influenced by outside factors such as weather or wind, external control is indicated. If, for example, a southern yellow pine has been affected by ice or tip moth so that it is no longer straight, the reaction wood resulting will differ a great deal from wood that will result under normal growth conditions no matter what the genetic situation is.

The control of wood formation is certainly not simple or clear-cut as a definition might imply. For example, tree straightness is the result of genetic control but is also affected by environmental factors. Thus, no matter what genetic controls are acting, major environmental differences can result in wood of differing kinds. However, the simplistic way to assess what the wood in a tree will be, is to consider the result of the interaction of both internal and external influences.

General Concepts

Wood is a very pliable and variable substance and can be changed in numerous ways as described below. In the past, when a lot of old, or virgin, timber was available, there was not much need, or effort, to change the wood quality available for use. As the practice of forestry has become more widespread and important, especially since plantation forests have become a major supplier of wood, it has been necessary to grow wood most suitable for given final products; this means methods must be developed to change wood qualities to meet the needs of the intended product.

I will use the southern pine forests in the USA and eucalypt plantations in Brazil as examples of the changes and needs to modify wood properties. Initially, almost all harvesting of softwoods in the southern USA was from quite mature pine trees, from 30 to 70 years of age. There was little concern about wood variation and wood quality as the wood harvested was mature and there was little concern about variation affecting its utilization. After more intensive forestry was practiced, wood quality has become variable enough to have a major effect on its utilization. Different products were found to require different kinds of wood to make the desired product efficiently. A personal example will illustrate this:

> In 1951, I gave a talk to the pulp mill managers and executives from the southern USA about wood, how it varied, and what this variation could mean to the industry. The audience was polite enough to listen but it was evident during the talk that the attendees did not think wood variation was a very important problem since they had good wood to work with which varied only a little. After my talk, the manager of the largest group of mills in the South came to the podium, put his arm around my shoulders and said: 'Son, your talk was interesting but we do not have to worry about wood variation. We are chemists; just grow us any kind of wood and we can make usable paper from it.'

Of course, in reality, this was true, but with the changes in wood from intensive forestry, it has become neither operationally nor economically correct. The differences in wood quality with shorter rotations (harvest age) and more intensive utilization of the trees available has resulted in a large proportion of juvenile wood being used. This, along with more intensive silviculture, has resulted in the costs, quality, and expected yields of the desired products changing. Because of this, the production of substandard products sometimes has been rather dramatic. Currently, wood quality has become recognized as of key importance for efficient production of the kind and quality of product to be produced. The properties of the wood used has become of major interest for pulp as well as for lumber, in both the conifers and hardwoods.

Although the emphasis here will be on wood quality and how it affects the final product, it is necessary not to underestimate the ability of the industry to alter methodologies to adapt to differing woods. Great progress has been made in this area; methods of sawing, methods of curing timber, particleboard construction, pulping technologies, and paper manufacture have all been altered to better use the younger, different-quality wood that is becoming available. Sometimes the changes have been reasonably efficient but too often they have resulted in increased costs and/or poorer-quality final products. The first need for an industry making a given product is to have the raw material it uses reasonably uniform. When this is so, it can develop the best methods of manufacture for a reliable and stable product.

It is necessary to note that the emphasis here is on solid wood and fiber production, used in construction and for paper products. However, there are other major uses for wood; reports are available that show that more than half the wood used on a world basis is for energy production. For example, until recently, a great proportion of the hardwood produced in Brazil was for charcoal, much being utilized for energy in the steel industry. (I worked for several steel companies in this area for a number of years, with the directive to develop wood most desirable for charcoal. This was done by changing species and selecting and breeding for fast-growing trees that had the genetic potential to produce the high-density wood best used for charcoal.) It has been well proven that the *Eucalyptus* wood ideal for tissue production differs greatly from that needed to make good charcoal. Because of the large basic variation in wood properties in the eucalypts, it has been possible to develop wood in the eucalypts most suitable for charcoal, or ideal for pulp, diverse as the needs for these products are. The details as to how such changes can be made will not be covered in this article (but see my books listed in the Further Reading section).

Important Wood Properties

Before one can consider changing wood, it is essential to know which properties are the most important. Although many wood properties can be altered, only a few are of key importance; five of these are listed below:

Wood Density

Wood density, or wood specific gravity, is by far the most important wood property, affecting nearly all products. Wood density and specific gravity measure the same thing – the solid wood substance in a given volume of wood – but they are expressed somewhat differently. (They are the ratio of the dry weight of wood in a given green volume of wood; this can be expressed as dry weight/green volume. The higher the ratio the denser the wood. In pine, a specific gravity of 0.41 is low density while one with a ratio of 0.62 is considered to be very high.) Wood density is normally the term used in the industrial area, while specific gravity is more commonly used by researchers. They can easily be determined from each other. They affect strength, stability, and appearance of solid wood products and grossly affect the kind and quality of paper produced. For example, low-density wood is best for quality paper products like writing papers and tissues, while high-density wood gives the best yields when pulped and is most suitable for fiberboard containers and paper that needs good tear strength.

Wood density is easily measured and can even be roughly estimated when looking at a piece of wood. It can be altered both through silvicultural and genetic manipulation.

Spiral Grain

Spiral grain is of primary importance for stability in solid wood products such as boards while it plays only a small role in its effect on pulp. Most spiral grain is found near the center of the tree; it varies from species to species and from individual to individual. Commonly, it is considered to be important if it exceeds 4 degrees, so is not important in some species with low spiral. Some species, especially in the tropics and sometimes in those like sweet gum (*Liquidambar styraciflua*) have an extreme spirality called interlocked grain. Such wood is extremely variable and not suited for solid wood products. However, there is a reasonable genetic component so a selection program will help.

Fibril Angle

Fibril angle (correctly called microfibrillar angle) is of increasing importance as its effects become better known and methods for its measurement are improved. The wall of a wood cell is not solid, it is made up of numerous microfibrills. The orientation of these in the wall is very important to the stability and quality of the products produced. Fibril angle is greatest near the tree center; it also varies greatly from tree to tree. It has a major effect on the stability of solid wood products and can have an influence on the quality of paper produced.

Wood Uniformity

Uniformity is of great concern to the manufacturer of wood products. The more uniform the wood, the better the product produced and the greater the efficiency in manufacture. As harvest periods for trees become shorter, a greater amount of juvenile wood is obtained, resulting in increased nonuniformity of the raw material available. Currently, there is much effort to change wood properties to obtain greater uniformity, and organizations that have been successful have benefited greatly economically.

Wood uniformity can be improved by controlling the time of harvest as well as growth conditions and silvicultural treatments such as fertilization and site preparation. We have found, in species such as loblolly pine (*Pinus taeda*), that a heavy nitrogen fertilization will usually result in low-density wood being formed for a few years but normally the use of phosphorus fertilizer has only a minor effect on wood density.

General Wood Properties

If space were available, one could list many other wood qualities that can be changed by external or internal means. Some of these can be of considerable importance under certain circumstances, such as the necessity for thin-walled cells and larger cell lumina in the manufacture of tissue papers or straight grain in quality boards. Other characteristics that may be of importance are cell length, resin content of the wood, amount of heartwood present, and numerous things depending on the product desired and the species of trees being used.

Methods of Making Changes in Wood

Wood can be altered in two major ways which will be described separately below: these are external and internal. The external one includes such things as altering tree form, differences in silviculture, and choosing the most desirable species and provenances within species. Internal changes can be obtained by controlling the amount and use of juvenile wood and through genetic manipulation and silvicultural control.

External Control of Wood Properties

Tree form is the most important tree characteristic that affects wood quality. Two major aspects of tree form are straightness of the bole and limb characteristics.

Straightness of bole Straightness of the tree bole is most important. Any time a tree is not straight, it forms a kind of wood called reaction wood. One can reduce the amount and severity of reaction wood by growing straighter trees, either through silvicultural manipulation or control of parentage using a breeding program.

Reaction wood in most conifers is called compression wood. It is formed on the inside of a 'bend' in the trunk of the tree or in the underside of limbs. Its main function appears to be to straighten the tree or push up the limb by pressure on the nonstraight area.

Compression wood has many unique anatomical and chemical characteristics, most of which are adverse to good wood quality. For example, it contains an excess of lignin, often as much as 9% more than the more normal wood; this results in low cellulose yields when pulped. The cells in compression wood have fissures that cause the cell to fragment into small segments not good for the manufacture of paper. The cell walls of compression wood are often unusually thick, resulting in a coarse fiber which is not suitable when making fine papers or absorbing tissues and which result in a nonuniform surface of the paper.

The cells of compression wood have flat fibril angles so it shrinks an exceptional amount longitudinally when dried (up to 9% or more). This makes for unstable boards. Quality is especially adversely affected when a board consists partially of regular wood and partially of compression wood; the result is that one part of the board shrinks longitudinally more than another portion which causes warping, cracking, and checking in the board.

In the hardwoods, reaction wood is called tension wood. It is formed on the outside of the curve in the tree bole. Its function is to pull the tree bole straighter. Opposite to compression wood, tension wood has an excess of cellulose, otherwise the short cells and other abnormalities in compression wood such as adverse fibril angles, are present. (Since paper is made from cellulose, years ago some industrialists suggested that we breed crooked hardwoods which would increase the amount of cellulose and reduce the lignin formed. However, the cellulose in tension wood is different than that in normal wood and, when pulped, gives low yields and inferior paper qualities.)

When tension wood is used for solid wood products, the boards often have a weak plane in them (high cellulose and low lignin) causing the boards to break easily. Also, because of the flat fibril angle, it is difficult to finish the boards by planing or use of sanding, because the angle of the fibrils prevents formation of a smooth surface.

One of the most interesting things relative to the biology of wood in trees is how such opposite methods (compression wood and tension wood) have developed in the conifers and in the hardwoods, both to straighten the tree. The wood properties resulting from the two methods differ greatly. The amount of reaction wood can be reduced by producing straighter trees. This can be partially done through the use of selection and breeding straight trees since the genetic control of straightness is usually moderate to high. Natural variability in straightness is large so the combination of that plus moderately high heritability results in dramatic improvement in the population resulting from a breeding program which emphasizes tree straightness. (Put roughly, gain is the product of variability in the characteristic times its genetic control.)

Straightness can also be improved through the use of good forest management. Uniform and well-spaced, well-established plantations will result in straighter trees. As one example, if a pine tree is planted poorly so the stem of the seedling is not above the root, the resulting tree will grow crookedly, with an excess of compression wood, for the rest of its life. Planting using machines often creates serious problems when the foot of the planting machine is too shallow, resulting in the planted tree's having trailing roots. Trees from such plantations have excessive crook in their stems causing a major degrade in their wood quality. Based on my experience, the fastest and best method to improve wood quality is to develop straight trees. Frequently, detailed studies as to the cause of crookedness have been made, blaming such things as seed source, when the act of good planting would have avoided the trouble.

Limb Characteristics

Altering limb characteristics can have a major effect on the type of wood product produced. Smaller and more horizontal limbs are most suitable for the quality of both solidwood and the strength and yields of pulp. These characteristics are influenced both by the knotwood itself and by the reaction wood which is associated with the knots. Limb size can best be controlled via tree spacing in the plantation; genetic control of limb size is relatively small. However, limb angle has a much stronger genetic control, and can be improved by a breeding program. When excessively limby trees are used, limb size and angle has an effect on product quality, especially on the stability of boards and the tear strength of the paper produced. Changes in limb characteristics are not as easy to obtain or as large as for wood density, but they can be very important for certain products.

Forest Management Approaches

Variation in methods of forest management can result in differences in wood. All management activities must be done carefully if wood quality is to be as desired.

Silviculture

Silvicultural treatments that change nutrients via fertilization can have a major effect on wood properties. Especially in the conifers, but also for some hardwoods, heavy fertilization, using a high nitrogen content, often causes a considerable lowering in wood density. In the hard pines, the wood produced when a heavy nitrogen fertilization is used is somewhat similar to juvenile wood with thin cell walls resulting in lower wood density and usually in shorter cells. The response to nitrogen rarely continues for more than 5 years. As a result, there will be excessive longitudinal shrinkage in the affected annual rings of boards made from this kind of wood which will be unstable when dried. Although detailed studies on the effect of fertilization on fibril angle have not been made, I predict that the wood from heavily nitrogen-fertilized trees will have flatter fibril angles than normal, making the wood similar to juvenile wood.

Phosphorus content of the soil usually has little effect on wood density, although a shortage of phosphorus sometimes results in higher wood density. Here, the addition of this substance will reduce the higher density to that of normal wood.

Fertilization Fertilization, especially in the tropics, is often mandatory if suitable growth is to be obtained; when this is so nitrogen fertilizer should be applied slowly in small quantities at each treatment, not in large amounts at one time during the midterm of the rotation. This is especially true in the pines; when a heavy application of nitrogen is made, the trees will form a band of wood in the tree trunk that is similar to juvenile wood, resulting in unsatisfactory lumber which is difficult to cure and stabilize.

Stand density A variation in normal stand density among trees will have little effect on wood other than the width of the annual rings; this can be very important for some products and species.

Species and provenance choice Matching species and provenance to site is of key importance. Normally, reasonably small site differences, or somewhat poor adaptability to the site, do not result in unusual wood but extreme site differences can result in wood so varied that it is not usable. For example, when *Pinus caribaea var. hondurensis* is grown in certain especially good environments the wood produced can be of very low density, making it undesirable for either solid wood products or pulp. The movement of slash pine (*Pinus elliottii*) to the same environment has resulted in very dense wood, with characteristics much like that of oak, making suitability for utilization very limited.

Pruning For most species, pruning is necessary if good solidwood products are desired, especially for conifers grown in the tropics. Under the environments there, limbs will hang on and not shed for many years and become almost like little steel rods; this results in degrade of the final product. Pruning is also usually necessary for quality tropical hardwoods but there are exceptions, like some of the best eucalypts, where the limbs die early and shed naturally. Caution is necessary when pruning; if done poorly leaving stubs, or if the bark is cut into the cambium when pruning, as almost always happens when machetes or axes are the tools used, pruning becomes adverse to quality. When the cambium is cut in the conifers, the result is pitch pockets and undesirable abnormal wood grain formation. In certain of the quality hardwoods, rot will occur which ruins the pruned log for quality products when harvested.

Pest Control

Both insects and diseases can cause major changes in wood properties. An example is fusiform rust on pine which results in a high resin content (double or more of the normal) and abnormally short, and sometimes forked, cell formation. Pulp yields from rust infected wood will be reduced as much as 50%; additionally, the wood will not be suitable for production of lumber. Eucalypt canker is similar to fusiform rust in that it affects both pulp yield and quality. Suitable boards cannot be sawn from the infected stem. Until brought under control genetically by the use of rooted cuttings from disease-free parents, the eucalypt canker had a major effect on the utility of wood from disease-sensitive species. There was considerable talk in the late 1970s of not growing eucalypts in parts of Brazil because of the high incidence of the canker and its effect on wood. It is important to control insect damage and disease in the tree trunks if normal wood quality is to be obtained. Additionally, supplemental nutrients, such as nitrogen, must be used carefully or there will be a degrade in wood quality.

Effectiveness of Forest Management

A good summary relative to the effect of forest management on wood is that anything that can cause growth differences in trees can also result in changes in wood properties. Such a reaction is especially obtained in the conifers, often less than for many hardwoods.

Internal Control of Wood Properties

There are two major causes affecting the internal wood properties of a tree. The first is the time of formation and location of the wood produced, generally subdivided as juvenile and mature wood. The second is the genetic and physiological control of the anatomy and morphology of the cells produced; these can be affected by breeding, as well as by some of the external controls outlined above.

Juvenile and Mature Wood

The quality and ratio of juvenile and mature wood are key to the determination of wood quality within the bole of the tree. All trees have a zone near the tree center (the pith) where there is a change, often rapid, in wood quality from the center of the tree outward. After a number of annual rings, the changes become smaller and more or less constant, sometimes with little change from ring to ring. This is mature wood; in juvenile wood, the variation is related to the number of rings from the pith, regardless of the height in the tree or the age of the tree. This results in a juvenile wood zone that has rapid changes followed by a mature wood zone with minor changes in wood properties, regardless of height in the tree. For example, a 30-year-old loblolly pine with 30 annual rings near the base of the tree will have about the first 10 rings from the pith as juvenile wood, the next 20 as mature wood. Therefore, a log from the base of the tree will consist largely of mature wood, while a log from the upper part of the tree is predominantly juvenile wood. Closer to the top of the same tree, where there might be only 12 annual rings; the first 10 will be juvenile wood with only the last 2 rings being mature wood. Although not strictly correct, the juvenile wood of a loblolly pine tree can be considered as being in a cylinder made up of the 10 rings from the pith. The wood qualities of this core will be essentially the same regardless of the height in the tree where they are measured. Differences in wood quality of each log is therefore dependent on the proportion of juvenile wood to mature wood. The age of the tree is not relevant to the presence of juvenile wood; it is determined at any height by the location of the cambium and by the number of rings from the pith, regardless of tree age.

Juvenile wood qualities vary from the pith outward. In the conifers the wood density becomes greater, the cell length increases, and spiral grain decreases and fibril angle decreases in wood produced from the older cambium as ring number becomes greater from the pith. Juvenile wood in most conifers has low density, short cells, a high spiral grain, and high fibril angle. Such wood gives low yields of pulp with weak tear strength. It is overall considered to be of poor quality related to strength and stability for boards when compared to the mature wood in the same tree. This pattern is usual for the hard pines and some diffuse porous (soft) hardwoods like sweetgum. Many of the hard hardwoods (like oak (*Quercus* spp.) and hickory (*Carya* spp.)) have a different pattern with high wood density near the tree center but with other wood properties that follow the same pattern as described for the pines. There are some diffuse porous hardwood species, like the eucalypts or poplars, whose juvenile wood is very similar to their mature wood.

There are many other wood properties that vary between juvenile and mature wood such as extractive content, or cell size. There are so many of these that they will not be dealt with in detail in this section.

Although often considered to be of low quality, juvenile wood is preferred for some products, like printing papers and tissues, where thin-walled cells are best. Such wood produces strong mullin (bursting strength) but the tearing strength is low. Juvenile wood of some conifers is somewhat similar to mature wood of the diffuse porous hardwoods and is sometimes used to supplement the need for hardwood fibers, such as when hardwoods are in short supply or are costly to obtain.

Wood from thinnings of pine in young plantations or tops from older trees is predominantly juvenile since mature wood has not yet has a chance to be formed. In some hardwoods like the eucalypts, the effect of juvenile wood is minor since the differences between juvenile and mature wood are quite small; this enables the use of short rotations without a major sacrifice in wood quality such as one finds in the conifers.

A major effect on wood and product quality differences within a tree relate to the ratio of juvenile wood present. One major control of the effect of juvenile wood is by varying the age of harvest or the part of the tree from which the wood is obtained.

Young plantations have a large proportion of juvenile wood; despite this, the economic importance of early harvest is often assessed without a proper consideration as to the kind of wood being obtained when there is a large amount of juvenile wood present.

There have been some studies on the genetic control of the amount and kind of juvenile wood. We have found considerable genetic control in loblolly pine but little has been done with this operationally since the effect of juvenile wood can be modified by changing rotation age or by use of the part of the tree bole with the desired percentage of juvenile wood.

Genetic Control of Wood Properties

The genetic control of wood properties is usually strong to moderate and the kind of wood can be influenced using selection and breeding. A strong additive genetic control is found for wood density but there is essentially none in cellulose yield. Strong additive genetic control along with a large suitable variation pattern makes possible the changing of important wood qualities in the desired direction when a selection and breeding program is followed. There are two major categories of genetic control, generally called additive and nonadditive. When the genetic variation is largely of the additive type, and where suitably large variation occurs, improvement by selection and breeding is relatively large and quick. The amount of additive genetic variation is usually represented by the term narrow-sense heritability (h^2) (common in the literature). This is a ratio indicating how much of the characteristic is controlled by additive genetic variation and how much results from other causes, including the environment and nonadditive variation. Thus, wood density has a high narrow-sense heritability (h^2) of 0.6–0.7, straightness of the tree of 0.3–0.5, and limb size shows a heritability of about 0.1–0.2.

Although a more exact formula is used by researchers, a working relation for estimating gain from selection is

$$\text{gain} = \text{SD} \times h^2$$

In this formula SD is the selection differential which is related to the variation in the wood property and the intensity of selection used to obtain the parents which give the desirable gain. Gain in a genetics program with a wood property is dependent on the variability present within the property, the intensity of selection used, and the heritability of that wood characteristic.

Only a few wood properties, like cellulose yield per unit weight of wood, have very little additive variation, but they have considerable non-additive variation. Gains from a selection program with them will be very small. When low additive variation is present, as for cellulose yield, the use of vegetative propagation (or a complex breeding system) is necessary to capture genetic variation in the new plantation trees. (A reduction or change in the amount of juvenile wood is difficult to achieve using a genetic breeding program, because the heritabilities are low).

Wood density Wood density is a characteristic that can be improved quickly and significantly through breeding because its genetic variation is large and consists mostly of the additive type. Other wood properties that are easy to change by selection are resin content of wood and cell length. Some of the more important wood characters like spiral grain and fibril angle (along with tree straightness) have intermediate inheritance and gains through selection will be less.

Operationally, then, when a high wood density tree with high heritability is crossed with another high density tree, its progeny will have relatively high density. If a high cellulose yielder tree (with very low heritability) is crossed with a similar tree, one cannot predict the cellulose yields of the progeny, because cellulose yield is inherited nonadditively. Many wood properties are intermediate, where about half the genetic variation is of the additive type, half nonadditive. When this occurs, a selection program is not fully efficient and is dependent on the amount of variation present.

Vegetative Propagation

Although genetic gain is more difficult to obtain when the genetic control is nonadditive, the use of vegetative propagation will enable good improvement. Vegetative propagation will result in the new plant having the characteristics of the donor parent, since the new plant (propagule), usually a rooted cutting, contains all the additive as well as the nonadditive genetic variation present in the donor tree. The use of vegetative propagation in producing trees for operational planting is becoming much more widely used as methodologies for successful vegetative propagation are being improved.

The simplest way of producing improved wood for characters with a large portion of nonadditive variation is to use vegetative propagation to produce plantable trees.

Wood Uniformity

Wood uniformity, both within a tree and among trees, is a most important characteristic. When wood used in a manufacturing operation is reasonably uniform, efficiency in manufacture and quality of the final product will be greatly improved. Conversely, however, if juvenile and mature woods are both included in the same mix or board, and are treated similarly in manufacture, the final product will be variable and the efficiency and the value of the manufactured product will drop considerably.

The best way to obtain uniformity among plantation trees is to use vegetative propagation since the wood of the propagules from a given tree will all have wood similar to its donor tree. This methodology is now being much used in operational programs; one of the best examples is for the eucalypts when their wood is intended to be used for tissues. The mills have determined the best wood for making tissues and then rooted cuttings from the donor trees with these characteristics are used in establishing plantations. Both the quality and yields of tissues made from such plantations are greatly improved. This method of producing planted trees is now being applied to many other species as techniques for developing the propagules improves; in the future a great proportion of the wood available from plantations will have the desired wood uniformity and properties suited for the final product.

For the long term, the major improvement in wood, both through external and internal sources, will be to develop wood that is uniform and ideal for a given product line. Both the internal and external methodologies of changing wood must be used it such a goal is to be achieved.

Genetics and Improvement of Wood Properties

J P van Buijtenen, Texas A&M University, College Station, TX, USA

Introduction

Wood quality must be defined in terms of the end product: what is good for linerboard is not necessarily good for newsprint. The most critical properties for breeding programs are usually wood specific gravity, tracheid length and microfibril angle, although many other properties are also important. In general, wood properties are strongly inherited, with heritabilities of 0.5 and up. This would make breeding for wood properties easy if they could be determined easily and cheaply. Unfortunately this is true only for wood specific gravity. Therefore, much effort has gone into developing assay methods suitable for small wood samples which can be taken from the tree with little damage.

Wood quality can be improved by silviculture and by breeding. Spacing, thinning, and fertilization all have major effects on the growth of the tree and the properties of its wood. Selective breeding also has a major impact. Traditionally, the selected trees are grafted into seed orchards, progeny tested, and rogued. The time between the start of the program and the harvest of the first trees is typically 50 years making it appropriate to breed for a general purpose tree. For species that can be vegetatively propagated another approach is feasible: clonal forestry. Using it with shorter rotations allows development of trees suitable for specific products.

What is Wood Quality?

This is a difficult question to answer. Many years ago some of the pioneers in forest tree improvement asked managers of the local paper mills what wood properties they considered desirable, and were unable to obtain helpful answers. It was not until the 1970s that breeders started to ask the right questions. The quality of any raw material is defined as its suitability for use and quality is affected by many properties. There is a wide range of products made out of wood and it is therefore necessary to define wood quality in terms of the end product. What is good for linerboard is not necessarily good for multiwall sack paper and might be disastrous for newsprint. This is the most important point to keep in mind when considering wood quality.

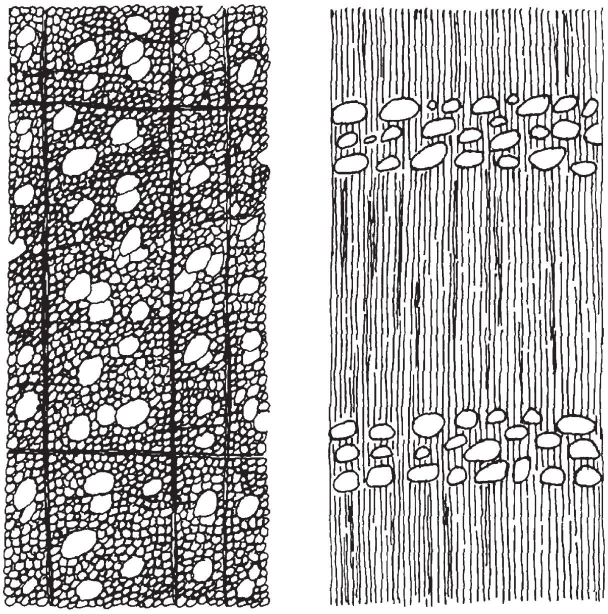
What Are the Important Products?

Wood products belong in two major groups: solid-wood products, and pulp and paper products. Solid-wood products include not only lumber, but also plywood, oriented strand board and particle board. They can be used for construction as well as furniture. Pulp and paper products can be produced by three major processes: the sulfite process, the kraft process, and mechanical pulping. The sulfite process is used extensively for spruces and firs. The kraft process is more flexible and can be used for most species, including almost any pine. Mechanical pulping is often used for lighter woods such as poplars, but can be used successfully for some pines. The sulfite process is very suitable for producing high quality writing papers. Unbleached kraft is used extensively for the production of linerboard and sack paper, while bleached kraft can be used for writing papers, computer paper and paper used in copy machines. Mechanical pulps are primarily used for newsprint.

What Are the Important Wood Properties?

First we must distinguish between the wood of two major groups of trees: hardwoods (essentially broad-leaved trees) and conifers. The two groups have distinctly different wood. That of hardwoods is more complex, and its most distinguishing feature is the presence of vessels the elements of which are connected to each other through large pores. Other elements include fibers, tracheids, and parenchyma. The hardwoods are further divided into ring-porous and diffuse-porous species (**Figure 1**). Conifers have tracheids, ray parenchyma, and resin ducts. The tracheids are much longer than those in hardwoods.

The wood in conifers usually has distinct springwood and summerwood, also called earlywood and latewood. Springwood has large-diameter tracheids



(a) (b)

with thin walls and looks light on a cross-section of wood, while summerwood has narrow, thick-walled tracheids and looks dark (**Figure 2**). The most important wood properties are wood specific gravity (dry weight divided by green volume), latewood percentage, tracheid length, tracheid diameter and wall thickness, microfibril angle (the angle of inclination of the cellulose microfibrils to the long axis of the tracheid), grain spirality (the angle of the tracheids to the vertical axis of the stem), and the chemical composition of the wood.

Techniques for Determining Wood Properties Using Small Samples

In a breeding program it is most important to evaluate wood quality without destroying the tree, and much effort has been expended over the years to develop techniques to make determinations on small wood samples. The favorite method is to remove one or more small radial cores (increment cores, ≤ 10 mm diameter) from the tree, which can be used for determinations. Methods have also been developed to pulp these on a very small scale and determine the pulp and papermaking properties. It is also relatively easy to determine anatomical properties on these samples. Almost all the important properties listed earlier can be determined from an increment core. Also, new high-throughput techniques have been developed recently such as near infrared (NIR) spectroscopy, image analysis, computer tomography, X-ray densitometry, X-ray diffraction, and pyrolysis molecular beam mass-spectrometry which allow very large numbers of chemical analyses on these small samples. Several techniques have been incorporated in the Silviscan equipment developed by Robert Evans at CSIRO, Australia (**Figure 3**). These approaches are ideal for a breeding program where large numbers of individuals must be screened quickly and cheaply.

Silvicultural Improvement of Wood Properties

Spacing

The initial spacing in plantations usually has no direct effect on specific gravity and tracheid length. A wider spacing results in larger juvenile cores. In spruce closer spacing results in better pulp yield and sometimes in greater strength. On sites where water availability is a problem, wider spacing may lead to a higher wood specific gravity.

Thinning

Thinning removes the poorer quality trees and therefore increases the quality of the timber left for the final harvest. Thinning removes trees that contain little of the higher quality wood (outerwood) that is formed after the first few rings from the pith, and

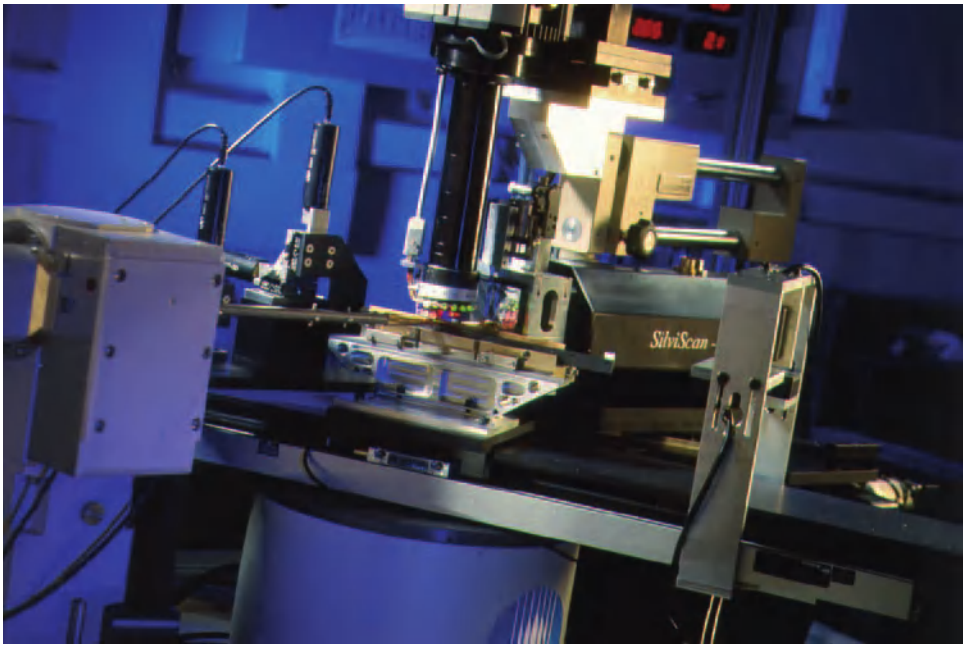

Figure 3 The SilviScan® instrument combines X-ray densitometry, diffractometry and image analysis to measure a variety of properties in a single wood sample. Photograph courtesy of CSIRO.

enhances production of such wood in the remaining crop. The effect of thinning is greatest in ring-porous species, less in diffuse-porous species, and least in conifers. Specific gravity and tracheid length are not much affected.

Fertilization

In general, soil fertilization has more effect on wood of conifers than of hardwoods. In particular, nitrogen fertilization decreases wood specific gravity in conifers and its effect may last 5–10 years. It also decreases tracheid length and increases earlywood production. To get the benefits of increased growth, while minimizing the adverse effects on wood properties, nitrogen fertilization should be light and frequent. The overall effect of fertilization both in hardwoods and conifers is beneficial, since the increase in volume more than offsets the loss in wood specific gravity. The effects of phosphorus and potassium are less pronounced than that of nitrogen. One should note that the effect of fertilization depends greatly on soil conditions. Obviously the effect is greatest when there is a nutrient deficiency.

Genetic Control of Wood Specific Gravity

The Components of Wood Specific Gravity

Wood specific gravity is a complex trait with many contributing factors. The major factor is usually the latewood percentage. Another important component is the cell wall thickness in the earlywood and the latewood. The diameter of earlywood tracheids is also important, but the diameter of the latewood tracheids is less so. The packing density, which is the specific gravity of the cell wall material itself, contributes to the actual density, but not to the variation among trees, since it is rather constant at $1.54\,\mathrm{g\,cm^{-3}}$. Extractives and insoluble deposits are the final components, which are particularly important in the heartwood.

Inheritance of Wood Specific Gravity in Conifers

Genetic variation among provenances Trends in genetic variation among provenances, if present at all, are usually weak. Specific gravity tends to be lower with increasing latitude and altitude. In the southern pines in natural stands wood specific gravity increases from the northwest to the southeast following the rainfall patterns in the southern USA. Genetic trends, determined by growing different provenances in the same location, are in the opposite direction. Clinal patterns are expected in the southern USA, the northeastern USA, and the boreal regions. This is not true, however, in the western USA with its mountainous topography. There, broad trends are expected to be less common except for elevational differences.

Tree-to-tree variation in wood specific gravity The literature on genetic differences among trees is abundant and is only outlined here. Narrow-sense heritabilities for wood specific gravity range from 0.4 to 0.7 in both corewood and outerwood. Low specific gravity species, such as Virginia pine, spruce, and silver fir, tend to have somewhat lower heritabilities than high specific gravity species such as the hard pines, larch and Douglas-fir. In general, the specific gravity of corewood and outerwood are well correlated, with genetic correlations frequently above 0.7. This makes it possible to select for specific gravity at an early age. For species that can be vegetatively propagated, the broad-sense heritability can be substantially higher than the narrow-sense heritability, which can be important for clonal forestry.

Inheritance of Wood Specific Gravity in Hardwoods

Not as much is published on the inheritance of specific gravity in hardwoods as in conifers, but the information is still substantial. Most of the work was done on eucalypts and poplars, with some on other species. In general, wood specific gravity is inherited quite as strongly in hardwoods as in conifers. In the eucalypts and poplars the heritability of specific gravity tends to range from 0.6 to 0.8, while in oak it ranges from a little below 0.4 to almost 0.6. In sycamore reported values range from 0.7 to 0.8. Juvenile–mature correlations in hardwoods are as high as in conifers.

Genetic Control of Other Wood Properties

Latewood Percentage

Differences between earlywood and latewood are so strong that they should often be evaluated separately. A fair amount of information is available on the relationship between latewood percentage and specific gravity, but far less on the genetics of it. There is no general trend in the earlywood : latewood ratio, although the higher latewood percentage is usually associated with high wood specific gravity. The heritability of latewood percentage is rather variable with reported values ranging from 0.25 to over 0.9. The narrow-sense heritability is often around 0.5, while the broad-sense heritability may be around 0.8. One should note that latewood percentage is related to other factors such as fertilization and it also affects the average cross-sectional tracheid dimensions which are very important for pulp and papermaking. On the average, latewood cells are slightly longer than earlywood cells.

Cell Dimensions

Tracheid length is moderately to strongly heritable, but information is somewhat limited, particularly in hardwoods. Most of the work in hardwoods has been with eucalypts and poplars. Estimated heritabilities ranged from 0.36 to 0.86. It has also emerged that polyploidy has a major effect on fiber length in both natural and artificially produced polyploids, increasing fiber length by 21% to 26%. Reported narrow-sense heritabilities in conifers range from 0.28 to 0.9 and broad-sense heritabilities from 0.56 to 0.86. In some species such as Scots pine (*Pinus sylvestris*), lodgepole pine (*P. contorta*), and shortleaf pine (*P. echinata*) differences among provenances have been reported.

Tracheid diameter and wall thickness are in general fairly strongly inherited, but information is quite limited. In loblolly pine (*Pinus taeda*) heritabilities up to 0.8 were reported. Inheritance in *Eucalyptus viminalis* was equally strong.

Spiral Grain

Spiral grain is probably related to wind resistance, but is difficult to measure accurately. If severe it can be a problem for solid-wood products, but generally it is not economically important. It has been intensively studied in *P. radiata* where it can cause problems. Heritability is strong enough to make genetic improvement feasible. There are also some data for eucalypts and beech indicating the same situation. Some species, such as sweetgum (*Liquidambar styraciflua*), have interlocking grain, which can be very troublesome but is also amenable to genetic improvement.

Chemical Properties

Genetic control of wood chemistry is topical, for two reasons. Much work is going on with control, at the molecular level, of lignin synthesis, and new techniques have been developed to analyze small wood samples in large numbers.

Traditionally the lignin, cellulose, and extractives content have been studied most extensively. Lignin content is very strongly inherited but its range of variation is small, indicating that it is very important and natural selection maintains it in a very narrow range. It can be determined extremely accurately. Cellulose cannot be measured as accurately; this lowers the heritability and makes genetic improvement more difficult. In eucalypts, however, considerable progress has been made in increasing cellulose content in clonally propagated trees.

Oleoresin components are quite often under the control of individual genes of large effect, and could be manipulated readily. There has been limited interest, with the exception of overall resin yield in pines, and the presence of limonene, which conveys insect resistance. In the decade 1970–80 some terpenes were used as a form of early genetic marker in studies of forest tree populations.

Other Wood Properties

Compression wood is rather strongly inherited both in loblolly pine and radiata pine. Surprisingly the relationship with form is rather weak, so factors other than straightness must play a major role. Another important property is heartwood formation, but its heritability is rather low.

A trait that is currently of major interest is microfibril angle. It is inherited rather strongly and is related to the strength of individual fibers as well as solid-wood stiffness. Bark percentage is rather variable in loblolly pine, being very important in young trees, where it can occupy as much as 50% of their volume. It is much less so in mature trees and it has a strong geographic component.

Finally, in eucalypts it has been found that collapse during drying, a rather common defect, is highly heritable.

Interrelationships among Traits

Interrelationships among traits are of great importance to the breeder. To select for one trait, but accidentally cause an adverse change in another, may be fruitless. For instance, if wood specific gravity and volume growth were negatively correlated, then selection just for wood specific gravity would decrease growth. This could be good or bad. Selection for low wood specific gravity could result in increased volume and wood that is more suitable for newsprint. On the other hand, selection for increased growth could result in wood less suitable for sack paper. In principle, one copes with this by using a selection index. Knowing the economic value of the traits under selection and their genetic and phenotypic relationships, one can assign a weight to each trait, to give a best estimate of the overall genetic value. A way to show the interrelationships among traits is by use of the so-called coefficient of genetic prediction. This shows the purely incidental change in trait 2 from a change of one standard deviation in trait 1. An example is given in **Table 1**.

Specific Gravity and Growth Traits

In general, there tends to be a weak negative correlation between specific gravity and height and diameter growth. Since in general the correlations between specific gravity and growth are not strong, it is usually not difficult to find individuals with desirable combinations for both traits. Specific gravity and date of bud break have a noteworthy correlation based on research done in Norway spruce. Early flushing is associated with less latewood, lower wood specific gravity, and greater ring width.

Wood Specific Gravity and its Components

Because of the totally different anatomy of the wood of conifers and hardwoods, they will be discussed separately. In loblolly pine latewood percentage, latewood specific gravity, earlywood specific gravity, and latewood tangential tracheid width showed the strongest genetic relationships to overall wood specific gravity. The first three factors have a positive association, while the tangential tracheid width has a negative relationship to overall wood specific gravity. Compression wood has a strong positive relationship with specific gravity.

In hardwoods little is known about the genetic relationships among the proportions of different cell types, but the important cell types are tracheids, libriform fibers, vessel elements, and medullary ray parenchyma.

Relationships among Other Wood Properties

In a few conifers tracheid length has a negative genetic correlation with wood specific gravity and growth rate and positive correlations with other

Table 1 Coefficients of genetic prediction (CGP). Selecting a population of parents one standard deviation above or below the average for a trait listed in one of the columns, will change the genotypic values of the progeny traits by the CGP times one standard deviation (based on data from the Western Gulf Forest Tree Improvement Program). The CGP is calculated as the phenotypic covariance of trait 1 and trait 2 divided by the product of their genetic standard deviations

	25-year height	*25-year DBH*	*25-year volume*	*Juvenile SG*	*Mature SG*	*Average SG*
25-year height	0.22	0.16	0.18	– 0.06	– 0.06	– 0.08
25-year DBH		0.25	0.26	– 0.12	– 0.11	– 0.14
25-year volume			0.26	– 0.12	– 0.11	– 0.13
Juvenile SG				0.19	0.16	0.21
Mature SG					0.36	0.30
Average SG						0.30

DBH, diameter at breast height; SG, specific gravity.

fiber dimensions such as lumen diameter, tangential and radial width, and wall thickness in the latewood.

In loblolly pine the microfibril angle in the earlywood is greater than in the latewood. It is fairly constant in the earlywood, but decreases from the pith to the cambium in the latewood.

In loblolly pine and eucalypts moisture content is negatively correlated with wood specific gravity. Hence, while wood specific gravity increases, the green weight stays relatively constant, since water is replaced with wood substance.

Controlling Wood Properties by Breeding

First one should consider the breeding objectives in terms of the end product. Since the trees will be harvested 50 to 75 years after the selections are made, it seems advisable to breed for properties that are generally desirable, because future wood technology is so uncertain. Increased specific gravity would be particularly suitable, since the use of thinnings and shorter rotations associated with plantation management depresses wood specific gravity (along with other components of wood quality), and it will be important to compensate for this, especially in corewood, which will make up a larger portion of the wood harvested. Another useful strategy is to try to reduce wastage and/or processing costs, e.g., by reducing lignin or by modifying lignin so it can be more easily removed by pulping. Significant reductions in lignin content probably cannot be achieved without major modifications in the system of growing, harvesting, and processing the trees. Wood uniformity within and between trees is also of great importance to the users of wood.

When designing a long-term breeding program for wood quality two key decisions must be made: (1) how to cope with the correlations among traits and (2) how to deal with the selection and progeny test phases. Index selection is, in principle, the best way to deal with adversely correlated traits. In order to cope with the negative correlations between specific gravity and growth, a multiple-population breeding strategy may be considered as an alternative to simultaneous improvement within a single population. Differentiated 'breeds' may be used for different end products or even for different categories of site.

Progeny testing is actually not necessary for traits as highly inherited as wood properties. Just selecting the individuals with the most desirable wood properties would suffice. Since selection for wood properties is generally combined with selection for other properties, such as growth rate, form, and disease resistance, progeny tests will be available anyway, and thus one only has to evaluate the best individuals already selected for other reasons. The age of testing is another major consideration. Since juvenile and mature wood properties are highly correlated, early selection is desirable. Another possibility is to use selection for wood properties in a stepwise screening program, where trees are evaluated first for the traits that can be measured easily and cheaply and are subsequently tested for properties that are progressively more expensive to determine.

Breeding for Wood Specific Gravity

A main consideration when breeding for wood specific gravity is whether wood specific gravity is a main objective or a secondary trait. Most breeding programs opt for the second alternative. One needs to consider, however, that it has a high economic worth, and the fact that an increase in quality generally means higher economic returns than increases in yield. Specific gravity should therefore be a high priority. An additional attractive feature of high wood specific gravity is that in the production of pulp and paper it allows a better combination of tensile strength and tear factor, which is desirable for some products such as multiwall sack paper. The economic effect of per-hectare fiber yield can vary according to the ownership. Since the weight of the green wood is not affected by wood specific gravity and pulpwood is often sold by weight, there is little incentive for a small private landowner to increase wood specific gravity. On the other hand, a company that grows wood on its own holdings has several incentives: increased dry matter production, increased quality, and reduced transportation cost.

Breeding for Other Wood Properties

This is not often done, because they are more expensive to evaluate and often less important. Tracheid length and microfibril angle are the two traits sometimes considered. However, owing to recently developed methods for high-throughput analysis of wood properties the situation is rapidly changing. There is an increased interest in microfibril angle, because of its effect on wood stiffness and pulp properties. Many chemical properties can be determined by the same methods as well.

Chemical properties can also be modified indirectly through improvement in stem straightness and branch size. This results in a reduction in reaction wood, which in conifers reduces lignin content and microfibril angle.

How Are Genetic Gains Obtained Operationally?

There are two major approaches: the seed orchard approach and clonal forestry. The seed orchard approach involves selecting the best individuals, grafting them in seed orchards, progeny testing the orchard to remove the less desirable clones and providing a new generation to select in. Operational plantations are generated from the seed produced by the orchards.

Clonal forestry depends on the availability of efficient vegetative propagation methods, usually rooted cuttings, sometimes tissue culture. A few highly selected individuals can than be propagated to reforest substantial acreages. Because of the cost involved this is most economical on the best sites, located close to manufacturing facilities. Because the time to deployment is shortened this method lends itself to tailor-making trees for specific products. For example the Aracruz company in Brazil has achieved rotations of 6 to 7 years with eucalypts. With *Gmelina arborea* 4 year rotations are possible. With blocks of well characterized clones, it is possible to fine-tune processing to the individual clones.

Breeding for Disease and Insect Resistance

B B Kinloch, Institute of Forest Genetics, Berkeley, CA, USA

Introduction

Pest resistance historically has been the single most important trait in crop breeding, reflecting the vast number of biotic agents that challenge domesticated plants. The number of diseases and insects that afflict forest trees may be even greater than their agricultural counterparts, but no comparable investment to combat them has been made, in spite of the fact that some forest trees have been victims of some of the most spectacular and disastrous epidemics known. Virtual elimination of American chestnut to chestnut blight and extirpation of large populations of American and European species of elm to Dutch elm disease, and white pines to white pine blister rust are textbook examples, as are the depredations of gypsy moth on North American hardwoods. Other important epidemics that started in the last century, some recently, include dogwood anthracnose, butternut canker, Port-Orford cedar root rot, pitch canker of pines, sudden oak death in North America, and the pinewood nematode in Japan. Almost all, of course, are the result of introduced pests. More will undoubtedly follow.

Exotic pests have caused immense economic and ecological damage, and, with few exceptions, are the only ones that merit serious attention. A few pathosystems that exhibit properties of both endemic and exotic diseases are often disturbed, or 'degenerate,' as a result of human intervention (for example, offsite planting, narrow genetic base, dysgenic selection). The same applies to insect pests. The far greater number of endemic forest pests has been regulated by natural selection over epochs of mutual adaptation through coevolution with their hosts.

While much basic understanding of pest resistance and breeding strategies have come from agronomic crops, distinctive properties of tree populations make the former incomplete models. The most important of these properties is the extension of trees in space and time. This has several important biological and practical consequences, especially for disease resistance. Great size projects a tree's parts into different microenvironments above and below ground, providing diversity of niches and habitats, while great longevity provides a perennial source of energy for different forest organisms, including pathogens and predators. Ontogenetic changes occur in morphology, physiology, and susceptibility to pests. Extension also imposes great logistical constraints to the breeder in time required for trees to reach sexual maturity, as well as access to flowers high in the crown. Great diversity (heterozygosity) of wild tree populations provides an abundant resource of variability, but is accompanied by high genetic load and inbreeding depression. This inhibits use of conventional agronomic breeding tools of selfing and backcrossing, complicating analysis of heritable traits, including resistance.

Mechanisms and Inheritance of Resistance

In comparison with crop pathosystems, relatively little is known about mechanisms and inheritance of resistance in trees to specific pests, especially insects, but several general characteristics are shared, such as hypersensitivity, partial resistance, ontogenetic (age-related) resistance, and tolerance. Morphological traits (e.g., leaf toughness, bark or cuticle thickness, trichomes, hairs) that impede pest feeding or ingress, or phenological traits that put host tissues out of synchrony with the life cycle of the pest are particularly important in host–insect interactions. Constitutive products of secondary metabolism (e.g., phenolics, tannins, monoterpenes) protect against herbivory. Behavioral characteristics (e.g., host preference, apparency, predator attraction) add a dimension of complexity to insect–tree interactions.

Genetic resistance is conditional: it depends as much on the genotype of the pathogen as it does on that of the host. The same is true of pathogen virulence and aggressiveness. Although emphasis is most often placed on host resistance, as if it were independent of the pathogen, it is the interaction phenotype that is inherited, and this is a property of both symbionts. This is made especially clear in gene-for-gene systems.

Hypersensitive reactions (HR) are often controlled by single, dominant, major resistance genes (R genes) in gene-for-gene systems. These systems exhibit precise specificity between interacting gene loci of host and pathogen, in which the resistant interaction phenotype is conditioned by an R allele in the host and a complementary allele for avirulence (AVR) in the pathogen. R alleles function in pathogen recognition and activation of host defenses, often leading to HR. HR causes necrosis in host cells immediately surrounding the lesion, effectively arresting further pathogenesis. The outcome is virtual immunity for the host. Virulence (vR) alleles function to avoid or suppress this recognition, thus genetically restoring a compatible (i.e., susceptible) interaction phenotype. R genes can impose intense selection pressure on pathogen vR genes, which may cause them to increase exponentially in frequency until the usefulness of the R genes deployed in the host population is nullified. However, except when selected for by R genes, vR genes are thought to be less fit than AVR genes, which may explain why they do not become fixed in natural pathosystems. HR and R genes are more likely to be found in specialized, biotrophic pathosystems, such as leaf rusts of poplars and stem rusts of pine. HR is also common in tree–insect interactions, but the genetic basis has not been determined.

Partial resistance (PR), as the name implies, restrains pathogen development and/or reproduction without entirely excluding disease. Epidemiologically, PR functions to reduce the rate of infection, and has often assumed names more descriptive of particular kinds of diseases (e.g., 'slow rusting,' 'slow mildewing'). The degree of protection PR affords ranges widely, but can be highly effective in ensuring survival and mitigating damage. It is usually more complexly inherited than major gene resistance (MGR), and may involve several to many genes. Although much less dramatic than MGR, resistance conferred by PR is likely to be more stable, because it is not vulnerable to pathogen races with specific virulence to it. MGR and PR can exist together and act synergistically.

Ontogenetic resistance (OGR) and tolerance are the least understood mechanisms, but may be the most widespread and important in regulating forest diseases and predators in natural ecosystems. These two mechanisms may represent the greatest contrasts with annual plants in disease interactions. OGR is resistance that increases with age (occasionally decreases, but not to be confused with senescence). It has both a seasonal component, similar to annuals, wherein tissues become morphologically or physiologically less susceptible to pathogenesis or herbivory, and a perennial component that extends over the tree's lifetime. Tolerance implies the ability of a tree to survive, grow, and reproduce despite harboring the pest. Although conceptually clear, it is often difficult in practice to separate tolerance from low levels of resistance.

Unique to woody perennials is the inherent capacity to create barriers that wall off and compartmentalize invading pathogens in living sapwood. Upon injury, parenchyma tissues in rays react, synthesizing phenolic and other toxic compounds that discolor wood in a zone surrounding the site of infection and confine spread of invading microorganisms to the limits of the reaction zone. Trees also protect living bark from injury from abiotic or biotic origin by formation of a nonsuberized impervious layer of cells in phloem and cortex tissues at the site of the lesion, temporarily isolating invaders from water and nutrients. Necrophyllactic periderms are then laid down behind the injury site which seal the wound. Although both of these reactions are nonspecific, reaction rates are genetically determined and amenable to selection.

General Considerations

Because tree breeding is expensive, there must be a clear economic benefit to justify a program. Usually, only pests of severe epidemic potential will justify the effort, and these are usually ones that have been introduced to a susceptible host population (or vice versa), although in some circumstances, such as widespread off-site planting, dysgenic selection, or crowded monocultures, endemic pests can become epidemic.

There should be some indication that selection and breeding for resistance to the pest will work. Addressing some of the following questions should assist in making a determination:

1. Is there a pattern of infection? Natural stands under strong epidemic pressure from the pest may reveal resistant phenotypes that are unlikely to be chance escapes. Provenance or family trials in established plantations may also show clear genetic differences that can be exploited.
2. Is there an efficient screening technique in place to evaluate candidate parental genotypes? Criteria for resistance should be clear, and expression of the traits selected for unambiguous. Most important, if artificial inoculation/infestation techniques are used, results should be consistent with field performance throughout the length of the rotation.
3. Is the pest more or less specialized in its host range? Usually, there are better chances of finding host genetic variation in resistance to specialists than generalists, and to biotrophs than heterotrophs.
4. Do exotic relatives of the host exist, especially at the pest's gene center, with resistance to the same or related pest? These may be able to be used as resistance donors in interspecific hybridization and backcross breeding.
5. How well is the genetic structure of the pest population known, both in its places of origin and introduction? Is its breeding behavior predominantly outcrossing or inbreeding (or clonal)? The amount of diversity and its potential for recombination will suggest the level of risk to races of wider virulence.

The goal of selection and breeding should always be for durable resistance. R genes, while highly effective in the short term, can be completely overcome by virulence genes with the appropriate specificity. Developing pyramids ('stacking') of different R genes in breeding lines, or buffering MGR with PR, are alternative breeding strategies to prevent or dampen exponential increases in pathogen virulence frequencies.

As detailed an understanding as possible of mechanisms and inheritance of resistance/virulence will always assist in making gene deployment strategies more effective. Nevertheless, resistance can still be used without such knowledge.

A clear distinction must be kept between breeding for production and for information. For example, if it is deemed necessary to understand the inheritance of resistance mechanisms, strict genetic control of both inoculum source and host material must be exercised in an appropriate mating design. If on the other hand the objective is simply to 'pick the winners' with as broad a base of resistance possible, bulk inoculum from throughout the range of intended deployment is more appropriate for screening candidates.

Maintaining as broad a genetic base as possible is probably the most essential requirement of any breeding program. Selection, by definition, narrows the genetic base. But sufficient diversity in either program breeding or archival populations is necessary as a hedge against the risk of new pests arising, or races of the same one with wider virulence. How much diversity is enough is a difficult and controversial issue, and will depend on the specific circumstances. Gene frequencies for resistance to exotic pests can be extremely rare, as for example those that confer resistance to white pine blister rust and root rot of Port-Orford cedar in North America. In such situations, availability of large, wild populations are the best solution, especially if natural selection is being imposed by the pest.

Examples of Active Resistance Breeding Programs

Table 1 lists seven major forest tree disease or insect epidemics that have motivated breeding programs. These include canker diseases, a vascular wilt,

Table 1 Examples of major pests with active breeding programs

Disease/pest	*Host*	*Pathogen/pest*	*Type of disease*	*Origin*	*Type of resistance (parameter)*
Chestnut blight	*Castanea dentata*	*Cryphonectria parasitica*	Canker	Exotic	PR (canker size)
Dutch elm disease	*Ulmus americana*	*Ophiostoma ulmi*, *O. novo-ulmi*	Vascular wilt	Exotic	Tolerance (% crown damage)
White pine blister rust	*Pinus* (subsect. *Strobi*)	*Cronartium ribicola*	Canker	Exotic	MGR, PR (infection frequency; canker abortion, size)
Leaf rusts	*Populus, Salix*	*Melampsora* spp.	Leaf rust	Exotic, Indigenous	MGR, PR (slow rusting)
Fusiform rust	*Pinus taeda*, *P. elliottii*	*Cronartium quercuum* f.sp. *fusiforme*	Canker	Indigenous (degenerate)	MGR, PR (% infection, canker size)
Port-Orford cedar root rot	*Chamaecyparis lawsonia*	*Phytophthora lateralis*	Root rot	Exotic	MGR?
White pine weevil	*Picea sitchensis*, *P. glauca*	*Pissodes strobi*	Shoot feeder	Exotic, indigenous	PR (% infested)

foliage rusts, a root rot, and a shoot-feeding insect. Thumbnail sketches of problems and progress in four of these follow, illustrating some of the general principles discussed above. Some are also covered in other articles in this volume (*see* **Pathology**: Vascular Wilt Diseases; Leaf and Needle Diseases; Stem Canker Diseases; Pine Wilt and the Pine Wood Nematode; Rust Diseases; Insect Associated Tree Diseases).

Chestnut Blight

Chestnut blight is responsible for one of the worst epidemics of trees, if not all plants, in history, having destroyed the dominant species (*Castanea dentata*) of an entire ecosystem that reached from Maine to Georgia. Caused by *Cryphonectria parasitica*, introduced from Asia, the disease also severely impacted European chestnuts (*Castanea sativa*). After a century of frustrated efforts, the biological tools and knowledge seem to be in place to make restoration of the American chestnut a real possibility. Critical elements consist of high crossability of American chestnut with Asian congeners; simple inheritance of effective partial resistance; a reliable and consistent screening technique; and sexual precocity enabling short intervals (5–6 years) between breeding cycles. It will nevertheless be a long-term endeavor.

No silviculturally useful variation in resistance was found in native chestnut stands, and early breeding efforts sought to exploit the inherent resistance of chestnuts from Asia, where the disease is endemic. The Chinese chestnut (*C. mollissima*), the most wide-ranging and resistant species, was used as the principal source of resistance. Although significant resistance was observed in F_1 hybrids in early trials, it was not adequate for deployment. Further backcrossing to the Chinese parent could increase resistance, but only exacerbate the problem of undesirable growth and form inherited from the Chinese parent.

However, early analysis of certain F_1 and backcross progenies suggested the possibility of relatively simply inherited resistance. Subsequent quantitative trail loci (QTL) mapping with molecular markers of progeny of an F_2 cross confirmed this, and indicated the presence of two or three partially dominant, independently inherited genes responsible for the phenotypic resistance observed. Resistance was expressed as a marked reduction in canker growth rate following artificial inoculation of stem bark with defined cultures of the pathogen. Now the stage was set for a new breeding approach: backcrossing could be done on the recurrent susceptible American parent, to introgress the few genes for resistance from the *C. mollissima* donor, while continually purging remaining Chinese background genes affecting the desired American phenotype. After three backcross (BC) generations from the F_1, only one-sixteenth of the genome, on average, remains Chinese. Each BC generation is screened in field inoculations, using uniform blight cultures placed in drill holes in the bark. Partial resistance is measured by the area of canker expansion after 9–11 months. After the most resistant offspring are selected in each round, a final cross between two BC3 trees ('BC3 F_2s') with partial resistance should theoretically result in one of 16 trees having two copies of both resistance genes, making them as resistant as the Chinese parents in their pedigree.

Diversity for local adaptation will be provided by including at least 20 different American parents in the BC3 breeding population for any given area. This model, currently being tested and implemented in Virginia, could eventually be applied to a large portion of American chestnut's range. It would involve pollinating American chestnut flowers on sprouting stumps in the wild to produce F_1 seed before they become lethally infected.

Dutch Elm Disease

The impact of Dutch elm disease on American elms has been almost as severe as chestnut blight on American chestnut, and has affected many more species worldwide. It is a more difficult and insidious disease to deal with, because of its complexity. It is a systemic vascular wilt, caused by a species complex of at least two fungal pathogens (*Ophiostoma ulmi*, *O. novo-ulmi*) from uncertain origin in Asia, each with different races spanning a wide range of virulence; it has a saprophytic stage, extending survival of the fungus beyond the disease cycle; it is vectored by several different species of elm bark beetles (Scolytidae), with all the problems of host preference, resistance, and environmental interactions that they entail; and resistance mechanisms and inheritance are difficult to assess and interpret. It is a breeder's nightmare, and were it not for the extremely high aesthetic and amenity value of some elm species for urban and landscape forestry, the nearly century-long effort to develop resistance might never have been attempted. Success has been elusive in both North America and Europe, yet some significant progress has been made.

The American elm (*Ulmus americana*) is the most susceptible of over 40 species in the genus, and over 40 million trees are estimated to have been killed by the disease, including 70% of landscape elms. Sources of resistance are abundant in Asia, especially in populations of *U. pumilla*, *U. parviflora*, and *U. japonica*. However, the relative ease with which resistance genes can be introgressed from Asian chestnuts into American chestnut does not apply to the corresponding elms, because *U. americana* is tetraploid, resulting in severe barriers to breeding with potential Asian donors. Additionally, Asian species tend to be highly susceptible to other diseases and insects, can be climatically maladapted, and generally lack the irreplaceable vaselike architecture that defines American elm. Nevertheless, a few promising *U. parviflora* × *U. americana* hybrids have been made in the University of Wisconsin program that seem to combine resistance traits of the Asian parent with morphological features of the American. Many more such hybrids from diverse sources will be needed for a successful breeding program, but these results are encouraging.

Like the experience with chestnut blight, early selection and testing of American elm were disappointing. Of many thousands of candidate phenotypes tested, only a handful survived for further breeding. These are usually referred to as having tolerance, rather than resistance, and perhaps only 1 in 100 000 American elms have this in useful amounts. To efficiently screen selections, the University of Wisconsin program uses artificially inoculated seedlings or rooted cuttings and measures the volume of discoloration in stems as an index of relative tolerance. Seedlings with less than 50% discoloration, with or without foliar symptoms, usually correlate well with field performance. The criterion for acceptable tolerance in the field was $<20\%$ crown damage. A few long-term survivors, intercrossed with each other and susceptible controls, have produced up to 50% of offspring with less than 20% crown damage after 1 year in the field. Recent results of tests conducted by the National Arboretum showed the ability of a few earlier as well as new selections to respond and then recover from heavy artificial inoculation in the field, equaling performance of some non-American tolerant clones. This suggests that extended evaluation of candidates in the field may be more rewarding in the long term than relying completely on artificial inoculation.

White Pine Blister Rust

The nine white pine species native to North America are highly susceptible to blister rust, and most have been severely damaged in parts of their native range since the disease was introduced over a century ago. All species have important ecological functions, but breeding has been focused on the tall timber species, western white pine (*Pinus monticola*) and sugar pine (*P. lambertiana*).

Unlike most other exotic diseases, a surprising number of resistance mechanisms have been found in white pines to blister rust, even though hosts and pathogen have not coevolved. Three general types of resistance are recognized:

1. MGR, causing classic hypersensitive necrosis in needles on challenge by the pathogen. R genes have been found in several white pines, and exist in a gene-for-gene relationship with cognate genes

for avirulence in the rust. Thus, virulence gene *vcr1* in *Cronartium ribicola* neutralizes resistance gene *Cr1* in sugar pine but not *Cr2* in western white pine, and vice versa for *vcr2*. Single recessive genes are also thought to contribute high levels of resistance in western white pine.

2. PR has two main components in white pines: reduced infection frequency, and different kinds of bark reactions that abort infections after they establish in stem tissues. These mechanisms are more complexly inherited, but can still give effective, if incomplete, resistance. Most important, they are not specifically vulnerable to major virulence genes in the rust.
3. OGR is recognized in adult trees that are free of rust when surrounded by heavily infected cohorts, either in natural stands or seed orchards, but which produce highly susceptible offspring. It is genotype specific, and appears to be very strong and stable. OGR would be useful in stabilizing a crop in later parts of a rotation, but is the least understood and probably most difficult of all the mechanisms to develop.

The problem for breeding is how to recognize, concentrate, and deploy these different mechanisms and the genes that control them into synthetic populations to effect durable resistance. Dominant R genes are easy to breed with and confer immunity to all rust biotypes that lack specific virulence to them. But they place severe selection pressure on the rust for these virulent mutants, which are usually rare in natural populations. When this happens, the selected virulence alleles increase exponentially in frequency in the ambient inoculum, nullifying the protection conferred by populations deployed with only R gene resistance. A strategy devised for sugar pine is to prevent or dampen sudden increases in virulence gene frequency by buffering MGR with different PR mechanisms. This is accomplished in a two-stage process. Seedlings are screened first for MGR by artificial inoculation. Those selected are then outplanted in a field location where the frequency of virulence has been maintained at high levels by continuous natural selection from planted MGR. Since MGR is neutralized in this environment, seedlings surviving have both PR and MGR, and by forward selection will constitute the new parental generation when they mature. Concentration of both MGR and PR genes are effected and increased in subsequent generations (**Figures 1–3**).

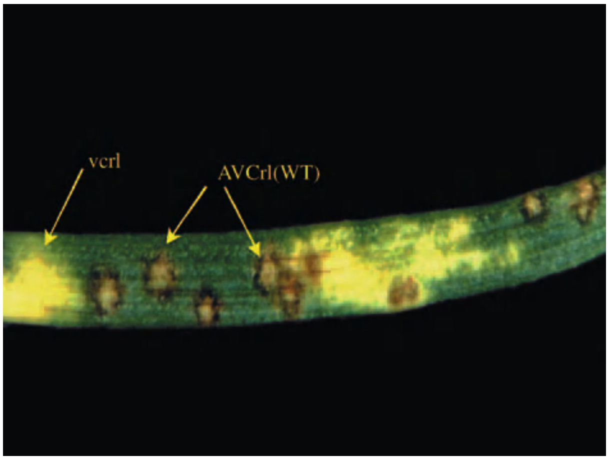

Figure 1 Interaction phenotypes in the white pine–blister rust pathosystem: needle symptoms on sugar pine with the Cr1 gene express as hypersensitive necrotic spots to inoculum carrying avirulence allele AVCr1 (wild type), but as normal yellow spots to inoculum with virulence allele vcr1.

Figure 2 Sugar pine families susceptible and resistant to white pine blister rust in a field trial. The resistant family (far right) has the major gene Cr1 in homozygous condition.

Phytophthora Root Rot of Port-Orford Cedar

Phytophthora lateralis was introduced into western North America from an unknown source over half a century ago, and has since caused widespread mortality in Port-Orford cedar (*Chamaecyparis lawsonia*), a narrow but valuable endemic of northwest California and southwest Oregon. Spread by motile zoospores is rapid and unstoppable – by water coursing through infested stands, or carried by vehicles, people, or animals passing through. Roots are the main infection courts, but foliage can also serve. Environmental variance is high, with low areas being most vulnerable, but root grafts extend infection foci uphill more gradually. The resulting pattern is a mosaic, making assessment of phenotypic resistance ambiguous and difficult.

Figure 3 Partial resistance in sugar pine to white pine blister rust. (a–c) Bark reactions of varying size; (d) low infection frequency. Both trees have Cr1, but have been exposed to natural inoculum with a high frequency of vcr1. b–d reproduced with permission from Kinloch BB Jr. and Davis D (1996) Mechanisms and inheritance of blister rust resistance in sugar pine. In: Kinloch BB Jr., Marosy M, and Huddleston M (eds) *Sugar Pine: Status, Values, and Role in Ecosystems*, pp. 125–132. Davis, CA: University of California, Division of Agriculture and Natural Resources.

Yet, this seemingly intractable problem has recently been overcome by exploiting Port-Orford cedar's unusual reproductive characteristics: precocious flowering (2–4 years) enables rapid turnover of generations compared with other conifers; breeding can be done in containerized orchards in greenhouses; seed is produced abundantly in the same season as pollination; and ease of vegetative propagation by rooted cuttings, even of older trees, permits establishment of ramets of selected candidates, or rapid multiplication of selected progeny genotypes.

Efficient screening is accomplished in two stages. Candidate trees are prescreened by dipping detached branches into zoospore suspensions, then measuring the length of the lesion formed under the bark after a few weeks. The most promising candidates are then rooted, dip inoculated in the same way, planted in nursery beds, and monitored for survival. Most mortality occurs within a year.

The high throughput enabled by these techniques has uncovered rare but highly effective resistance. Although the exact mechanism is not known, progeny of controlled crosses among a few highly selected parents have shown Mendelian segregation of healthy/living : dead offspring, implicating a single dominant gene for resistance. This will greatly facilitate deploying resistant genotypes for restoration of this species. Whether or not the pathogen harbors virulence capable of overcoming this resistance is unknown, but its overall diversity, based on molecular markers, is very low. Partial resistance or tolerance may also be found in the host that could be combined with MGR to mitigate the effect of wider virulence arising. The distribution of MGR is not known, and its rarity could be an impediment to restoring locally adapted, resistant Port-Orford cedar throughout its range. However, the ability to rapidly turnover breeding generations in Port-Orford cedar renders this problem soluble by introgressing nonlocal sources of resistance into local populations through backcrossing.

Genetic Improvement of Eucalypts

B M Potts, University of Tasmania, Hobart, Tasmania, Australia

Introduction

Eucalypts are virtually endemic to Australia; they are the tallest flowering plants on earth and the most widely grown hardwood plantation species. No sector of world forestry has expanded as rapidly as the industrial use of eucalypts and, while they are still at the early stages of domestication compared with crop species, they are fast becoming amongst the most advanced genetic material in forestry. This article overviews (1) the unique biological features of the genus, including its distribution and taxonomy, breeding systems, and natural regeneration mechanisms; (2) the history of its domestication, from its first discovery in the late eighteenth century, through its rapid dispersal around the world in the nineteenth century to its prominent role in the industrial plantations of the late twentieth century for the pulp and paper markets; (3) the genetic improvement of species, from provenance selection to advanced generation breeding strategies, including definition of breeding objectives and large-scale assessment of key biological traits affecting profitability; (4) the important role played by eucalypt hybrids, particularly in tropical and subtropical zones; (5) deployment options through seed and clonal propagation systems; and (6) progress towards molecular breeding and genetic engineering.

The Genus

Eucalypts are generally long-lived, evergreen hardwood species belonging to the predominantly southern hemisphere, angiosperm family Myrtaceae. They range in habit from shrubs and multistemmed mallees to enormous trees some which include the tallest flowering plants on earth (*Eucalyptus regnans*, up to 96 m). Most species are endemic to Australia but five tropical species are confined to islands north of Australia (e.g., *E. urophylla* and *E. deglupta*). A small group of species also extends outside of Australia into Papua New Guinea (e.g., *E. alba* and *E. tereticornis*). Eucalypts are the dominant species in open forests and woodlands throughout Australia but extend into a great diversity of habitats. They occur naturally from sea level to the alpine treeline, from high rainfall to semi-arid zones, and from the tropics to latitudes as high as 44° S, but they are absent from true arid and rainforest environments in Australia.

In the broad sense, eucalypts include the genera *Eucalyptus, Corymbia,* and *Angophora*. A key feature of the majority of eucalypts is the fusion of either the petals and/or sepals to form an operculum from which the eucalypts derive their name (from a Greek root *eu* – well and *calyptos* – covered). The operculum appears to have evolved independently in different eucalypt lineages and has not evolved in *Angophora*. There is some debate as to whether the *Corymbia* and *Angophora* genera (bloodwood taxa) warrant separation from the genus *Eucalyptus* in the strict sense (non-bloodwood taxa), but this split is supported by several independent DNA studies and is adopted herein. This dichotomy appears to be associated with differences in the structure of raised oil glands (termed bristle glands), wood properties (the bloodwood lineage for example only has solitary vessels in the xylem), leaf venation, and ovule arrangement. The latest taxonomic revision of the eucalypts recognizes just over 700 species that belong to 13 main evolutionary lineages (**Table 1**) but still treats the bloodwood eucalypts as subgenera of *Eucalyptus*. Most species belong to the subgenus *Symphyomyrtus*, and it is mainly species from three sections of this subgenus that are used in plantation forestry.

Eucalypts have several noteworthy biological features. Many species are heteroblastic, with leaves changing from a sessile, horizontally orientated juvenile form to a petiolate, vertically orientated adult form. This is also accompanied by changes in leaf anatomy, physiology, and chemistry. The timing of this heteroblastic transition is under strong genetic control and susceptibility to many pests is dependent upon the leaf type present in the canopy. Eucalypts also have well-developed mechanisms for vegetative recovery from defoliation arising from factors such as fire, drought, frost, or herbivory. The bark often protects numerous dormant vegetative buds that sprout to form epicormic shoots after defoliation. If the whole stem is killed by, for example fire, many species also have the possibility of resprouting from lignotubers. Lignotubers are organs that develop as swellings in the axils of the cotyledonary and early seedling nodes and comprise a mass of vegetative buds, vascular tissue, and food reserves. They usually become buried and allow the plant to regenerate after the death of the main stem. Epicormic or coppice shoots exhibit varying degrees of reversion to the juvenile leaf form. Other vegetative regeneration mechanisms such as rhizomes or root suckering have been reported in *Corymbia*. Regeneration usually occurs by seed that is stored in woody capsules, 5–30 mm in diameter, and often held on the

tree for several years. In good years, large numbers of seed are shed, particularly following wildfire. The seeds generally have no special adaptation for dispersal and, with the exception of a few cases of water dispersal (e.g., *E. camaldulensis*), seed dispersal is mainly by wind and normally occurs over short distances. Eucalypt seed is short-lived in the soil seed bank.

Eucalypt flowers are occasionally solitary (e.g., *E. globulus*), but often occur in clusters of three or more in umbels (**Figure 1**) or terminal inflorescences. The eucalypt flower is normally bisexual, with numerous stamens that expand outwards after the operculum is shed to form the conspicuous floral display. Eucalypts are predominantly animal-pollinated, with vectors encompassing a wide variety of insects, birds, and marsupials, and a few bat species. They have a mixed mating system, but are generally preferential outcrossers, with high levels of outcrossing maintained by protandry and various incomplete pre- and postzygotic barriers to self-fertilization. The postzygotic barriers include intense selection against the products of inbreeding. For example, inbreeding depression for growth in selfed *E. globulus* is nearly 50%, and this is quite typical. Consistent with most myrtaceous genera, eucalypts are diploids with virtually all having a chromosome

Figure 1 Flowers and flower buds of *Eucalyptus nitens*. *Eucalyptus nitens* bears its flowers in umbels of up to seven flowers. The figure shows buds just about to shed their inner operculum and those from which the operculum has been shed. In this group of eucalypts, the inner operculum is derived from fused petals and shed just before the anthers expand and shed pollen. The outer operculum is derived from the fused sepals and is shed early in bud development. The stigma of this species becomes receptive 5–7 days after operculum shed, at a stage when most pollen has been released from the anthers. Photograph courtesy of Dean Williams.

number of $2n=22$. While the major eucalypt subgenera do not hybridize, reproductive barriers between species within subgenera are often weak. Hybridization and intergradation between recognized taxa are common in nature, often making delineation of species difficult. Many artificial hybrid combinations have been produced. In general, hybrid inviability tends to increase with increasing taxonomic distance between the parents, but there are exceptions.

History of Domestication

Eucalypts are the most planted hardwood trees in the world. Following their discovery in the late eighteenth century, they were spread rapidly around the world and were early introduced into countries such as India (*c.* 1790), France (*c.* 1804), Chile (1823), Brazil (1825), South Africa (1828), and Portugal (1829). Initially they were introduced as botanical curiosities but, as the potential for some species to grow fast was quickly recognized, they were grown for windbreaks, land reclamation, and leaf-oil production, but mainly for fuel wood and timber production. Plantations were established, for example, to provide railway crossties and fuel for wood-burning locomotives in Brazil and South Africa, mine props in Chile and South Africa, and charcoal in Brazil for iron and steel production. One factor causing their rapid early spread appears to be the belief that growing eucalypts could banish diseases such as malaria, and they became known as 'fever gums' in the latter half of the nineteenth century.

Eucalypts became renowned for species with fast growth, straight form, valuable wood properties, wide adaptability to soils and climates, and ease of management through coppicing. They are now found in more than 90 countries where the various species are grown for products as diverse as sawn timber, mine props, poles, firewood, pulp, charcoal, essential oils, honey, and tannin as well as for shade, shelter, and soil reclamation. The exotic eucalypts became an important source of fuel and building material in rural communities in countries such as India, China, Ethiopia, Peru, and Vietnam. However, it was the great global demand for short-fiber pulp that drove the massive expansion of eucalypt plantations throughout the world during the twentieth century. Their high fiber count relative to other wood components, coupled with the uniformity of fibers relative to other angiosperm species, has caused high demand for eucalypt pulp for coated and uncoated free-sheet paper, bleach board, sanitary products (fluff pulp), and secondarily for top liner on cardboard boxes, corrugating medium, and as a filler in long-fiber conifer products such as newsprint and containerboard. New technologies are also increasing interest in the use of plantation eucalypts for sawnwood, veneer, medium density fiberboard, and as extenders in plastic and molded timber.

No sector of world forestry has expanded as rapidly as the industrial use of eucalypts. While precise global figures are difficult to obtain, it is estimated there were 9.5 million ha of industrial eucalypt plantations in the world in 1999 (**Table 2**), with the vast majority of these established since the 1950s. This area is predicted to reach 11.6 million ha in 2010 (**Table 2**). Other less conservative global estimates suggest that there were nearly 16 million ha of general eucalypt plantations by the 1990s which would reach 20 million ha by 2010. These figures compare with the estimated 30 million ha of tall (>30 m tall) and 240 million ha of open (10–30 m tall) native eucalypt forest in Australia in 2001. The majority of plantations consist of only a few eucalypt species and hybrids. The most important plantation eucalypts around the world are *E. grandis, E. globulus,* and *E. camaldulensis*, which together with their hybrids account for about 80% of the plantation area; these are followed by *E. nitens, E. saligna, E. deglupta, E. urophylla, E. pilularis, Corymbia citriodora*, and *E. tereticornis*. In the case of pulpwood, the market favorites are *E. grandis, E. urophylla*, and their hybrids in tropical and subtropical regions and *E. globulus* in temperate regions. However, eucalypt plantations of the traditional pulpwood species as well as other species (e.g., *C. citriodora, C. maculata, E. cloeziana*, and *E. nitens*) are increasingly being managed for solidwood production. While there are reports of eucalypt plantations achieving growth rates of over $60\,m^3\,ha^{-1}\,year^{-1}$, with intensive management, typical growth rates reported for the *E. grandis* plantations in Brazil and South Africa are $40\,m^3\,ha^{-1}\,year^{-1}$ with a harvest age of 6–8 years,

Table 2 Area of industrial plantations of eucalypts (millions of hectares)

Region	*1999*	*2010*	*Change*

and 20–22 $m^3 ha^{-1} year^{-1}$ for *E. globulus* plantations in Portugal and Chile with a harvest age of 8–10 years. The world average is suggested to be more like 20 $m^3 ha^{-1} year^{-1}$, but it is anticipated that this could reach 25–30 $m^3 ha^{-1} year^{-1}$ in the future with better silviculture and breeding.

Initially, the botanical gardens of southern Europe played a major role in the introduction of eucalypts to other parts of the world, including Africa and South America. Later in the nineteenth century eucalypts were introduced directly from Australia with, for example, large quantities of seed being sent out of Australia by Ferdinand von Mueller, a government botanist and eucalypt specialist. These early introductions were often used as the base to establish large-scale plantings, resulting in narrow, potentially inbred, genetic bases in some cases (e.g., *E. globulus* in South Africa and Ecuador). In other cases, seed for plantation establishment was collected from ornamentals or multispecies plantings, and appears to have contained high frequencies of interspecific hybrids. In the latter case, F_1 generation hybrids may have performed well but subsequent seed collection from these hybrid plantations resulted in F_2 and subsequent generations with poor growth and form as well as extreme variation (e.g., those derived from the Rio Claro *E. urophylla* hybrids in Brazil 'Brazil alba,' or Mysore *E. tereticornis* hybrid in India). In many countries where eucalypts have been introduced for a long time and continually reproduced from local seed sources, they have formed landraces that are adapted to the specific environment of the country. However, there are many examples where the initial use of a limited sample of the genetic diversity in the native gene pools, the use of suboptimal provenances, inbreeding, or hybrid breakdown have led to landraces being outperformed in field trials by seedlots from some native-stand provenance collections (e.g., *E. globulus* in Argentina, *E. grandis* in South Africa). The planting of suboptimal germplasm is particularly problematic in rural communities where seed obtained for new plantings has been collected with no or only little phenotypic selection from local plantings, generation after generation. In a few cases, where more active breeding has occurred the local landrace has outperformed newly imported native stand seedlots (e.g., *E. grandis* in Florida).

Some of the earliest breeding of eucalypts was undertaken by French foresters in Morocco in 1954–1955. Coincident with the increasing interest in industrial plantations of eucalypts, the 1960s saw a more formal approach to genetic improvement with, for example, the commencement of the Florida *E. grandis* breeding program in 1961, *E. globulus* breeding in Portugal in 1965, and establishment of large provenance tests of *E. camaldulensis* in many countries. Major advances in domestication of the genus occurred in the 1970s with, for example, the first commercial plantings of selected clones derived from hardwood cuttings at Pointe Noir in the Congo followed by Aracruz in Brazil (many of which were spontaneous hybrids), and the establishment in many countries of the first large base-population trials of species such as *E. urophylla* and *E. globulus*. These trials were established from open-pollinated seedlots collected from range-wide provenance collections and formed the bases for deployment and breeding populations in many countries. Many other major international base-population trials were established through the 1980s for species such as *E. grandis, E. tereticornis*, and *E. viminalis*, and using more intensive collections of elite provenances identified in earlier collections.

While eucalypts are still at the early stages of domestication compared to crop species, they are fast becoming amongst the most advanced genetic material in forestry, with stock originating from the *E. grandis* program in Florida already in its sixth generation. In Brazil, around 500 000 ha of plantation were apparently established with 'Brazil alba' seed between 1940 and 1970 before it was realized that the quality of the new plantations was much inferior to earlier plantations and *E. grandis* due to hybrid breakdown. The company Aracruz Celulose S.A. has subsequently doubled yields from its Brazilian plantations through species and provenance selection, breeding, and the use of proven clones. Domestication of eucalypts has proceeded faster in countries like Brazil that rely on plantations for their eucalypt wood than in Australia, where up until the 1990s wood products of eucalypts were derived almost entirely from native forests. However, major provenance trials of species such as *E. regnans, E. delegatensis, E. globulus*, and *E. nitens* were established in Australia in the late 1970s, and major breeding programs for *E. globulus* and *E. nitens* were started in the 1980s.

Species Improvement

A key feature of eucalypt species is the great diversity of the native gene pools. Large, genetic differences between provenances are the rule rather than the exception. In some cases, provenances of a single species may vary from tall forest forms to small trees and even shrubs when grown in common environment trials (e.g., *E. globulus*). This diversity may occur for all traits of interest to breeders such as growth and survival, pest resistance, and wood properties, as well as flowering season and precocity. Such provenance variation makes it important that, firstly, species-elimination trials are based on adequate provenance representation and, secondly, when establishing base populations for breeding the full range of genetic diversity is assessed. This is further complicated by the large provenance × environment interactions that have been revealed in multisite field trials of species such as *E. camaldulensis, E. deglupta, E. delegatensis, E. nitens, E. urophylla*, and *E. viminalis*. Increasing information is available for environmental matching of species and provenances to sites through comparison of local environmental profiles with native ranges in Australia as well as exotic environments where they have been successfully grown. However, a traditional approach for formation of base populations for breeding has been the establishment of large rangewide provenance trials, supplemented with more intensive collection from elite provenances in a second stage. While early provenance trials pooled individual-tree seedlots, later trials have tended to maintain family identity to allow better pedigree control and conversion of trials to seed orchards. Increasing international exchange of eucalypt germplasm amongst breeding programs now means that base populations are comprising not only seedlots from native stand collections in Australia but also material from landraces and more advanced breeding programs.

A focus of eucalypt breeding in recent years has been the clear definition of breeding objectives and identification of relevant selection traits. Major developments were made in the 1990s in clarifying breeding objectives for kraft and mechanical pulpwood production using eucalypt wood. Wood density, pulp yield, and volume per hectare were identified as the key biological traits influencing the economics of pulpwood production. Economic weights have been determined to allow estimation of total breeding value in terms of monetary value to the industry sector. Wood density and pulp yield were rarely considered in earlier selection programs, yet they can account for over 70% of the benefits from breeding for pulp production. Approaches have now been developed for the quick, cheap, and nondestructive measurement of many key wood properties (e.g., pilodyn, mechanized coring (**Figure 2**) and near-infrared reflectance analysis (NIRA)), allowing their widespread application in breeding programs. Extending such work beyond pulp to paper is the next step. There is increasing work being undertaken on identifying breeding objectives and selection traits for solidwood products; however, this is complicated by the greater range of products involved from sawn timber, composites, and veneer, and changing technologies, as well as the fact that plantations may be required for multiple products through thinning or changes in product pricing.

Figure 2 Coring *Eucalyptus globulus* for wood density assessment using a mechanized coring machine. Photograph courtesy of Carolyn Raymond, Cooperative Research Centre for Sustainable Production Forestry.

The amount of genetic variation and intercorrelation among selection traits in the breeding population has a major effect on genetic progress. The genetic correlation between growth and wood density, for example, is probably slightly adverse in species such as *E. globulus* and *E. nitens*, but estimates are variable ranging from zero to significantly adverse. Most genetic parameters such as heritabilities and genetic correlations published for eucalypts to date refer to the additive genetic variation within provenances and have been calculated based on open-pollinated progeny trials. As eucalypts have a mixed mating system and the male parent is unknown, the accuracy of these genetic parameter estimates is questionable, particularly from native-stand seed collections where outcrossing rates may vary markedly. In *E. globulus*, for example, no correlation has been observed between open-pollinated and control-pollinated breeding value estimates for growth traits, but the correlation is significant for traits of higher heritability such as wood density and disease-resistance traits. The other types of heritability often reported include additive and nonadditive components of genetic variation and are the clonal and family heritability (or repeatabilities of their means). This is a measure of the relative differentiation between genotypes or families and is a measure of the repeatability of performance for clonal or family deployment respectively.

Traditionally, eucalypt breeding has involved open-pollinated breeding strategies using single populations or sublines, possibly coupled with open- or controlled-pollinated nucleus populations of the most elite selections or specialized breeds (**Figure 3**). In programs where clones are deployed, the standard approach has involved progeny testing, and phenotypic or genetic selection of elite genotypes, followed by various stages of selection on cloning potential and clonal elimination trials. Selected clones are frequently used as parents in the subsequent generations. Traditionally, breeding programs have involved discrete generations. However, programs in Australia and Portugal are now implementing a 'rolling front' breeding strategy that has overlapping generations with selection, crossing, and trial planting done each year. This strategy is believed to be more flexible in the face of changing breeding objectives, technologies, resource allocation, and industry reorganization, which are becoming increasingly common. In this scheme, decisions are defined in terms of dynamic rules, where a general objective function guides the

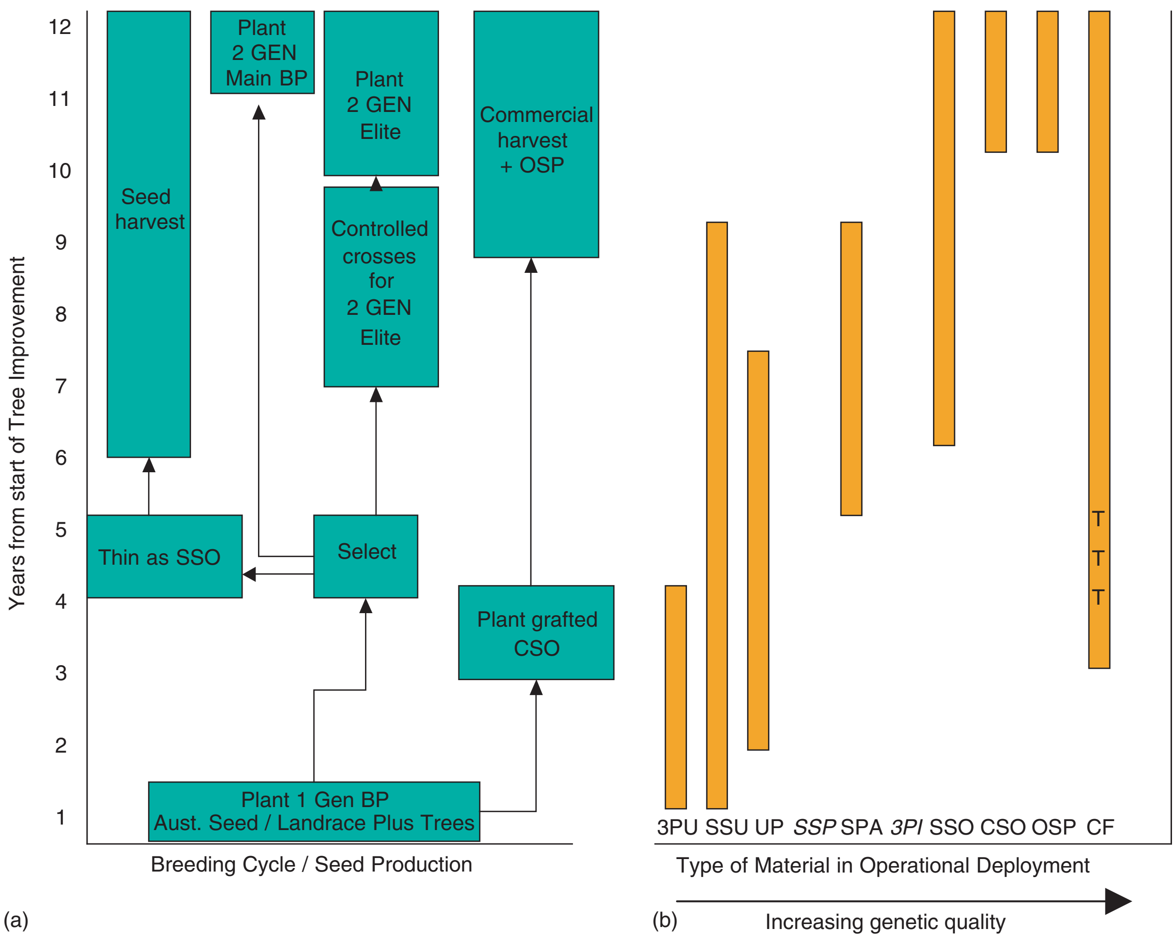

Figure 3 Elapsed time for first generation breeding and take-up of deployment options for *Eucalyptus globulus* in the company Forestal y Agricola Monteaguila S.A. in Chile (year 1 = 1990). (a) The type of genetic material deployed. The breeding population contained two sublines, a large Australian native stand collection and the other the Chilean landrace. The breeding populations (BP) were planted on multiple sites, the majority of the landrace selections from which seed was collected were also grafted and used to develop a clonal seed orchard (CSO) and a mass controlled pollination system based on 'one-stop pollination' (OSP). One site of the Australian subline was converted to a seedling seed orchard (SSO). (b) Planting started with importation of Australian seed (3PU), supplemented by harvests from the best trees in the plantations of the Chilean landrace (SSU). Within 3 years the superiority of the Jeeralang provenance in Australia (UP) was demonstrated and imported native stand seed formed a main component of the plantations established for the next 5 years until SSO and CSO seed came on stream. In 2000, backward and forward selected families from OSP contributed 30% of plantings and was expected to yield 30% volume improvement relative to Jeeralangs (UP). A clonal program (CF; T, test scale) was commenced in 1991, with cloning high rooting, selected families from the landrace and cold tolerant selection and later selections from the first generation breeding population (1GEN BP) trails. Commercial planting started in year 6 and by year 11, 20% of the total planting used clonal stock. Seed stands derived from plantations of selected provenance (SSP) or third party improved seed (3PI) were not utilized. From Griffin AR (2001) Deployment decisions: capturing the benefits of tree improvement with clones and seedlings. In *Developing the Eucalypt of the Future*, IUFRO International Symposium, 10–15 September 2001, pp. 16. Valdivia, Chile: INFOR.

selection and crossing done each year. Such a strategy exploits advances in genetic evaluation through best linear unbiased prediction (BLUP) methodology using individual-tree models that allow for overlapping generations, and complex pedigree- and field-trial structures. The costs of controlled pollination of many eucalypts have now been reduced substantially, through the development of techniques requiring only a single visit as opposed to three visits to the flower. Such reductions in costs have now made controlled crossing of the breeding population viable in species such as the large-flowered *E. globulus*, allowing improved accuracy of genetic evaluation over open-pollination where the male parent is unknown and breeding values could be biased by selfing and nonadditive genetic effects. Other major advances in genetic evaluation have come through improved trial designs such as incomplete-block and row–column designs, as well as including clonal information into evaluation models.

Interspecific Hybridization

Interspecific eucalypt hybrids have been used in forestry for decades and are a significant component of eucalypt plantation forestry, particularly in the tropics and subtropics. While some multiclonal seed orchards are used for F_1 hybrid production, cost-efficient clonal propagation is the key to their successful exploitation. Failures to develop such systems has limited deployment and hence reduced use of many desirable species combinations, particularly in temperate regions.

Clones of *E. urophylla* × *E. grandis* are easy to propagate and are widely planted in Brazil and Congo (**Figure 4**). Most eucalypt hybrids tested or deployed are either F_1s or composites derived from spontaneous hybridization (e.g., 'Brazil alba,' or Mysore hybrid in India) or more recently manipulated F_1 hybrids. The main hybrids used in industrial plantations are *E. grandis* × *E. urophylla, E. grandis* × *E. camaldulensis* (**Figure 5**), and cultivars including at least one of *E. saligna, E. pellita, E. exserta*, and *E. tereticornis*. Such hybrids are planted on a relatively large scale in Brazil and Congo, although sizeable plantations also occur in China, Indonesia, and South Africa. While hybrids are less utilized in more temperate zones, eucalypt hybridization programs involving controlled crossing were undertaken early in countries such as Russia and France, but hybrid development was curtailed by extreme frosts. Such artificial hybridization was undertaken early in temperate Australia, mainly aimed at understanding trait inheritance and the reproductive barriers between species. Hybrid development has focused on F_1 hybrids and has aimed to combine species with complementary attributes. However, as most traits are inherited in a more or less intermediate manner in the F_1s there is increasing interest in backcross and other advanced generation eucalypt hybrids to provide desirable combinations of traits. Some desirable species combinations produce high proportions of inviable/uncompetitive hybrids (e.g., *E. grandis* × *E. globulus, E. camaldulensis* × *E. globulus, E. urophylla* × *E. dunnii, E. dunnii* × *E. grandis*) and the key to hybrid selection appears to be rapid production and testing of large populations and application of high selection intensities. There are also advantages in selecting seed parents for both sexual and vegetative propagation traits.

Deployment

Seedlings

In rural communities outside Australia, eucalypts have historically been propagated from the most accessible seed that is often derived from ornamentals or local plantations, with little attention paid to its

Figure 5 A phenotypically outstanding *Eucalyptus grandis* × *E. camaldulensis* F_1 hybrid in a family trial in Guangxi Dongmen Forest Farm, China. At 10 years the diameter at breast height of this tree was 32 cm compared with the adjacent tree in the foreground that measured only 11.3 cm. Such individuals are damaged at the base to cause coppice shoots that are multiplied by tissue culture to provide sufficient stock plants for production of hardwood cuttings for clonal tests.

Figure 6 Seed production stand of landrace *Eucalyptus globulus* near Lota, Chile after seed-bearing branches were harvested by climbers.

genetic quality. However, seed with varying levels of improvement has been obtained for deployment in industrial plantings from the best native-stand provenances in Australia, seed production areas (**Figure 6**), seed orchards, and more recently, mass controlled or supplementary pollination. The main problem with collection of seed from native stands is that genetic gain, from even the best provenances, may be limited due to varying degrees of inbreeding from selfing or crossing between related individuals which often grow in close proximity in the forest owing to limited seed dispersal. Self-fertilization is particularly a problem when seed is collected from isolated trees. Nevertheless such an approach has been a means of rapidly obtaining genetic gain in plantations during the early stages of domestication (**Figure 3**). Similarly, seed-production areas were often established early by visually thinning even-aged exotic plantations to leave large trees of good form for seed collection in subsequent years (**Figure 6**). While this will avoid the problem of the neighborhood inbreeding that may occur in native forests, it does not avoid problems of inbreeding due to selfing or a narrow genetic base, and genetic gain may also be limited by the low heritability of growth and some tree-form traits.

A large component of improved seed for the main plantation species is now available from open-pollinated seedling or clonal seed orchards established in many countries (**Figure 3**). Seedling seed orchards can be rapidly obtained by thinning pre-established progeny tests based on phenotypic selection, or preferably breeding-value estimates. In species such as *E. globulus*, large genetically based differences in the season and age of flowering may limit outcrossing and the number of effective pollen parents. To improve flowering synchrony, specialized thinning or planting designs are often employed. Higher genetic gains are expected from the more expensive, clonal seed orchards established by either forwards or backwards selection of elite genotypes. Mature scion wood of most commercial eucalypt species can be grafted onto seedling rootstocks using a variety of techniques including bottle-, top-cleft-, patch-, and micrografting, but the success rate is variable at the species and genotype level. Loss of trees due to late-acting graft incompatibility can be a significant cost with such clonal orchards and can be overcome by the use of cuttings or micropropagated clones.

Two major advances have occurred in the production of improved eucalypt seed in the last decade. One was through the discovery that the gibberellin inhibitor paclobutrazol could be used not only to reduce tree growth and allow easier canopy management, but also to enhance flowering. The other advance has been the discovery that the stigma is not necessary for successful pollination and that the pollen will germinate on the surface of the style when it has been cut either just after or even just prior to operculum shed, which often occurs about a week before stigma receptivity. This development has enabled pollination to be undertaken at the same time as emasculation and, coupled with single-flower or style-isolation procedures, has allowed controlled pollination to be undertaken in a single visit to the flower (termed 'single-visit pollination' (SVP) or 'one-stop pollination' (OSP)) (**Figure 7**). The traditional approach involved three visits – emasculation and isolation at operculum shed, pollination at stigma receptivity, and then removal of isolation bags. In the large-flowered species, *E. globulus*, orchards are now established for the manual production of elite full-sib families for deployment using SVP, with or without style isolation and emasculation (**Figure 8**). This approach is also being widely adopted with small-flowered species such as *E. grandis*, for the large-scale production of interspecific hybrids for clonal testing.

Vegetative Propagation

Industrial-scale clonal propagation of eucalypts is widespread, particularly in the tropics and subtropics. Selected eucalypt clones are now used routinely in countries such as Brazil, Congo (**Figure 4**), Morocco, and South Africa. Most clonal systems use hardwood (ripened-shoot) cuttings. Micropropagation is mainly used to rejuvenate adult material or rapidly bulking up mother plants for hardwood cutting production. Embryogenesis is still in the research stage with eucalypts. Cuttings can be obtained relatively easily from seedlings or from basal coppice of most eucalypts, but the ability of shoots to produce roots rapidly declines with tree age and with a few exceptions (e.g., *E. deglupta*), adult shoots will not root. Maturation usually occurs rapidly and appears to be due to the production of a rooting inhibitor in mature apical or epicormic leaves. However, rejuvenation of shoots from the crown of mature trees is possible through rapid, 'cascade' grafting (including micrografting) on juvenile rootstocks or micropropagation (five to six transfers are usually required). Felling mature

Figure 8 Grafted seed orchard of *Eucalyptus globulus* of Bosques Arauco S.A., Chile. The orchard is being used for the production of controlled cross seed using one-stop pollination procedures similar to those shown in **Figure 7**.

trees will usually result in stumps producing juvenile coppice shoots from which cuttings can be obtained and used to establish mother plants for subsequent harvesting. The rooting potential of cuttings is generally increased in the next phase when shoots are harvested directly from well-maintained mother plants. Rapid multiplication is often achieved by using sequential generations of cuttings for mother plants. Clone banks of mother plants from which basal shoots are regularly harvested are either maintained in containers or in field plots.

Cuttings are usually obtained by dipping stem cuttings of one or two nodes into 1–3% indole butyric acid (IBA) rooting hormone. Rooting is usually obtained within 6–12 days and aided by high humidy (e.g., misting) and bottom heating. However, species vary in their propensity to form well-rooted cuttings and the conditions to achieve their maximum rooting potential, particularly mother-plant environment and handling. Species such as *E. globulus, E. nitens*, and *E. regnans* have a reputation for being difficult to root, whereas *E. camaldulensis, E. deglupta, E. grandis*, and *E. robusta* are easy. Even within species, there is considerable variation between families and genotypes. Genotypes of a species may vary in the proportion of cuttings that root from 0% to 90%. For example, in *E. globulus* only 25% of selections have been reported to root at rates of over 75%. In *E. deglupta*, the mean success is between 85–90%. However, good rooting does not ensure high growth rates and there are many examples of good rooting clones which have below-average growth rates. High rooting ability is essential for the successful exploitation of eucalypt hybrids, and most indications to date suggest that it will be inherited in a predominantly additive manner in most interspecific combinations. For economic production of clones, rooting success greater than 70–80% is usually required, which often results in a large number of individuals initially selected on breeding-objective traits being discarded.

Recent advances in technology for industrial-scale clonal propagation of eucalypts have occurred with the development of intensive micro- and minicutting systems in Brazil. Microcuttings use apices obtained from micropropagated plantlets, while the minicutting is based on the rooting of axillary shoots derived from rooted stem-cuttings. In both systems, field clonal hedges are replaced by intensively managed minihedges grown indoors using hydroponic systems (**Figure 9**). This reduces costs and can also make the propagation cycle less dependent on weather conditions.

Figure 9 Indoor hydroponic, minicutting systems developed at Klabin Riocell, Brazil. Mother plants (left bottom) are grown indoors in hydroponic beds (left top) from where shoots are harvested for minicuttings. Cuttings are set in indoor rooting facilities (right top) and well-rooted cuttings obtained by 30 days (right bottom). Photograph courtesy of Teotônio Francisco de Assis.

Genetic Modification and Molecular Breeding

Development of genetically modified (GM) eucalypts has been slow compared with *Populus* species. Traits being considered for modification are no different from those being examined in other forest tree genera. Most transformation has involved marker genes, although genes of commercial significance including herbicide and insect resistance have been stably inserted. Genetic engineering of sexual sterility has been a major focus of research in Australia where eucalypts are native. Transgenic plantlets have been recovered from species such as *E. grandis, E. camaldulensis, E. globulus, E. saligna, E. urophylla, E. dunnii*, and various hybrids of these species. Field trials were established in the UK in 1995 and in Spain, Portugal, and South Africa in 1997. However, the development of fully tested GM clones to the stage of large-scale planting is likely to be a slow process, taking up to 12 years, and owing to regulatory problems research has, for the moment, shifted more towards molecular breeding through marker- or gene-assisted selection.

The first eucalypt gene sequenced was the important lignin gene CAD of *E. gunnii*, published in 1993 by French researchers working at the University of Toulouse. The first genomic maps of *Eucalyptus* appeared in the early 1990s and were based on random amplified polymorphic DNA (RAPDs) which are dominant polymerase chain reaction (PCR) markers or codominant restriction fragment length polymorphisms (RFLPs), and were used to study the genetic control of quantitative traits in species such as *E. grandis, E. urophylla, E. nitens*, and *E. globulus*. There are now hundreds of codominant (more informative) microsatellite loci developed for eucalypts that are transferable across species and have allowed alignment of genome maps from different studies and species. High consistency in marker order (synteny) is being revealed, and generic maps are emerging with candidate genes (e.g., for flowering and wood properties) positioned. Considerable progress has been made toward identifying genomic regions and markers associated with variation in quantitative traits (quantitative trait loci, QTL). QTL have been detected for numerous traits of economic significance including growth, propagation and wood properties, and in several cases these have been shown to colocate with candidate genes (e.g., *cinnamoyl* CoA reductase (CCR) gene with pulp yield, cellulose yield, and lignin quality (S/G ratio)). Research is now focusing on identifying genes and alleles responsible for the variation in traits of economic significance, particularly the highly heritable and expensive-to-measure wood property traits, through QTL and association studies. The next decade will see major advances in our understanding of the eucalypt genome and molecular breeding. There are now several privately owned databases containing partial sequences of many of the genes expressed in various tissues (e.g., cambium) of *Eucalyptus*, microchips have recently been produced to study eucalypt gene expression, and there is growing interest in large-scale sequencing of the eucalypt genome.

Nitrogen-fixing Tree Improvement and Culture

J L Brewbaker, University of Hawaii, Honolulu, Hawaii, USA

Introduction

This review focuses on the genetic improvement and culture of important tree species that fix nitrogen. About 700 tree species are known to fix nitrogen, among approximately 3000 suspected to do so. They represent 11 plant families. Most N-fixing trees (NFTs) are multipurpose and tropical in origin. They are often as valuable as fuelwood, green manure, or forage as they are for lumber or craftwood, and they are cultivated in a great diversity of agroforestry systems. A majority are legumes nodulated by *Rhizobia* or *Bradyrhizobia* bacterial species. However, 10 dicotyledonous families fix nitrogen with the aid of actinomycetes of the genus *Frankia*. Legume trees that fail to fix nitrogen are primarily in the subfamily Caesalpinioideae and include highly selected tropical ornamentals, commonly grown as clones, in genera such as *Bauhinia, Caesalpinia, Cassia, Delonix, Haematoxylon*, and *Parkinsonia*. The great majority of significant NFT species can be thought of as newly domesticated. Only a few NFT genera (e.g., *Acacia, Casuarina, Erythrina, Leucaena, Prosopis*, and *Robinia*) have attracted the investment of provenance collections and strategic plant improvement. The review is in alphabetic order by genus, and within genera by species. An especially useful reference is the book by K.G. MacDicken (see further reading list).

The Genus *Acacia* (Mimosoideae: Leguminosae)

This large genus dominates NFT literature and embraces three great groups of species – about 850 Australian (now assigned by some authors to a genus *Racosperma*), 200 African, and 200 American. Most American species are shrubs and most African species are thorny trees. Diploid species are largely outcrossing, often due to self-sterility, but about one-third of acacias studied are polyploid, and polyploidy in legumes is often associated with self-fertility. Many species of great forestry potential are in early phases of domestication, provenance collection, and evaluation, among them the moist tropical species *A. aulacocarpa, A. cincinnata, A. crassicarpa, A. holosericea, A. leptocarpa*, and *A. polystachya*. Only limited provenance studies or genetic improvement is reported for many important acacias, including the following:

- *A. albida* ($2n = 26$) (= Faidherbia albida): this large, slow-growing tree of dry African tropics is widely distributed for its use as shade and forage on arid lands.
- *A. confusa* ($2n = 26$): 'Formosan koa,' a native of the Philippines and Taiwan, is a small tree grown as fuelwood and as an ornamental and soil-stabilizer, especially on wetter, acid soils. As with many other acacias, some selection has occurred for ornamental use.
- *A. farnesiana* ($2n = 52$): as with other polyploid legume trees, this small, thorny, tropical American tree is widely adapted, self-fertilizing, and often weedy. It has been grown for fuelwood and forage, and provides gum for glue and black dye for ink. It was planted and selected for flowering in France, as the 'cassie' flowers yield a pleasant perfume.
- *A. nilotica* ($2n = 52, 104$): 'Babul' is a thorny Indian and African tree used as firewood, fodder, charcoal, gum, and tannin. A polyploid, it is extremely variable genetically, and several varieties are recognized commercially. These probably include both self-fertile and self-sterile types.
- *A. saligna* ($2n = 26$): this small tree of south-west Australia is highly variable and grows rapidly in a wide range of ecosystems. It provides fodder and fuel and has been planted widely for sand-dune and mine-dump stabilization.
- *A. senegal* ($2n = 26$): this slow-growing, thorny African tree is the source of gum arabic and can be used for fuel, charcoal, and feed. Limited selection has been made to optimize productivity of gum under severe harvest stress conditions.
- *A. tortilis* ($2n = ?$): this thorny, polymorphic African tree (**Figure 1**) provides firewood and fodder in the dry, hot tropics. It tolerates alkaline soils and is often shrubby in growth.

Widely cultivated acacias that have been the subject of provenance and family evaluations and of other genetic improvement include the following species.

Acacia auriculiformis and *A. mangium*

These are related, rapidly growing trees from Australia to New Guinea, whose hybrid is of increasing genetic interest. The former is a smaller, rather crooked tree widely adapted and grown since 1900 throughout the tropics for shade, fuelwood, furniture, and pulpwood. The latter is taller but less forked and has large phyllodes and branches with much fluting; wood is lower in specific gravity. Both are diploids ($2n = 26$) that can be selfed and show low isozymic heterozygosity values, although outcrossing by bees

Figure 1 Naturalized stand of *Acacia tortilis* in Kenya, often coppiced for fuelwood and fodder.

Figure 2 *Acacia mangium* trial in Chumphon, Thailand, age 3 years.

Figure 3 High-value hardwood trials of *Acacia koa* in Hamakua, Hawaii, age 8 years.

occurs (pollen is in polyads). Both can be cloned from cuttings, and both thrive on acidic soils. *A. mangium* (**Figure 2**) was introduced into Malaysia for pulpwood in 1967 (to 25 000 ha) as seeds from a single tree. A broader sample of germplasm was introduced in the 1980s to overcome the loss of form and vigor that occurred due to inbreeding. Extensive provenance collections have been made and evaluated throughout the world for both species. Vigorous hybrids of good form among the two species were then observed and came to dominate scientific interest. As yet the marketing of hybrid seeds or clonal propagules from hybrids is not economic. Provenances from Papua New Guinea have generally dominated yield trials, and growth habit shows startling differences on different sites. Related, interfertile species of interest include *A. aulacocarpa, A. crassicarpa*, and *A. leptocarpa*.

Acacia koa Gray ($2n = 52$)

Koa (**Figure 3**) is a high-value hardwood that is endemic to Hawaii, polyploid, and largely or completely self-sterile. Among 700 accessions evaluated since 1989 in Hawaii, 40 were chosen as parents for seed orchards. Genetic advance through selection was seen in degree of forking, improved bole form, tolerance of koa wilt (*Fusarium oxysporum*), and high wood yield. Seed orchards began bearing in 3–4 years. Genetic advance is sought particularly for tolerance of wilt, a limiting factor in growing koa at lower elevations.

Acacia mearnsii ($2n = 26$)

Australia's black wattle is a temperate tree now found worldwide as a source of tannin (35–40% recovery from bark), fuelwood, charcoal, poles, windbreaks, and other benefits. This self-sterile species is aggressive, however, and can become weedy. Provenance selections in the mid-1900s for high bark tannin contents at the Wattle Research Institute in South Africa (now the Institute for Commercial Forestry) and in Zimbabwe's Rhodesian Wattle Co. led to varieties preferred for production of tannins. Trees were felled after approximately 10 years, selection focusing on rapid growth. Provenance evaluations and plantations for wood also developed extensively in China. Selected provenances also proved of major value in the reforestation of Korea after the Korean war. With the advent of synthetic tannins and leather substitutes, bark tannin production greatly declined. It is agreed that genetic diversity is great and selection for wood productivity could be profitable, but limited investment is currently made in improvement. Related wattle species of less value for tannins include the green wattle (*A. decurrens*) and silver wattle (*A. dealbata*) that have also been planted widely in the tropics.

Acacia melanoxylon ($2n = 26$)

Australian blackwood is a fine hardwood of the quality of kauri or walnut that occurs over a wide latitudinal range on the east coast of Australia. It is noted for its environmental plasticity and for the importance of locally adapted provenance evaluations. It was introduced widely into East Africa and Sri Lanka in the 1950s.

The Genus *Albizia* (Mimosoideae: Leguminosae)

This is a genus of 150 tropical species of trees, shrubs, and lianas. Many have been domesticated and widely planted but little studied for genetic improvement (e.g., *Albizia chinensis* of the Himalayas, *A. odoratissima* and *A. procera* from South and Southeast Asia). Also important but little bred is *A. lebbek* ($2n = 26$), the 'siris tree,' a widely adapted tree evidently native from Africa to Australia. Limited variation among local and very seedy populations suggests that it is self-pollinated, with abundant dried pods that rattle 'like a woman's tongue.' It is used as an ornamental, for timber and fuelwood, and for fodder. The following species have been the subject of some provenance evaluation, selection and improvement.

Albizia falcataria ($2n = 26$)

Also known as *Paraserianthes falcataria,* albizia (**Figure 4**) is one of the fastest-growing trees of the world. This Southeast Asian tree is planted widely in the tropics as a shade tree and favors moist and acid to neutral soils. Its wood is of low density and of low caloric value, but it is used for pulpwood, boxes, and particle board. Varieties have been selected for use as matchsticks and other products in the Philippines, where plantations are harvested on 10–15-year cycles.

Figure 4 Naturalized stand of *Albizia falcataria* on acid soils in Hawaii.

Albizia saman ($2n = 26$) (= *Samanea saman*)

The classic parasol-shaped 'raintree' or 'monkeypod' shares with many legumes a host of Latin and common names. It was distributed worldwide from its Central American center of origin as an ornamental, timber tree, craftwood, and shade tree. It was distributed throughout the tropics from unknown sources and from narrow gene bases, not unlike most tropical trees. Almost no genetic variation occurs, for example, among Hawaii's beautiful, spreading raintrees, that appear to be highly self-pollinated and abundantly seedy in our fuelwood trials. Several accessions of the raintree were included in the gene conservation program of Oxford Forestry Institute.

The Genus *Alnus* (Betulaceae)

This amazingly widespread genus of alders is largely temperate. It includes 35 species, all NFT through association with *Frankia* actinomycetes. They grow rapidly and aggressively (to 30 m in 10 years), and are often considered weeds, although they provide significant soil improvement for forests. Most are $2n = 28$ and outcrossing. Like many NFTs, the alders are widely planted, fully domesticated, poorly represented by forest genetic resources, and managed with little view to genetic improvement. Among these are:

- *A. acuminata*: a Central and South American species planted extensively throughout Latin America for timber and fuelwood.
- *A. glutinosa*: black alder, a widely distributed European species that provided wood for early violins and that is grown as a fuelwood and craftwood and as a stabilizing tree along rivers and roadsides.
- *A. nepalensis*: the Nepal alder of Himalayan origin, planted extensively worldwide for timber, forage, and firewood.
- *A. rubra*: the red alder of northwest North America, a tree up to 40 m tall that is used for construction and furniture, as fuel and in pulpwood mixtures. It can become annoyingly weedy in young stands of pines. As with other alders, the red alder varies greatly in ecosystem adaptability (latitudinal, elevational).

The Genus *Calliandra* (Mimosoideae: Leguminosae)

Most of the 132 species of this predominantly American genus are shrubby, and few enter commerce, but the genus is noted for growth on acid tropical soils. Several are common as ornamental shrubs or trees selected for red, pink, or white flowers, including *C. inaequilatera* and *C. haematoma*.

Calliandra calothyrsus (2*n* = 22)

Calliandra is a small, clonable, rapidly growing tree used less in its native America than in countries like Indonesia, where it serves as fuelwood, green manure, and fodder. It is sparsely seedy due to its nocturnal flowering habit and cross-pollination largely by bats and moths. The US National Academy of Science supported an early publication on calliandra, and Oxford Forestry Institute provided seed collections for >120 international trials of different seedlots and species. Wide variations were recorded in wood yield, branching, and growth habits. Selection in Australia and Costa Rica has focused on variations in fodder utility and digestibility, which are very low in fresh foliage due to high condensed tannin contents.

The Genus *Casuarina* (Casuarinaceae)

This Australian genus is now recognized to include 17 tree species, with about 70 related polymorphic species assigned to the genera *Allocasuarina*, *Ceuthostoma*, and *Gymnostoma*. The true casuarinas are noted for hardwood, fuelwood, and shade on tropical beaches and waterways. Major shelterbelts occur along coastlines in China and in Pacific islands. N fixation is by *Frankia,* pollination is by wind, and some species are dioecious. The species below have been hybridized and evaluated widely in China.

Casuarina cunninghamiana and the related (and cross-fertile) *C. glauca* (2*n* = 18)

These are of less significance as plantation species than *C. equisetifolia*, but their genetic variation is much better studied. *C. glauca* can be weedy due to root-sprouting. These species have a broad ecological range as riverine species of eastern Australia, and extensive provenance collections have been made and studied, e.g., in California, China, and Egypt. Genetic diversity was similar to that of other tropical wood species (0.2–0.3, probabilities that any two alleles are different) with unusually large between-provenance variations. Significant variations are reported in traits like freezing survival, tree height, and diameter. Clinal variations by latitude were very significant. Selected families and species hybrids dominate modern plantings.

Casuarina equisetifolia (2*n* = 18)

The ‘ironwood’ is the most extensively planted casuarina, noted for fuelwood, pulp, and timber, and as a shade tree. Provenance collections are somewhat limited and significant variations occur among them. Clones based on its stately hybrid with *C. junghuniana* (= *C. montana*) are prominent in Thailand and India (**Figure 5**).

The Genus *Dalbergia* (Papilionoideae: Leguminosae)

The ‘rosewoods’ of fame occur among the 100 species of this tropical papilionoid genus of trees, shrubs, and lianas. Many species are known for their high-value hardwood and widely planted, but have been the subject of no major genetic improvement. These include *D. decipularis* (Brazilian tulipwood), *D. latifolia* (Indian rosewood, blackwood), *D. melanoxylon* (African blackwood), and *D. nigra* (Brazilian rosewood). The rosewoods are often endangered by deforestation and major genetic erosion.

Dalbergia sissoo Roxb. (2*n* = 20)

‘Sissoo, shisham’ is a widely planted high-value hardwood endemic to the Himalayas (**Figure 6**). It is also recognized for shade, soil enrichment,

Figure 5 Three years' growth of hybrid *Casuarina equisetifolia* × *C. junghuniana* in Chumphon, Thailand.

Figure 6 Logs of *Dalbergia sissoo* with Director C. Sheikh of Pakistan Forest Institute.

fuelwood and charcoal, honey, and traditional medicines. While it thrives on gravelly outcroppings in the terai at the foot of the Himalayas, it also grows under a wide range of stressing environmental factors, including aridity, mild frost, and very high temperatures. Sissoo is self-fertile but appears to be partially outcrossed in nature and provenance variations are large. Like most legume trees, sissoo is light-seeking and invariably crooked, and genetic variability is high for stem form and growth habit. Estimates of heritability for stem form are high (40–50%) but these assume complete outcrossing. They have led to optimistic projections for expanded use of genetically improved sissoo throughout the tropics, despite its relatively slow growth and lack of institutional investment.

Figure 7 Hawaii's largest tree is the Costa Rican earpod, *Enterolobium cyclocarpum*.

The Genus *Elaeagnus* (Elaeagnaceae)

This European genus includes 40 species of shrubs and trees that fix nitrogen through association with the actinomycete *Frankia*. Similar American NFTs occur in the genera *Shepherdia* and *Hippophae*, often noted as fodder trees but 'armed' with spines for protection. *Elaeagnus angustifolia*, the Russian olive, is commonly cultivated as an ornamental and has been planted widely as a shelterbelt companion of trees that do not fix nitrogen. Selected cultivars and clones are reportedly of better form and appearance.

The Genus *Enterolobium* (Mimosoideae: Leguminosae)

A small genus of five tropical American species, this is related to the genus *Albizia*. A widely cultivated rapidly growing ornamental (**Figure 7**) is the giant, spreading *Enterolobium cyclocarpum*, known as 'guanacaste' or 'elephant's ear.' Like *Albizia saman*, its roots are often superficial and it is undesirable as a street tree. The wood ranges widely in density and quality, and the wood dust causes allergies. Foresters favor trees with dark walnut-like wood, but there is no evidence that these selections are prominent in plantations. Fuelwood plantings in Hawaii (1×1 m spacing) yielded well but showed great intraprovenance variations.

The Genus *Erythrina* (Papilionoideae: Leguminosae)

The 112 species of 'coral trees' are tropical and worldwide in origin, with *E. fusca* native to three continents, its seeds surviving in sea water. Most are small thorny trees with soft wood and high alkaloid contents in leaves. Truly multipurpose but low in value, their uses range from fodder, food, and medicinal to fencepost, shade tree, green manure, and ornamental. Interspecific hybrids were evaluated widely and proved highly interfertile. All appear to be $2n = 42$ and outcrossed by hummingbirds. Many are American in origin, with one endemic to Hawaii, *E. sandwicensis*. *E. abyssinica* and *E. crista-galli* are grown as ornamentals worldwide. Erythrinas are easily cloned from stakes or cuttings. Centro Agronomico Tropical de Investigacion y Enseñanza (CATIE) in Costa Rica maintains a clonal and provenance collection, and the following species are largely grown as locally adapted clones selected for specific use.

- *E. berteroana*: a coral tree that is highly tolerant of aluminous clays, and is often cloned to serve as fence posts in its native tropical America.
- *E. fusca*: the most international species, a classic multipurpose tree. It often serves as shade and green manure for coffee and cocoa and as fenceposts.
- *E. poeppigiana*: a tall South American tree that serves widely as a shade or nurse tree for coffee and as fodder (despite high alkaloid contents).
- *E. variegata* (= *E. indica*): used as a thorny living fence, ornamental, shade for coffee, and support for viny crops. A fastigial, erect cultivar is widely cultivated throughout the Pacific as hedgerows.

The Genus *Gliricidia* (Papilionoideae: Leguminosae)

This small meso-American genus (four species) is known primarily for the species *G. sepium*.

Gliricidia sepium ($2n = 20$)

Gliricidia (**Figure 8**) is a small, rapidly growing, and thornless tree with bright pink flowers in the spring that appear to be entirely outcrossing. It has been spread internationally as an ornamental, green manure, fodder, and firewood tree. The trees clone easily from stem cuttings but develop better roots from seedlings. Planting of gliricidia clones as living fences, as support trees for peppers and yams, and as shade for cacao and coffee, often involves 'seat of the pants' selection of erect, less-forked types. A joint series of provenance collections was made in the 1980s, with inputs from International Livestock Center of Africa, University of Hawaii, Nitrogen Fixing Tree Association, Oxford Forestry Institute, Food and Agriculture Organization of the UN and other organizations. Genetic variations were great both between and within provenances. An outstanding provenance, Tequisate, from Guatemala, was observed in trials from Hawaii and the Philippines to Nigeria. Its superior growth was evident in both fodder and total biomass. Extensive studies were conducted in Nigeria of gliricidia in alley farming systems with crops like maize, and as a leguminous fodder supplement in animal diets. The fresh fodder was not palatable to animals, but palatability increased upon drying, and digestibility of the pure legume was relatively low (55%) but increased when in grass mixtures. Improvement in forage quality with selection was predicted among gliricidia provenances and clones.

Figure 8 *Gliricidia sepium* managed for alley farming trials at Ibadan, Nigeria.

The Genus *Inga* (Papilionoideae: Leguminosae)

Over 200 species of tropical American origin are in this genus of woody shrubs and trees, studied taxonomically by the Oxford Forest Institute. The species *Inga laurina* ('icecream bean') is used as a food and shade tree in Latin America, *I. vera*, *I. edulis*, and others serve variously as shade, fuelwood, and food (sweet pulp), notably on acid soils in humid tropics. Seeds are recalcitrant, restricting the cultivation and improvement of these species.

The Genus *Intsia* (Caesalpinioideae: Leguminosae)

This tropical Asian genus of three species includes *Intsia bijuga* ($2n = 24$), a handsome timber tree called 'ipil' in the Philippines. The hard, rot-resistant timber of this and *I. palembanica* (Borneo teak) are noted for use in decking and truck bodies. Ipil is believed to be highly variable genetically in the Philippines but there is little evidence of selection and breeding. Debate also exists about its ability to fix nitrogen.

The Genus *Leucaena* (Mimosoideae: Leguminosae)

No NFT genus has been selected or bred more extensively than this American genus of 22 species ranging from Peru to Texas, from sea level to 3000 m. Among the fastest-growing trees, all are woody and most will flower the first year. All are polyploids, ranging from $2n = 52$ to $2n = 112$. The predominant diploid species ($2n = 52$, 56) are self-sterile, while three of the four polyploids ($2n = 104$, 112) are self-fertilized. A single self-pollinated variety of the $2n = 104$ species, *Leucaena leucocephala*, circumnavigated the world four centuries ago, accounting for early interest in this model multipurpose tree for agroforestry systems. Cultivation and management systems differ greatly for leucaenas; some are maintained as shrubs for fodder, some as trees for a wide variety of uses. All species have been included in >2500 seed collections made by University of Hawaii, Oxford Forestry Institute and Commonwealth Scientific and Industrial Organization (CSIRO) of Australia, with evaluations in Hawaii, Queensland, and Nicaragua. In Hawaii, 232 interspecific hybrids were made among 16 species, resulting in 77% interfertility. Many of the 73 hybrids grown were heterotic for growth rate and involved attractive combinations of parental traits. Many species are widespread, at least partially domesticated and of use as fodder or fuelwood, e.g., *L. collinsii*, *L. lanceolata*, *L. macrophylla*, *L. shannonii*, and *L. trichandra*. Much current breeding is based on populations from interspecific hybrids, involving taxa such as *L. pallida* ($2n = 104$), *L. diversifolia* ($2n = 104$), and *L. pulverulenta* ($2n = 56$). Species fully domesticated and of breeding interest include the following:

- *L. diversifolia* ($2n = 104$): self-fertile tree of highland Mexico, now widespread, used as coffee shade, fuelwood, and green manure. Fertile hybrids with *L. leucocephala* are being evaluated for timber and fuelwood.
- *L. esculenta* ($2n = 52$): widely grown outcrossing food tree (edible pods) of highland Mexico, also used as shade. Seedless hybrids with *L. leucocephala* are attractive as high-value hardwood, widely adapted in elevation and resistant to psyllid insects.

Leucaena leucocephala ($2n = 104$)

Leucaena leucocephala is the familiar leucaena throughout the lowland tropics on less acid soils, known by a hundred vernacular names. Among 700 international collections of this self-fertile species grown in Hawaii, most were identical seedy shrubs, the 'common type' widely used for fodder and fuelwood in warm tropics. In contrast, seed collections in its native Mexico and Central America range widely in ideotype, including arboreal types from which 'giant' cultivars have been bred and are now international in use. These are distributed largely as pure lines, e.g., K8, Cunningham, K636, and Tarramba, for fodder and wood uses, and are not inclined to be weedy. Hybrids among pure lines show some heterosis, and one F_2 population (K636 × K584) is marketed. However, interspecific hybrids with highland species are of great commercial interest. KX2 derives from the fifth cycle of recurrent selection following the crossing of *L. leucocephala* with a small Mexican tree, *L. pallida*, a self-sterile polyploid that confers resistance to psyllids and to cold weather. Another, KX3 (**Figure 9**), is from hybrids with *L. diversifolia*, described above. An attractive, clonable, seedless triploid hybrid is K1000 (**Figure 10**) showing impressive hardwood quality and growth rate derived from the cross with *L. esculenta*.

Figure 9 High-value hardwood from 12-year old hybrid, *Leucaena leucocephala* × *L. diversifolia*, in Waimanalo, Hawaii.

Figure 10 Seedless triploid clone K1000, *Leucaena esculenta* × *L. leucocephala*, age 7 years, Waimanalo, Hawaii.

The Genus *Millettia* (Papilionoideae: Leguminosae)

This genus of 90 African and East Asian species now embraces the genera *Pongamia* and *Derris,* and includes a number of lesser-known fuelwood and timber trees. The pongam or Indian beech is *Millettia* spp., formerly known as *Pongamia pinnata* and as *Derris indica*. It is a native of East Asia that is now widespread and used in many ways, providing a seed oil as fuel and medicinal, fuelwood, postwood, shade, and ornamental. Profuse root suckers and weediness limit its use.

The Genus *Mimosa* (Mimosoideae: Leguminosae)

Few arboreal species occur in this large genus of 400 species, and these are often thorny and shrubby. *Mimosa scabrella* ($2n = ??$), bracatinga, is an exception. It is a fast-growing Brazilian legume of good form with diverse use as fuelwood, lumber, charcoal, ornamental, pulpwood, and shade for coffee. It is believed to be outcrossing and one study showed wide provenance variations.

Figure 11 Variegated-leaf clone of *Pithecellobium dulce* as ornamental, Honolulu, Hawaii.

The Genus *Parkia* (Mimosoideae: Leguminosae)

Forty species of this genus range from Africa to Southeast Asia, and a few are now worldwide. They are bat-pollinated and probably self-sterile, and have recalcitrant seeds. They are observed to vary genetically, but with no evidence for breeding and selection. Two species are outstanding:

- *P. javanica* (= *P. roxburghii*): an imposing tree to 40 m with umbrella crown, used as ornamental or timber tree, with seeds used medicinally.
- *P. speciosa*: a source of food in Southeast Asia (seeds, from the large pods), known to produce hybrids with *P. javanica*.

The Genus *Pithecellobium* (Mimosoideae: Leguminosae)

The 20 tropical American trees of this genus are largely thorny and best known as sources of sweet fruit. It was earlier treated by early botanists as a much broader taxon, including genera like *Albizia*.

Pithecellobium dulce ($2n = 26$)

Manila tamarind is a thorny American tree up to 15 m tall that can be found throughout the drier tropics (**Figure 11**). Its multiple roles include food use of the pods and seeds, honey, postwood, fuelwood, shade, and ornamental. It is alternately planted and cursed, as its thorns and weediness (seeds are spread by birds) reduce its utility and attractiveness. Variegated mutants are selected as ornamental trees, and thornless mutants (as in *Prosopis*) are known to occur.

The Genus *Prosopis* (Mimosoideae: Leguminosae)

The 44 species of this genus are American in origin, and most are drought- and salt-tolerant, thorny,

$2n = 28$ and self-sterile. They include the mesquites of fuelwood and charcoal fame (*Prosopis glandulosa* in North America) that add flavors to many a grill. They are also known as honey and fodder trees and occasionally provide high-value hardwood. Among species that are fully domesticated and widely planted but little studied genetically are *P. cineraria* (= *P. spicigera*), a widespread Indian tree of the hot tropics used as firewood, fodder, green manure, and charcoal. It segregates for thorns, and thorny trees are favored for goat-proof fences. Also of fame is *P. tamarugo*, a slow-growing Chilean species widely planted locally for its saline tolerance under annual rainfall <100 mm. It has not been adapted effectively outside of Chile. The following two species complexes have been more widely evaluated as provenances or localized selections. However, as with most NFTs, expert panels routinely recommend the increased availability of genetically improved materials, if research money could accompany the recommendations.

Prosopis alba ($2n = 28$) and *P. chilensis*

These are algaroba trees from a related complex largely found in highland subtropics that also includes *P. flexuosa* and *P. nigra*. All serve as sources of honey, firewood, and charcoal, and the sweet succulent pods are used for food and cattle fodder. Seedlot variations are reported for growth rate, limbiness, stem form, and thorniness. Phenotypic selection in natural stands was declared ineffective, due to environmental plasticity, a phenomenon with which all NFT breeders are familiar.

Prosopis pallida ($2n = 28$) and *P. juliflora*

These ($2n = 28$, 56) are two closely related mesquites from Peru north into Central America that are now abundant worldwide; their awkwardly forking trees often dominate arid landscapes and seascapes (**Figure 12**). Known best for their excellent charcoal and dense fuelwood, they were also planted internationally as animal fodder (pods). The wood has very high calorific value (4200–4800 kcal kg^{-1}), and the relatively slow-growing trees offer a durable postwood and an excellent source of honey. *Prosopis pallida* in Hawaii segregates about 1/8 thornless, suggesting single-gene control based on the presumed two-tree origin (introduced from Paris Botanical Garden in 1828). Such a narrow gene base is undoubtedly common in many countries. Trees are coppiceable and cuttings and grafts take fairly well, permitting some use of clones. Thornless trees are universally favored for tropical beaches but do not breed true due to self-sterility. Some selection has also occurred for pod yields, tree form, and growth, but serious genetic improvement awaits financial support.

Figure 12 The Peruvian *Prosopis pallida* dominates Pacific beaches, such as this in Molokai, Hawaii.

The Genus *Pterocarpus* (Mimosoideae: Leguminosae)

Many fine timbers (bloodwood, narra, padouk, Philippine mahogany, vermilion wood) derive from the 20 species of this tropical Indian and African genus of tall leguminous trees. Narra is probably the best known and most widely cultivated. Timber, dye, and shade use are also made of many other taxa, notably *Pterocarpus erinaceus* (kino, Burmese rosewood), also referred to as *P. angolensis* and *P. echinatus*. Other important species include *P. dalbergioides* (Andaman padauk), *P. macrocarpus* (Burma padauk), *P. marsupium* (malabar kino, source of astringent resin), *P. santalinus* (red sandalwood), and *P. soyauxii* (West African padauk). All are characterized by winged pods, presumed outcrossing, clonability, and extensive natural variability.

Pterocarpus indicus ($2n = 22$)

This majestic spreading tree (up to 40 m tall) is known as narra, Burmese rosewood, and Andaman redwood, and is native over a wide ecological range from Myanmar to Borneo and the Philippines. It is cultivated as an ornamental and street tree and is harvested as a choice timber for furniture and flooring. Flowering occurs in short intervals and pod set appears to be due to self-pollination. Much variation is seen in tree form, fluting, forking, and growth rates of narra. Cuttings root easily from trees of all ages and clones have been selected for adaptability to location, ecology, and use. It responds well to deep, high-quality soils of reduced acidity.

The Genus *Robinia* (Papilionoideae: Leguminosae)

Four interfertile species make up this North American temperate genus, a relict of tropical origin related to gliricidia and sesbania that becomes deciduous only upon frost. Like sesbania, it has a unique N-fixing spectrum of rhizobia. The shrubby species *Robinia hispida*, rose acacia, is planted as an ornamental but has little selection history. In contrast, the black locust is among the most intensively studied and bred NFTs.

Robinia pseudoacacia ($2n = 20$)

The black locust (or false acacia) is widely naturalized throughout North America, where the borer *Megacyllene robiniae* has restricted commercial plantings to erosion control, land stabilization, and as postwood. It is nodulated by both *Rhizobium* and *Bradyrhizobium* bacteria and can become weedy. Away from the borer, black locusts have been planted worldwide and cultivated intensively in Eastern Europe as a pulpwood, postwood, and fuelwood tree. Its outcrossed papilionoid flowers also serve as a bee pasture for honey and cultivars have been selected for use as an ornamental. It was introduced to Europe in the 1700s, where 'shipmast locust' arboreal types were selected and grown intensively (250 000 ha in Hungary) as a timber tree on a 30-year harvest cycle. Great genetic variability (average heterozygosity 0.30) and breeding progress were recorded for height, yield, spinelessness, and coppiceability. In contrast, much less variation was observed in specific gravity (average 0.62 at age 20 years). Intensive studies have been made to accelerate planting of uniform clones from vegetative and root cuttings, tissue cultures, and from grafts.

The Genus *Sesbania* (Papilionoideae: Leguminosae)

This genus includes 50 species of shrubs and small trees in the section Robinieae, now scattered worldwide. Most species are annuals, of which many are important as fodder (**Figure 13**) and ornamental. All nodulate aggressively, some having nodules on the stems. A very fast-growing fodder and multipurpose species is *Sesbania sesban* (= *S. aegyptica*; $2n = 12$) a short-lived shrub or tree now planted worldwide, and a similar shrub called 'ohai' is native to Hawaii, *S. tomentosa*.

Sesbania grandiflora ($2n = 24$)

S. grandiflora, called 'agati,' is a small polyploid tree from Southeast Asia or Indonesia with showy flowers that are self-fertile but largely outcrossed. It is planted internationally as a multipurpose tree for fodder, fuelwood, ornamental use and often for food (flowers, young pods, and leaves). It is recognized by farmers as a source of fixed nitrogen and green manure. It coppices vigorously for use as fodder or fuel (fast-burning), and selections have been made for ornamental or food use, e.g., with larger flowers or with red (versus white) flowers.

Figure 13 Forage trials in Maseno, Kenya, of several arboreal and shrubby species of the genus *Sesbania*.

The Genus *Sophora* (Papilionoideae: Leguminosae)

This genus includes 52 species of temperate and tropical origin, several noted as ornamentals or as source of hardwood and of toxic or medicinal chemicals. *Sophora japonica* ($2n = 28$; Japanese pagoda tree) is a large deciduous tree native to China and Korea that has been cultivated for more than 30 centuries in China as an ornamental, dye, and medicinal plant. Flowering begins only on very old trees and the outcrossed flowers cause stains to form where they fall. Genetic variations exploited by horticulturists include weeping, fastigiate, and variegated-leaf trees, and cloning or grafting is common.

The Genus *Tipuana* (Papilionoideae: Leguminosae)

This is a monotypic South American genus with *Tipuana tipu* ($2n = 20$) as the sole species. The 'pride of Bolivia' is a fine timber (rosewood) and ornamental, and is widely planted for fodder, windbreak, and as a street tree to 20 m height in Argentina and Bolivia (to 3000 m elevation). The outcrossed large yellow flowers produce winged one-seeded pods, and it can be weedy. It has an irregular bole similar to most legume trees and it is coppiceable and clonable. Limited studies suggest major provenance variations in ecosystem adaptability (elevation and cold tolerance).

Genetics of Oaks

A Kremer, L A Xu, and A Ducousso, INRA, UMR Biodiversité Gènes et Ecosystèmes, Cestas, France
L A Xu, Nanjing Forestry University, Nanjing, Jiangsu, China

Introduction

Oaks (*Quercus* spp.) belong to the most widely distributed genus of forest trees. Besides their economic and ecologic importance, oaks are also considered in many countries as cultural and patrimonial resources. Despite their value, they have received very little and spasmodic attention in genetic research in comparison to other forest trees. They were some of the earliest species that were investigated for inheritance studies in Europe, but were neglected in genetics for almost a century. The first international conference on oak genetics was organized in 1991, whereas international working groups in conifers had been well established for decades. This conference synthesized the state of knowledge in oak genetics. Over the past 10 years, significant contributions have been made in population and evolutionary genetics of oaks. This contribution adds to the 1991 synthesis the genetic knowledge of oaks that has accumulated over the past decade.

Biogeography

The genus *Quercus* is distributed over the northern hemisphere in Asia, North America, Europe, and Africa. There are more American than Eurasian species. The highest oak species diversity exists at 15–30° N, in Central America and Mexico and in Southeast Asia (Yunnan province in China). Species richness decreases northward and southward from both Mexico and southern China. The northern limit of distribution is at 50° N, except for the European *Q. petraea* and *Q. robur*, which extend up to 60° N. The southern limit of the genus is reached in the southern hemisphere in Colombia and Indonesia, where oak species exist at higher altitudes. Oak species grow from sea level to very high altitudes, up to 4000 m in Yunnan province in China.

Throughout its natural range, the genus has differentiated into numerous species adapted to extremely variable habitats, from swamps to deserts. For example, evergreen species have differentiated under Mediterranean climates as *Q. agrifolia* and *Q. wislizenii* in California, and *Q. coccifera* and *Q. ilex* in southern Europe. Typical examples of extremely wide distribution are *Q. rubra* and *Q. alba* in North America, *Q. acutissima* and *Q. mongolica* in Asia, and *Q. robur* and *Q. petraea* in Europe. In most cases the widely distributed species are those that have received the most intensive genetic studies.

Taxonomy and Phylogeny

Depending on the authors, there are between 300 and 600 reported oak species. Since the beginning of Linnaean taxonomy, classification within the genus *Quercus* has been controversial, and more than 20 classifications have been proposed. Disagreements involve the characters to be used for the classification, the infrageneric subdivisions adopted (subgenera or sections), and species delineation. There is so much variation within some species that several authors have questioned the concept of species, and further complications in taxonomy are due to frequent interspecific hybridization. The most complete classification is that proposed by Camus (1936–1954), which has recently been supported by molecular approaches. Classification criteria are mostly based on foliar and fruit characteristics. In Camus' classification, the genus *Quercus* (*sensu lato*) is subdivided into two subgenera: *Euquercus* (*Q. sensu stricto*) and *Cyclobalanopsis*. About 150 species belong to *Cyclobalanopsis*; these only exist in South Asia, whereas species belonging to *Euquercus* are the more familiar oak species. The subgenus *Euquercus* (now called subg. *Quercus*) has been further subdivided into six different sections by Camus, and into three sections in a more recent review based on phylogenetic inferences of morphological characters. Earlier taxonomists considered *Cyclobalanopsis* and *Quercus* (*sensu stricto*) as two separate genera. Recently taxonomy in the genus *Quercus* has benefited from phylogenetic approaches based on molecular data. Analysis of nuclear and chloroplast DNA sequences showed that the genus was composed of three major clades: *Cyclobalanopis*, *Cerris*, and the remaining three main sections that form one monophyletic group (*Protobalanus*, *Erythrobalanus* (red oaks), and *Lepidobalanus* (white oaks) *sensu* Camus). A major finding of the DNA data in comparison to previous morphological data was the ancient evolutionary separation of *Cerris*.

Genomics

Although a few cases of naturally occurring triploids have been mentioned in the literature, oaks are diploid species, bearing $2n = 24$ chromosomes. Extra chromosomes ($2n = 24 + 1$, 2, or 3) have been reported as consequences of irregular segregation in mitoses. The diploid DNA content per cell is remarkably homogeneous across species and botanical sections, as reported values only vary between 1.88 and 2.00 pg ($= 10^{-12}$ g per cell). The DNA content of two widely separated sections was 1.88 pg for *Lepidobalanus* (*Q. petraea* and *Q. robur*) and 1.91 pg for section *Cerris* (*Q. cerris* and *Q. suber*), and these species are representative of the most widely separated sections (*Lepidobalanus* and *Cerris*). The genome of oak species contains 40% guanine + cytosine (G + C) base composition, which is similar to most higher plants. Genetic mapping in *Q. robur* resulted in 12 linkage groups and a total map length ranging between 1200 and 1800 cM. The map length of the different linkage groups in *Q. robur* varies between 10 and 200 cM. Eighteen percent of the genetic markers used in the mapping study deviated from Mendelian segregation as a result of a high genetic load in the species. The physical characteristics of the oak genome (number of chromosomes, physical and genetic size, genetic map length) are similar to tomato (*Lycopersicon*)! The oak genome is six times larger in physical size and three times larger in genetic size than *Arabidopsis*, the prime model species in plant genomics.

Genomic research has further addressed the molecular differentiation among species and gene discovery. Phylogenetically closely related oak species exhibit limited molecular variation among species, as a result of their interfertility. In the case of *Q. robur* and *Q. petraea*, the interspecific differentiation, regardless of the molecular markers used, is only slightly larger than the intraspecific variation. Hence genomic regions responsible for species variation are extremely rare. As a result of the similarity between genomes, molecular markers as microsatellites could easily be transferred across species and botanical sections.

Evolutionary Biology

Origin and Diversification

Fossil remains of oaks are common and have been discovered on the three continents. Earliest remains found in China, Europe, and North America come from the Eocene. The almost simultaneous appearance of the genus on the three continents has raised the question of its geographic origin and radiation.

Two scenarios were proposed to reconstruct the history of the species. In the first, the genus appeared in Southeast Asia, deriving from a sister genus *Trigonobalanus* during the Palaeocene, and migrated in two directions: to Europe and America via the North Atlantic land bridge before the Eocene, and via the Bering strait after the Miocene. In the second scenario, the genus *Quercus* derived from the widely distributed boreal–tropical deciduous forest that occupied the northern hemisphere at the beginning of the Tertiary. The genus further differentiated as the continents separated further. As a result, oak species arose 'simultaneously' on the different continents and differentiated from the ancestral group composing the boreal–tropical forest. Between the Oligocene and Miocene, oaks diversified extremely rapidly as a response to important climatic changes. Most fossil remains of that period are similar to extant samples. Hence it is believed that most of the extant species already existed at the mid-Miocene.

Postglacial Migration

During the Quaternary, oaks underwent important migrations in response to climatic changes. There were about 17 Milankovitch climate oscillations (alternation of glacial and interglacial periods) when oak species, like other plants, were subjected to successive contractions and expansions of their distributions. A glacial period lasted 50–100 thousand years, whereas interglacial periods were much shorter and lasted 10–20 thousand years. Climatic oscillations were strong selective forces, favoring species that were vagile enough to track their moving habitats. They were most likely responsible for the selection of a reduced number of species that occupy today large continental distributions (*Q. robur* in Europe, *Q. alba* in America, or *Q. acutissima* in Asia). These movements have profoundly influenced the genetic diversity of the species, but in rather different ways between North America and Europe. A large survey conducted recently in Europe comparing the remaining historical footprints (pollen deposits) with genetic fingerprints (chloroplast DNA (cpDNA) polymorphisms) demonstrated how the extant distribution of genetic diversity was shaped by the dynamics of postglacial colonization. At the end of the last glaciations, European oaks were restricted to three major refugia (southern Iberian peninsula, central Italy, and southern Balkan peninsula). As glacial periods lasted up to 100 000 years, species were most likely genetically differentiated among these refugial zones, as shown by the completely different haplotype lineages (=cpDNA variant) occupying these regions. In less than 7000 years (from 13 000 to 6000 years ago), oaks recolonized the majority of their modern ranges. On average, the migration was extremely rapid (300–500 m year^{-1}). Rare long-distance dispersal events contributed significantly to the rapid spread of the species. These dynamics had various consequences for the diversity of the species. Despite the strong founder effects that accompanied the recolonization, oaks were able to maintain high levels of genetic diversity. Although the highest neutral diversity is restricted to the southern areas of Europe, the level of diversity is still important in the central part of Europe, where the different migration fronts originating from the refugial zones merged. However, today's distribution of adaptive diversity is not correlated with neutral diversity; there is no footprint left by the maternal origin on the variation of adaptive traits. Genetic variation for adaptive traits resulted from more recent local selection pressures. Interspecific hybridization was a key migration mechanism as it facilitated the introgression of late-successional species (*Q. petraea*) into the pioneer species (*Q. robur*). The systematic sharing of the same cpDNA haplotype by different white oak species occupying the same stands indicates that hybridization was extremely important during recolonization. Postglacial colonization dynamics in North America were quite different from Europe. Species were not restricted to genetically separated refugial zones. Furthermore, oak stands persisted as low-density populations close to the Laurentide ice sheet. Hence postglacial recolonization was more diffuse than in Europe.

Reproduction and Mating System

Reproduction in oaks can be either vegetative or sexual. Coppicing has been a widely used vegetative system to regenerate oak stands. Stump sprouting is also a natural way of propagation for oaks after forest fires and, when repeated over generations, creates clonal structures in natural stands. The production of root suckers is a less frequent natural means of propagation, but has been reported in *Q. pyrenaica* and *Q. ilex*. Oaks are predominantly monoecious species with distinct male and female flowers, although cases of floral hermaphroditism have been reported. *Quercus* is anemophilous (wind-pollinated) whereas other genera of Fagaceae (except *Fagus* and *Nothofagus*) are entomophilous. There are important differences among species groups in the lag between pollination and fertilization. In the *Lepidobalanus* section (white oaks), acorns mature at the end of the growing season in which the pistillate flower is pollinated. In contrast, in the

Erythrobalanus and *Cerris* sections, fertilization occurs more than 12 months after pollination.

Oaks are also predominantly outcrossing species. All reported values of effective outcrossing rates using the mixed-mating model exceed 0.90. Hence it has often been suggested that a self-incompatibility mechanism existed in oaks, although no experimental data have yet been published on the subject. Mating studies have also indicated that crosses among related trees are rare.

Hybridization

There is much literature on oak hybridization. Hybridization was first investigated by using morphological traits as diagnostic markers, but this has raised controversy as the range of within-species variation of morphological features remains largely unknown. During the past 10 years, gene markers have been applied to study introgression that provided new interpretations on the ecological and evolutionary role of hybridization in sympatric oak species. In two examples, one in European oaks (*Q. petraea* and *Q. robur*) and one in North American oaks (*Q. grisea* and *Q. gambellii*), hybridization was shown to be asymmetric. In the European example, *Q. petraea* preferentially pollinated *Q. robur*, whereas in the other example *Q. grisea* was the predominant male parent. As indicated earlier, asymmetric hybridization can reinforce the succession of species replacing the pioneer species (*Q. robur*) by a late successional species (*Q. petraea*) and is thought to have facilitated the dispersal of species during the postglacial recolonization. The use of molecular markers also permitted estimation of the level of introgression and revisiting of former interpretations of the geographic distribution of hybrids. Occurrence of hybrids has been reported more frequently at the margins of the natural distributions of sympatric species where typical parental habitats are less frequent. The hypothesis of higher fitness of hybrids under nonparental habitats has recently been challenged by an alternative interpretation. In the *Q. grisea*/*Q. gambellii* example, it was suggested that the mate-recognition systems can be impaired under stress conditions prevailing at the margin of a species' range. It was found in this example that the formation of a hybrid zone resulted from the diminishing male function due to environmental stress.

Hybridization in natural stands was further confirmed by artificial crossings. Extensive controlled crossing was done within and between species belonging to the three sections *Lepidobalanus*, *Erythrobalanus*, and *Cerris*. Among the 75 intersectional crosses, only three resulted in viable seedlings (*Q. turbinella* (section *lepidobabanus*) × *Q. cerris* (section *cerris*), *Q. turbinella* (section *lepidobabanus*) × *Q. suber* (section *cerris*), and *Q. turbinella* (section *lepidobabanus*) × *Q. marilandica* (section *erythrobabalnus*)), and were confirmed by segregation analysis of the progeny. Hence hybridization is mostly intrasectional, as has been extensively reported in the *Lepidobalanus* section. Artificial controlled crosses also confirmed the preferential asymmetric crosses between *Q. petraea* and *Q. robur*, and challenged the use of morphological features for hybrid identification. Hybrids resulting from controlled crosses between *Q. petraea* and *Q. robur* exhibited foliar characteristics that were not intermediate between the parental forms, as they resemble more the female parent.

Gene Flow in Natural Populations and Neighborhood Size

Oaks have small pollen grains that can be physically transported over long distances. Physical models of oak pollen dispersal pointed to maximum theoretical distances of several hundreds of kilometers. Investigations on oak pollen production and dispersal in California indicated that pollen grains can be transported at least 16 km. In Finland, at the northern margin of *Q. robur*, pollen grain capture on traps along a gradient was recorded at 7 km from the source stand. However, pollen may lose viability quite rapidly. Effective pollen dispersal has recently been measured using parentage analysis with microsatellite fingerprinting obtained in *Q. macrocarpa* and in *Q. petraea* with *Q. robur*. In both examples, it was shown that more than half of the male parents contributing to pollination of female parents on a 5-ha study stand were actually located outside the stand, and that the mean distance of pollen dispersal exceeded several hundred meters. Although nearest neighbors contributed preferentially to pollination in these two examples, pollen dispersion curves are clearly composed of both a short- and a long-distance contribution, most likely related to different wind-transport mechanisms. These data were obtained in rather dense stands (10–100 trees ha^{-1}), and contrasted sharply with those obtained in a savanna landscape where oak trees are more sparsely distributed. In a pollen-dispersal study of the Californian *Q. lobata* (1–2 trees ha^{-1}), effective pollen flow was much more limited (mean dispersal distance = 65 m) as a result of the low density of trees. There is an important asymmetry between pollen and seed dispersal: the ratio of the number of gene migrants by pollen and seed between populations amounts to several hundreds, even though parentage analysis has indicated that long-distance seed dispersal can also occur. Based on dispersal curves from gene-flow data, attempts were made to estimate neighborhood sizes. In dense stands (100–200 trees ha^{-1}), as with *Q. petraea* and *Q. robur*, the neighborhood size was estimated at 12–20 ha, representing 1200–4000 trees. However, these numbers are lower for more sparsely distributed species, as for *Q. lobata* where a male neighborhood size of 3 ha was inferred.

Genetic Diversity

Genetic variation for morphological and adaptive traits has been investigated in oaks for more than a century. Provenance tests were established in Europe at the end of the nineteenth century, and progeny tests in the 1950s. Similar efforts were made in North America in the second part of the twentieth century. During the past 15 years, genetic surveys have been conducted in many oak species to monitor the level and the distribution of genetic diversity with various molecular tools in response to conservation issues. While investigations of phenotypic traits were mostly concentrated on economic important species for which provenance tests were established, molecular diversity was assessed for a greater range of species.

Diversity of Phenotypic and Adaptive Traits

Levels of diversity Phenotypic and adaptive traits exhibit extremely high levels of diversity, even for fitness-related traits. Heritability values (h^2) were estimated by many authors in progeny and clonal tests for the commercially important species (*Q. petraea, Q. robur, Q. rubra*, and *Q. acutissima*). The highest estimated heritabilities were for phenological characters like bud burst (0.35–0.80) and leaf retention (0.35–0.65), and for wood quality (0.15–0.87). Genetic variability for height growth is extremely variable among species and case studies (in *Q. petraea* estimated h^2 ranges from 0.15 to 0.78, in *Q. acutissima* from 0.43 to 0.44, and in *Q. rubra* from 0.15 to 0.25). Most of the crown-architecture characters of oaks have given low estimates of heritability (<0.05) except for the presence of epicormic shoots (0.38). These heritability values are statistical estimates and their range of variation does not correspond to confidence intervals but rather variation between estimates made among different experiments.

Geographic distribution of diversity Phenotypic traits exhibit important population differentiation but not as much as for the chloroplast genome. However, differentiation values (Q_{st}) reach 0.06–0.6 for height and phenological traits in *Q. petraea*. Geographic trends of variation exist for phenological growth, and form traits. Geographic gradients are, however, most evident in phenological traits (dates of bud break and growth cessation). In the European species, *Q. petraea*, there is a clinal trend of variation with latitude and altitude, with southern origins flushing earlier than northern origins; these trends are consistent across the different, widely scattered provenance tests that were established. In the widely distributed American species, *Q. rubra*, there are contrasting patterns depending on the site where the provenance test was established. Longitudinal clines were observed in tests planted in Nebraska whereas an altitudinal cline was found in tests established in Tennessee. These trends are different from those observed in widely distributed north temperate conifers, suggesting that not only climatic factors may impose selection pressures, but most likely also biotic factors, such as defoliating insects. For other traits such as growth and form, no consistent geographic gradient of variation was observed in either American or European species.

DNA and Protein Diversity

Levels of diversity There is now evidence that, in respect of their DNA features, oaks are among the most diverse species of forest trees. This is particularly so for species with large continental distributions, such as *Q. robur* and *Q. petraea* in Europe, *Q. macrocarpa* in North America, or *Q. acutissima* in Asia. These can exhibit high levels of heterozygosity both within a population and throughout their ranges. For microsatellites, the number of identifiable alleles present at a locus within a population can frequently exceed 20. There is also evidence that levels of diversity differ between the two major botanical sections: white oaks (section *Lepidobalanus*) are more variable than red oaks (section *Erythrobalanus*), as shown by a comparative allozyme analysis between these two sections. High levels of diversity are most likely due to the maintenance of large population sizes, the ability for long-distance gene flow, and prevalent interspecific hybridization. Long generation intervals may be advocated for managing oak populations, to minimize the allele losses associated with genetic drift.

Geographic distribution of diversity Most nuclear genetic diversity resides within populations, as is usual for wind-pollinated species. With a few exceptions, genetic differentiation among populations (F_{st} or G_{st}, which are analogs of Q_{st}) is less than 10%. Earlier results obtained with allozymes were confirmed by other molecular markers, random amplified polymorphic DNA (RAPD), amplified fragment length polymorphisms (AFLPs), or microsatellites (simple sequence repeats). As for the level of diversity, substantial pollen flow, large populations, and long generation intervals may account for these results. The geographic distribution of genetic diversity of chloroplast genomes is strikingly different from those of nuclear markers. Oak stands tend to be completely fixed within populations for the chloroplast genome but fully differentiated among stands. Hence differentiation values (F_{st} or G_{st}) in most cases exceed 0.80. The discrepancy between nuclear and chloroplast genome differentiation is due to their different inheritance. As chloroplast genomes are maternally inherited, and as seed exhibits restricted dispersal, diversity within a stand rapidly becomes eroded as a result of stochastic effects. These trends are facilitated during the initial establishment of the stand, which is often associated with low population sizes due to founder effects. Fixation of chloroplast genomes is enhanced by the limited number of founder individuals and the restricted dispersal of seed. When these mechanisms are extended to larger geographic scales, they lead to strong geographic patterns of cpDNA diversity that reflect the colonization dynamics of the species, resulting in strong phylogeographic structures. In conjunction with historical records gathered from fossil pollen, phylogeography of cpDNA permitted reconstruction of postglacial colonization pathways of oaks throughout Europe.

Genetic Improvement

Oaks have several features that limit operational breeding. Besides the biological constraints of longevity, such as delays in the onset of flowering, and the impossibility of seed storage, the uncertainty of long-term breeding objectives makes the implementation of improvement programs economically questionable. Hence research in breeding and improvement has been much less intensive than in shorter-rotation species, even for highly valuable tree species. The general understanding is that tree improvement would be a rather risky initiative for such long-lived species and that research in genetics should be oriented towards a sustainable management of oak stands rather than to the improvement of the existing resources by breeding and selection methods. Hence objectives of tree improvement initiatives were limited to the selection of seed stands, or the installation of first-generation seed orchards.

Europe

There is a long tradition of oak improvement in Europe, although it has not taken the typical form of a modern tree-breeding program. In the Netherlands, it was traditional to raise *Q. robur* for several years in the nursery and to select for stem form. These procedures resulted in the selection of various cultivars that were used in horticulture. Classical tree breeding started in the early 1950s in Germany, and even earlier in Eastern European countries when the earliest plus-tree selection was done and clonal seed orchards were established. Ongoing activities in tree improvement are being conducted on three species: *Q. petraea*, *Q. robur*, and *Q. suber*. For these species, European countries have selected seed stands which are clustered in provenance regions following European Community regulations on reproductive material. For *Q. petraea* and *Q. robur*, progeny tests associated with seed orchards were installed in Belgium, Croatia, Denmark, Hungary, Germany, Ireland, Lithuania, Netherlands, Slovakia, Ukraine, and the UK. Objectives of improvement are wood quality (including the quality of cork for *Q. suber*), stem form, and adaptation to the site. Research to solve the problems posed by the poor storage ability of seed was also pursued. Besides improvement of seed-storage protocols, techniques were developed for vegetative reproduction either by traditional cutting propagation or by using *in vitro* techniques and somatic embryogenesis.

North America

At the first international conference on oak genetics held in 1991, 27 ongoing oak improvement programs were reported on a total of nine species (*Q. alba, Q. falcata, Q. macrocarpa, Q. nigra, Q. phellos, Q. prinus, Q. robur, Q. rubra*, and *Q. velutina*). These programs were mainly conducted by public agencies and institutions in the eastern USA, whereas two projects in Canada were mentioned. In this period, some of the oldest provenance and progeny tests were established for *Q. rubra*. Objectives of breeding programs were timber and veneer for *Q. rubra* but more generally, juvenile growth and plantation success. Other objectives were also pulp production or use as shelterbelts (for *Q. macrocarpa* in the Great Plains). Breeding efforts varied from only plus-tree selection (in about half of the programs) to also producing seedlings or clonal seed orchards. However, owing to the decline of oak plantations and to reduced public budgets (national or state agencies), these projects have all been reduced in the past 10 years. Recent initiatives have, however, revitalized tree improvement activities in northern red oak, such as the creation of the Hardwood Tree Improvement and Regeneration Center (HTIRC) in Purdue (Indiana). HTIRC aims to improve the genetic quality and regeneration of *Q. rubra* through application of classical breeding, genomics, and advanced propagation technology.

Exotics

Oaks have been transferred to various regions in the world. Red oaks from the eastern USA have been introduced in Europe, and *Q. rubra* is currently used throughout western Europe, not only as an ornamental tree but also as a plantation species for veneer or timber production. Hence tree improvement activities in *Q. rubra* were implemented in France, Germany, and the UK, starting with the installation of combined provenance and progeny tests. As the introduction in Europe began at the end of the eighteenth century, there have been only a few generations since the species was introduced in Europe but landraces (a landrace is a population that became adapted in a new environment to which it was transferred) have already been genetically differentiated in Europe. Similarly, *Q. robur* was introduced in many countries throughout the world, but no genetic improvement program has been reported outside its natural range and Europe.

Pinus radiata Genetics

R D Burdon, New Zealand Forest Research Institute, Rotorua, New Zealand

Introduction

Pinus radiata is arguably the most domesticated of all forest trees. It is grown in exotic plantations occupying over 4 million ha, an area roughly 500 times its natural extent. Overall these plantations are highly productive, and many are intensively managed. Associated with the intensive management, several large-scale, intensive genetic improvement programs have developed, which have prompted a large volume of genetic research on the species. Indeed, this genetic research, and commercially motivated research on most other aspects of the species' biology, have led to the species assuming the role of a model species for research into forest trees. The genetics of the species are of twofold interest. On the one hand, the story typifies that of many conifers, and pines in particular, in respect of karyotype, genomic characteristics, and genetic system in general. On the other hand, there are a number of features that are highly distinctive of the species. Notable among these are the biogeography, with five discrete natural populations that are differentiated by a combination of adaptive features and apparent founder effects, and the conspicuously high level of functional genetic variation from tree to tree. Intensive genetic improvement began from around 1950, and is now being pursued at varying levels of sophistication in at least five countries. It has delivered major genetic gains, in growth rate, tree form, and disease resistance. Improvement work is shifting in emphasis towards improving wood properties, while differentiated breeds are being developed. Challenges remain in the management of gene resources.

The Genetic System

Breeding System

Like almost all pines (*Pinus* spp.), *P. radiata* is an outbreeder. Effective self-fertility, reflected in filled seed produced upon selfing, is very incomplete, but highly variable from tree to tree. This is consistent with the postulated mechanism of a fairly high 'load' of recessive embryo lethal genes, combined with the archegonial polyembryony – with this polyembryony, the set of viable seed can be much higher than the percentage incidence of viable zygotes resulting from inbreeding.

The viable offspring produced by self-pollination show, on average, marked inbreeding depression, with poorer growth and competitive ability than outcross progeny. This inbreeding depression reflects sublethal deleterious recessive genes. It varies markedly according to parents and individual offspring. This variability, in both effective self-fertility and inbreeding depression in viable offspring, is consistent with random variation among parents in the load of deleterious recessive genes.

Matings between relatives that are less extreme than selfing also cause inbreeding depression, roughly in proportion to the relatedness between the seed- and pollen parents.

Seed collections made from natural stands show appreciable inbreeding depression, resulting from neighborhood inbreeding whereby neighboring trees tend both to be related to each other and to interpollinate. In plantations, the natural neighborhood structures are typically broken down, and seed collections from plantations show negligible signs of inbreeding. Self-thinning evidently eliminates inbred individuals preferentially during the life of a natural stand.

Genomic Characteristics

Pinus radiata is strictly diploid with a haploid chromosome number of 12. Any departure from the diploid state evidently reduces natural fitness to zero. Regarding the karyotype, the chromosomes are extremely large, all of similar size and metacentric, with only subtle distinguishing features. In these respects the species is typical of pines (*Pinus* spp.) in general, and also of most other conifer genera.

In keeping with the size of the chromosomes, the genome is enormous, around 2×10^{10} basepairs, but over 95% noncoding. However, despite the extremely stable karyotype, it appears that there is a relatively high mutation rate, judging from the level of the genetic load and the general sensitivity of pines to gamma rays. In keeping with the genomic stability, DNA analysis has revealed a very high level of homologies, in respect of functional genes and their loci within chromosomes, between *P. radiata* and *P. taeda*, which has become another main 'model-species' pine.

Crossing-over of chromosomes in meiosis is high – estimated map length is around 1800–2000 centi-Morgans – and is evidently slightly higher in male than female meiosis.

Genetic Architecture

Taxonomic Position and Crossability

Pinus radiata belongs within the subgenus *Pinus* (syn. *Diploxylon*) or the 'hard pines.' It has recently been assigned to a section Attenuatae van der Burgh (the 'California closed-cone pines') which has recently been separated from the section Oocarpae, which now comprises a group from Mexico–Central America. Within the Attenuatae, it is readily crossable with *P. attenuata* and moderately crossable with some southern populations of *P. muricata*, but tends to be reproductively isolated from both species by pollination season and distance. However, there is one area where hybrids with *P. attenuata* occur naturally, but without conclusive signs of long-term introgression. *Pinus radiata* is also known to be weakly crossable with three or four members of the Oocarpae.

Population Differences

The pattern of natural population differences reflects the distinctive natural distribution. The species occurs in just five discrete natural populations (**Figure 1**). While all populations exist in a particular variant of a Mediterranean climate, created by a cold ocean current reducing summer temperatures and causing summer sea fogs, the habitats of the populations differ significantly (**Table 1**). In addition, the geographic separation between populations varies widely. In keeping with that, the degree of taxonomic separation varies. The southernmost populations, from Cedros and Guadalupe Islands, are recognized as separate varieties, vars *cedrosensis* and *binata* respectively, both having their needles usually in pairs rather than threes. The three northern populations, on the mainland, are assigned to var. *radiata*; that from Cambria is apparently the most distinct.

Chemotaxonomic information is very incomplete, but it serves to reinforce a picture of highly multidimensional differentiation among the various natural populations. In this pattern, the apparent affinities between individual populations can depend greatly on the trait in question, such that many traits have to be considered simultaneously, preferably in common-garden experiments, for the overall pattern to become clear. However, immunoassay techniques have been used to give a measure of genetic distances between populations, with results that generally match the classical taxonomic picture.

The populations differ not only in traditional taxonomic traits and phytochemistry but also in tree morphology, growth rate, site tolerances, and pest and disease resistance (which are often the effective manifestations of site tolerances).

Some population differences for morphological traits, turpentine composition, and wood density are summarized in **Table 2**. Corresponding differences in growth rate, site tolerances and disease and pest resistance are summarized in **Table 3**. In some morphological features, such as cone size and branching pattern, marked population differences are superimposed upon large tree-to-tree differences. However, for needles per fascicle (except on vigorous shoots of young trees) and bark thickness (except in old trees), tree-to-tree differences are totally subordinate to population differences.

The pattern of population differences can in part be interpreted in terms of adaptation to the different environments. For example, the strong taproot development of the Cedros population, and to a lesser extent the Guadalupe population, are presumably an adaptation to more intense drought on the islands. The greater palatability of Guadalupe to browsing animals can be readily interpreted as reflecting a lack of browsing mammals on the island. However, there are other population differences that are difficult to interpret as being adaptive. It therefore appears that some of the differences reflect founder effects and genetic drift occurring in the processes of colonizations, local extirpations, and coalescences that evidently resulted from climatic fluctuations and eustatic sea-level changes that have occurred since the Pleiocene.

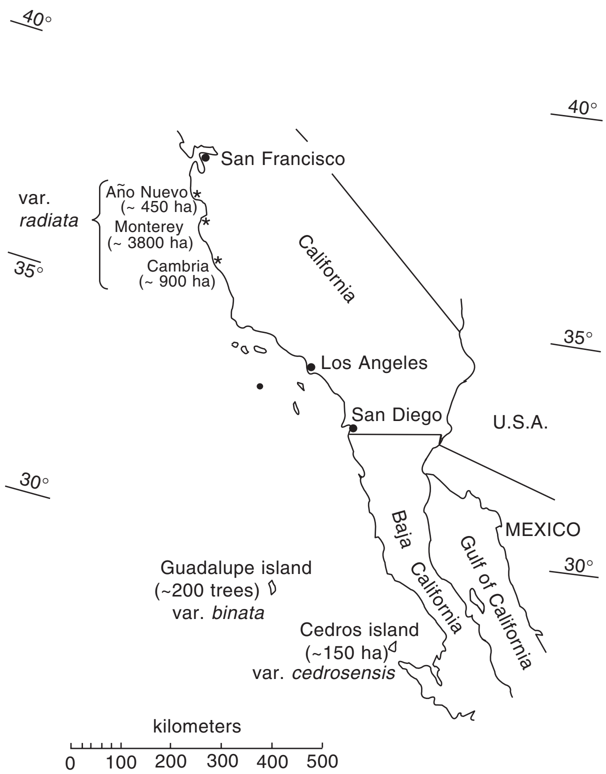

Figure 1 Map showing natural distribution of *Pinus radiata*. Current extent is shown for each population, being reduced by urbanization at Monterey and Cambria and grossly reduced on Guadalupe island. Adapted with permission from Burdon RD (2000) *Pinus radiata*. In: Last FT (ed.) *Ecosystems of the World*, vol. 19. *Tree Crop Ecosystems*. Amsterdam, The Netherlands: Elsevier.

Marker and Genomic Differentiation

Some strong population differences exist within *P. radiata* with respect to the standard isozyme systems, in contrast to the norm of isozyme variation within species being almost entirely among individuals within populations. Indeed, there are electromorphs that represent high-frequency private alleles for some of the populations. Actual DNA marker differentiation has not been studied thoroughly. Markers (simple sequence repeats or SSRs) have been developed that give excellent 'fingerprinting' of individual genotypes and pedigree verification, but such markers, because they are so polymorphic within populations, are inherently unsuited to differentiating among populations. Thus, while populations will surely be differentiated by DNA markers,

Table 1 Natural occurrence and habitats of *Pinus radiata*

Population	*Latitude (°N)*	*Altitude (m)*	*Exposure*	*Rainfall (mm)*	*Geology/soil*	*Extent (ha)*	
						Historic	*Current*
Año Nuevo	37	0–330	Very varied	675–900?	Argillite-derived, slightly calcareous	450	450
Monterey	$36\frac{1}{2}$	0–420	Generally moderate	400–650?	Very varied geology and soils	7400	3800
Cambria	$35\frac{1}{2}$	0–180	Varied	450–575?	From single sandstone formation	1400	900
Guadalupe	29	330–1200	Severe	150–500?	Basaltic, rocky	250?	200 trees
Cedros	28	380–640	Locally severe	150–250?	Skeletal, old sediments and metamorphics	150	150

there are not yet the markers identified whereby a tree can be assigned unequivocally to a single native population, let alone to its correct hybrid ancestry.

Within-Population Genetic Variation

Tree-to-tree genetic variation, both visible and cryptic, is a striking feature of *P. radiata*, which has led to much past confusion among taxonomists. Cone size and shape show much variability, which is superimposed upon the considerable population differences. Dramatic variation exists in branching pattern (**Figure 2**), with neighboring trees often ranging from being monocyclic or uninodal (with only one cluster of branches produced in a year's growth on the leader) to highly polycyclic (with up to six such clusters); this variability is of profound importance for breeding programs and wood utilization. Considerable tree-to-tree genetic variation is also evident for growth rate, resistance to some diseases, stem straightness, a wide range of wood properties, turpentine composition, rate of onset of

(a) (b)

Figure 2 *Pinus radiata* trees of contrasting branching patterns. (a) This tree has a highly polycyclic (or multinodal or short-internode) branching habit, producing several quite closely spaced branch clusters on each year's growth of the leader. In consequence, the branches are relatively small, giving a dispersed pattern of knots in timber, which favors producing structural grades. It is usually associated with less susceptibility to malformation and often better straightness and faster growth, at least early in the rotation. This sort of habit has been favored for the main breeding programs of New Zealand and Chile. Preferable for structural timber, it requires pruning in order to produce clear timber, which has been widely practiced in New Zealand. (b) This tree has an essentially monocyclic (or uninodal or long-internode) branching habit. The branches are large and steep-angled, but clearcuttings can be obtained between branch clusters without pruning. Prone to malformation and general poor form on many sites, this habit has been pursued in a subsidiary breeding program in New Zealand to produce a long-internode breed. This variation is strongly heritable, with the two trees representing extremes of an essentially normal distribution. For many sites, the ideal might be two co-equal branch clusters per year's leader growth, but that can only be expected reliably through mass propagation of well-proven clones. Courtesy of New Zealand Forest Research Institute Ltd.

some adult characteristics, and soil tolerances. Soil tolerances can generate substantial genotype–site interactions among phosphorus-deficient sites and elsewhere.

Estimated heritabilities and additive genetic coefficients of variation (which between them encapsulate the scope for genetic improvement) are shown for a range of traits in **Table 4**. While some of the values relating to branching pattern and cone characteristics may be exceptional, those for other traits seem fairly typical for the genus. For many additional wood properties only broad-sense estimates are available; while generally very high, they are unlikely greatly to exceed narrow-sense heritabilities. Some of the wood properties, e.g., grain spirality and percentage heartwood, can show very high coefficients of variation, but such figures need to be interpreted with caution. As always, heritabilities for individual traits can depend, to varying degrees, on both the populations and the environments.

Relatively few between-trait genetic correlations are known at all well (**Table 5**), although, as with heritabilities, the values may vary according to both population and environment. Those best known involve positive associations between growth rate, frequency of branch clusters, light, wide-angled

Table 4 Estimated heritabilities and phenotypic coefficients of variation among individuals within base populations in *Pinus radiata* for different traits, together with likely economic significance for genetic improvement

Trait	*Heritability*	*Coefficient of variation (%)*[a]	*Economic significance*
Turpentine composition	>0.9		Negligible
Wood density (cores or disks)	0.7	7	Sometimes major
Cone characters[b]			
Volume, seed weight	>0.5	20–35	Minimal
Length, shape, scale no.	>0.5	12–18	Minimal
Grain spirality	0.3–0.7	~45	Sometimes major
Branch clusters on bole	>0.5	20–30	Often high, but indirect
Stem sinuosity[c]	0.4		Not major (−ve)
Wood density (penetrometer or torsiometer measurements)	0.3–0.4		As for wood density
Branching habit overall[c]	0.3		Generally high
Height to first cone	0.3	20–30	Little direct importance
Dothistroma attack[c]	0.3		Locally major
Cyclaneusma needle cast[c]	0.1–0.35		Considerable (−ve)
Branch angle (steepness)[c]	≤0.2		Considerable (−ve)
Height	0.2	12	Limited in itself
Stem diameter	0.1–0.3	15	Major
Stem volume	0.1–0.3	30	Major
General stem straightness[c]	0.1–0.3		Generally major
Branch diameter	0.2		Major (−ve)
Frost resistance (growth room)	0.2		Minor overall
Butt sweep[c]	0.1–0.2		Often major (−ve)
Forking, etc.	0.05–0.1		Major (−ve)
Wind damage	0.05		Locally major (−ve)
Leader dieback	0.05		Sometimes important

[a] Where measurement scale allows valid estimate.
[b] Broad-sense heritability, instead of narrow-sense, but unlikely to be much greater than narrow-sense.
[c] Based on visual scores, with observer error depressing effective heritability values.

Table 5 Approximate values of the better-estimated between-trait genetic correlations in *Pinus radiata*

	Height	*Wood density*	*Stem straightness*	*Branching frequency*	*Forking (incidence)*	*Branch diameter*	*Branch angle*
Stem diameter	0.7	−0.2 to −0.4	0.1	0.15–0.45	0.1		0.1
Height		0.15	0.2	0.2–0.45	0.35		0.25
Wood density			0	−0.05	0		
Stem straightness				0.4	0.5		0.15
Branching frequency					0.3–0.5	0.75	0.6
Forking						0.3	0.4
Branch diameter							0.65

Note: Positive signs denote favorable genetic correlations in relation to ideal of fast growth, high wood density, small, wide-angled branches, zero forking, and polycyclic (multinodal or short-internode) branching habit. Hence there are a number of adverse correlations in relation to an ideal of long internodes that would allow significant clear cuttings without pruning, more so on some sites than others.
After Burdon RD (1992) Genetic survey of *Pinus radiata*. Parts 1–9. *New Zealand Journal of Forestry Science* 22: 275–298.

branching, stem straightness, and freedom from malformation, and a negative association between wood density and stem diameter. Significant constraints therefore face the breeder in trying to pursue long internodes (which offer clear cuttings without pruning) along with improved growth and form, or both increased wood density and volume production.

Genotype–environment interactions are evident in respect of both variation among sites in expression of genetic variation and rank changes among sites in performance of genotypes. Differences in tree form can be more strongly expressed on fertile sites. Rank changes are strongly evident between phosphorus-deficient sites and elsewhere (pointing to genetic variation in tolerance of this deficiency) but otherwise tend to be limited.

Within-population variation in genetic markers (isozymes, restriction fragment length polymorphisms

(RFLPs), randomly amplified polymorphic DNA (RAPDs), amplified fragment length polymorphisms (AFLPs), SSRs) is significant, but it does not stand out from other conifer species in the way that much of the morphological variation does.

Early Domestication Genetics

Domesticated stocks of the species have arisen since the species was first introduced as an exotic, around 1850–1860 for South Africa, Australia, New Zealand, and Spain, and in 1885 for Chile. New Zealand evidently became self-sufficient for seed by the early 1880s, and made significant exports of unimproved seed to South Africa at least in the 1920s and to Australia until the middle of the twentieth century. Documentation of follow-up seed importations by Chile and Spain has not been traced. It appears that the two northernmost of the natural populations, Año Nuevo and Monterey, have been the progenitors of almost all the domesticated stocks, with a disproportionate contribution from the small Año Nuevo population. For many purposes these are the natural populations that are best adapted to the exotic environments, but even broader adaptation can presumably be obtained from drawing germplasm from the other populations.

While domesticated stocks may have come from a very incomplete and unbalanced representation of the natural range, seed importation records for New Zealand and genetic evidence indicate a fairly broad ancestral base in terms of numbers of individuals.

Even before intensive breeding began, some genetic improvement occurred in a process of landrace development. Release from the 'neighborhood inbreeding' of natural stands has evidently been a positive factor. There have also been some genetic shifts in response to pressures of natural and silvicultural selection in the adoptive environments, although it is difficult to quantify these shifts accurately. Heterosis, or hybrid vigor, from crossing between two natural populations, has been postulated but not proven.

Intensive Genetic Improvement

General History

Pioneering research on genetic variation in *P. radiata* began in Australia during the 1930s, under the auspices of the (Commonwealth) Forestry and Timber Bureau, Canberra. Intensive breeding programs began in New Zealand, Australia, and South Africa in the 1950s. These were based on local stocks, in the belief that provenance variation would not be important. This decision was put to the test in parallel or subsequent provenance or provenance/progeny trials. In fact, it proved to be justified, despite initial underestimation of provenance variation and the likelihood that additional germplasm from the natural range could bring long-term benefits. However, some of these benefits may only be realizable in segregating generations, after the F_1.

Improvement began with very intensive selection of 'plus trees,' mainly in commercial stands (**Figure 3**). Selection criteria varied significantly among agencies according to perceptions of whether growth rate or form was the higher priority for improvement. The plus trees were grafted into archives prior to establishing grafted clonal seed orchards. This put tree breeders on a long 'learning curve' in the siting, establishment, and management of the orchards. Difficulties arose with delayed incompatibility of grafts (or else obtaining cuttings from postjuvenile trees), achieving good pollen isolation, and with seed yields.

An interim improvement measure, pending self-sufficiency for orchard seed, has been collection of seed from the best trees in stands, either at felling or on standing trees. This was much helped by the serotinous cones which could store several years' seed crops on the trees. In addition, progeny trials were available as back-up seed sources.

Figure 3 One of the original *Pinus radiata* plus trees selected in a closed stand in New Zealand, shown well after the selection age. The outstanding vigor of this parent ('Clone 55') characterizes almost all its progeny. The wood of the progeny, while of low density, has some very desirable technical properties. Courtesy of New Zealand Forest Research Institute Ltd.

Progeny testing was embarked upon from the outset, with varying thoroughness and success. However, it became appreciated, by the late 1960s, that the extremely intensive selection of plus trees left little scope for reselection on the basis of progeny-test information, and severely restricted the genetic base for long-term breeding. Further selection of first-generation plus trees was done, making vastly more selections.

Despite the technical problems, clonal seed orchards came close to meeting planting requirements, and actually exceeded them in some areas. However, the slow and incomplete capture of genetic gain prompted the development of new delivery systems. Selection of orchard sites was greatly improved. Hedged seed orchards were adopted in some quarters, which allowed controlled pollination with full capture of genetic gain and greater flexibility, and they are easier and safer to manage and harvest. Other types of orchard that allow controlled pollination have also been developed (**Figure 4**). Vegetative multiplication of small amounts of top-quality seed is a slightly more recent development that can further speed up the capture of genetic gain. It is being done on a large operational scale using nursery cuttings, and on a smaller scale using tissue-culture plantlets, while embryogenesis from seed embryos is being pursued. Embryogenesis, while more difficult to achieve in pine than in spruces (*Picea* spp.), offers a platform for future genetic transformation. Clonal forestry, based on mass propagation of well-characterized, intensively select clones, is being pursued by a few agencies, and is close to being fully developed, although there still remain some problems of long-term storage of clones to retain full vigor and ease of propagation.

Figure 4 Clonal seed orchard of *Pinus radiata* designed to produce seed of superior genetic quality by controlled pollination. This is one of several types of orchard that has been developed to avoid the operational problems of producing seed on tall, tree-form grafts or cuttings, and is an adaptation of the meadow orchard system of producing apples. A site has been chosen that favors early and profuse seed production on the grafts. Often such seed is now produced in limited quantities for mass vegetative multiplication, still mainly by nursery cuttings. Courtesy of New Zealand Forest Research Institute Ltd.

As befits the species' commercial importance and its model-species status, it is the subject of a full-scale genomic sequencing project, but the information is proprietary.

Early improvement work was directed mainly at improving growth rate and tree form, in varying emphasis on the two. Genetic gains achieved have generally been large (**Figure 5**), typically reflecting

Figure 5 Trees of *Pinus radiata* produced by early pair-crossing between intensively select parents on a very high-quality site in New Zealand. Tree form is strikingly good for the site and stocking. Planted at 750 stems ha^{-1} in pasture, and thinned at age 8 to 215 stems ha^{-1}, 18-year predominant mean height was 33.5 m, mean breast height diameter 54 cm, with 480 m^3 stemwood ha^{-1}. The better pair-crosses of similar material, kept at higher stockings but on a similar site, gave mean annual increments approaching 50 $m^3\,ha^{-1}\,year^{-1}$ at age 27, compared with an expected value of 30–35 $m^3\,ha^{-1}\,year^{-1}$ for unimproved stock. With large genetic gains achieved in growth and tree form, attention is shifting to improving wood properties to help produce high-quality raw material on short rotations. Courtesy of New Zealand Forest Research Institute Ltd.

the relative emphasis on growth and form respectively. Since then there has been some focus on resistance to needle-cast diseases, with local or sporadic efforts directed at resistance to some other diseases. More recently has come increasing emphasis on improving wood properties (**Figure 6**), to offset the impacts of various measures that cut effective growing costs, viz. shorter rotations, fertilizer use, heavier thinning regimes.

Genetic Improvement in Individual Countries

New Zealand The breeding program was initiated by the Forest Research Institute (FRI) within the New Zealand Forest Service. FRI also conducted associated research, gathering up some earlier work. A national program was effectively operated until 1987, when the Forest Service was dissolved. Following that, the New Zealand Radiata Pine Breeding Cooperative was created, with FRI doing the breeding and genetic research, but with increasing in-kind contributions from member companies after corporatization and then privatization of Forest Service plantations. Cooperative members have come to include some from Australia, the Forestry Commission of New South Wales and some smaller concerns. During 2000–2002, the Cooperative became a limited-liability company. In the meantime, some companies have developed their own propagation and clonal programs as their own intellectual property. In 2003 a decision was made to terminate state funding of breeding and gene-resource work and immediately associated research.

Intensive plus-tree selection began in the early 1950s, for establishing regional seed orchards, although the regionalization proved to be unnecessary.

Figure 6 Sampling a *Pinus radiata* candidate for selection for determining several key wood properties by taking a core of 12 mm diameter. Courtesy of New Zealand Forest Research Institute Ltd.

The first block of orchard was planted in 1958, to start producing seed in 1968. Orchards produced enough seed for the whole country by 1986. Since then, control-pollinated orchards have become predominant, with considerable vegetative multiplication. Fully clonal systems, while still hampered by imperfect control of maturation, are being implemented on a significant scale by two companies.

Following the initial round of plus-tree selection, many more first-generation plus trees were selected in 1968–1970, to give a broadly based breeding population, with a further round during 1984–1987.

Selection was initially for growth and form, arriving at a strongly polycyclic (or multinodal or short-internode) ideotype (**Figure 2a**), although a side-program pursued a long-internode ideotype (**Figure 2b**) as an insurance. Recently a portfolio of differentiated breeds has been created, to serve different sites and end-uses as well as addressing market uncertainties.

Australia Although the federal organization (Forest and Timber Bureau, later the Division of Forestry and then Forestry and Forest Products) of the Commonwealth Scientific and Industrial Research Organisation (of Australia) (CSIRO) started the research, breeding programs began under the auspices of individual states and Australian Capital Territory (ACT). Of the states, New South Wales, Victoria, and South Australia had a major involvement in the species, with lesser involvements on the part of Western Australia, ACT, Tasmania, and Queensland. All the states and ACT began intensive breeding by 1960 or soon after, with two programs in Victoria, although some programs have effectively lapsed or been absorbed. Lack of coordination among the states, and the consequent thin spread of expertise, hampered progress, but some coordinated efforts were eventually achieved under the auspices of the Australian Forestry Council. The Council established a research working group that met biennially to address forest genetic improvement in general, and New Zealand participants were eventually admitted.

Selection emphasis has been more on growth rate and less on tree form than in New Zealand, but some shifts towards establishing new plantations on more fertile ex-pasture sites call for greater emphasis on improving tree form.

In 1978 CSIRO led a major initiative to collect seed from natural stands for *ex situ* gene resources. Numerous plantings resulted from that, but are in need of active management. Further seed collection was done on Guadalupe island in 1991.

In 1983, after disastrous fires in South Australia, the Southern Tree Breeding Association was formed, initially to address a crisis of availability of seed of acceptable genetic quality. Members now include, in addition to various South Australian agencies, ones from Victoria, Western Australia, and Tasmania.

South Africa Despite an early start with breeding, in the 1950s, activity has been limited by the restricted areas over which the species succeeds.

Chile An abortive start by Instituto Forestal in the early 1970s was followed by the successful establishment of a Cooperative (initially Convenio) between the Southern University of Chile and industry parties. Established along the lines of the Industry/North Carolina University Tree Improvement Cooperative, it began with individual members setting up their own seed-orchard programs. However, it appears not to have led to a coordinated national program based upon free exchange of genetic material, although some interregional integration has occurred within large corporate structures.

Initial plus-tree selection was intensive, aimed at much the same short-internode ideotype as in New Zealand. Each member company established a 42-clone grafted seed orchard. Choice of orchard site was guided by experience in New Zealand and Australia, and was mostly very successful, leading to orchards meeting most members' seed requirements in about 10 years.

Among major member companies there have been separate developments, pursuing vegetative multiplication, and sophisticated biotechnology for appropriating intellectual property.

Spain In the late 1980s a breeding program was set up for the Basque autonomous region, on the northern coast just west of the Pyrenees, based in Vitoria. By far the main emphasis has been on breeding for diameter growth. Problems in finding a suitable seed-orchard site within the region have led to the establishment of an orchard far to the south, in Andalusia.

Hybridization

Experimental hybridization of *P. radiata* was undertaken as early as the 1930s, the main success being crossing with *P. attenuata*. While this hybrid had advantages, difficulties of mass production, and limited availability of sites where it had a decisive advantage prevented its large-scale planting. Interest in interspecific hybrids has been rekindled by a combination of availability of technology for vegetative multiplication of seeds or seedling stock, combined with a desire to extend site tolerances and/or improve resistance to diseases that are threats.

Genetic Transformation

Genetic transformation is being researched in *P. radiata*, initially as proof of concept, with current emphasis on control of reproduction and herbicide resistance, but with a view to other goals, notably manipulating wood properties. It is serving as a research tool. Operational use is envisaged as being in the context of clonal forestry.

TREE BREEDING, PRACTICES

Breeding and Genetic Resources of Scots Pine

O Savolainen, University of Oulu, Oulu, Finland
K Kärkkäinen, Finnish Forest Research Institute, Vantaa, Finland

Introduction

This article covers Scots pine (*Pinus sylvestris*) genetic resources and breeding, and especially contrasts issues in this species to those in other important species of conifers. The emphasis is on results on northern countries, where this species is very important and has been intensively studied. As most pines are at early stages of domestication, breeding is still largely aided and/or constrained by the natural features of the species. Breeding programs have not advanced beyond F_2 generation seeds and advanced generations are not yet available. Commercially sold improved seed is still based mostly on first-generation seed orchards. Further, the silvicultural production populations are in cultivated forest-like situations rather than intensively managed plantations. In these conditions Scots pine has to grow for the full rotation, even 80–100 years.

Biological Characteristics of Scots Pine

Scots pine's natural distribution ranges from western Scotland to eastern Siberia and from northern parts of Scandinavia to central Turkey or southern Spain. It has the widest distribution of all pine species, and, in relation to its range, the discontinuities in its distribution are minor. The species is wind-pollinated and predominantly outcrossing. Very efficient pollen flow has been documented through direct measurements of radioactively labeled pollen or by measuring seed set in isolated young stands that do not yet produce any own pollen. Early on, it was evident that seemingly functionless (nonadaptive) variation in seed cone morphology is not differentiated across populations, consistent with the high gene flow. Many studies on a wide range of populations have shown that at neutral (or near-neutral) genetic markers, such as isozymes or repeat sequences of DNA (microsatellites), allelic frequencies in populations over the whole area of distribution are quite uniform, with less than 5% of the total variation between populations. The same finding has also been made in initial studies of nucleotide sequence variation. Thus, all available evidence suggests that the whole distribution area of Scots pine functions in many ways as a single enormous population, with very minor differentiation at marginal very isolated populations, e.g., in Spain. Initial studies of maternally inherited markers, in mitochondria, confirm that seed migration is not as efficient, but thorough studies of maternally inherited markers are still lacking. This picture of the enormous population size with efficient gene exchange gains further support from the fact that the levels of variation, e.g., at the standard isozyme loci, have been among the highest in any organism. Further, even if quantification of variation at the DNA level has not been done extensively, it has been rather easy to detect genetic variation for genetic mapping with various DNA techniques.

The broad area of distribution covers a wide range of climatic conditions. Even within Finland the length of the thermal growing season ranges from 120 days in the north to 170 days in the south (latitude 60° N to 68° N). Consistent with the large range of environmental variation, many adaptive traits, such as timing of growth or the development of frost tolerance show steep clines, correlated with the environmental gradients. In common-garden experiments in greenhouses, first-year seedlings of northern populations form the terminal buds and become frost-tolerant several weeks before the southern Finnish strains. Such clines extend also south of the Finnish populations. While populations in different latitudes are highly differentiated, they still contain much genetic variation in these traits, as documented by quantitative genetic studies. The adaptive significance of the variation has been demonstrated by extensive transfer experiments between latitudes and altitudes in Sweden. Results from large-scale provenance trials suggested that 1° of latitudinal transfer northward causes a decrease in survival of approximately 10%, while an increase of 100 m in elevation results in a reduction of survival of approximately 3%. The evidence thus suggests that the patterns in quantitative traits are due to intense natural selection that overcomes the high level of gene flow at the relevant loci, and creates a pattern of detailed adaptation to the climate. In the north the relevant trait is adaptation to the short growing season and survival in cold conditions, in the southern margin (e.g., Spain) traits like drought resistance may be most important. This high differentiation for quantitative traits affecting survival has to be taken into account when breeding the species. Note that the parallel selection for, e.g., early cessation of growth and early frost tolerance results in high correlation of these traits among populations. However, this does not imply that the traits are genetically correlated at the within-population level. In fact, initial quantitative trait locus (QTL) mapping studies have shown that different loci are responsible for growth cessation and the development of frost tolerance.

Many other conifer species are much less sensitive to such transfers between areas, and breeding for specific geoclimatic zones may not be as important, e.g., in *Pinus radiata* or *P. taeda*.

Breeding System

Another important trait of Scots pine is its breeding system. There is no self-incompatibility system, and wind pollination results in considerable proportions of self-pollination and self-fertilized zygotes. Direct measurements at the zygote stage have not been made, but it can be inferred that the primary selfing rate must be often at least 20%. In the mature seed, however, there are usually only a low percentage of selfs. There seems to be little occurrence of other kinds of inbreeding. Several studies have shown that adult Scots pine populations do not have any selfs. Thus, between the zygote stage and the adult tree stage the selfs are preferentially eliminated by usually severe inbreeding depression. Much of the elimination takes place very early, during seed development. At the age of a few years natural populations show little evidence of inbreeding. When selfs survive in experimental conditions, they show a cumulative decline in relative survival with lowered fitness over several decades due to poorer growth, which results in size-specific elimination of selfs by competition. The inbreeding depression is presumably due to a large number of deleterious recessive genes in the Scots pine genome. The average tree is heterozygous for 8–10 so-called embryo lethals, which means that Scots pine is among the species with the very highest genetic loads. Scots pine reproduction is exclusively sexual. Note that the generation time is very long; the trees do not become fully reproductively mature before the age of 20. Not only is there no asexual reproduction in the natural populations, but Scots pine has also proved a very recalcitrant species for various modes of vegetative propagation.

Natural versus Artificial Regeneration

A large proportion of Scots pine forests is still naturally regenerated. In some areas, e.g., in Russia, the huge annual requirement for Scots pine seed still exceeds the supply of genetically improved seed. Artificial regeneration is either with seedlings or through sowing of unimproved seed. In Scandinavia, natural regeneration has an established role in forest management practices even in areas with ample breeding material available. Natural regeneration is preferred over artificial regeneration mainly because of the lower cost. Moreover, problems in the development of planted seedlings have resulted in decreased use in some areas. Furthermore, problems in producing seeds adapted to the intended area (owing to problems with background pollen contamination in seed orchards) have slowed the use of improved material in northern areas. This has forced foresters to use natural regeneration and/or seeds from natural seed-tree stands in artificial regeneration in the northern areas.

Breeding Goals

The boreal flora with only a few tree species is challenging for tree breeders: seedlings of Scots pine may be planted, e.g., on dry and poor or relatively moist and nutrient-rich soils. The rotation age of Scots pine is much longer (80–100 years) than in some other conifers, e.g., loblolly pine in the southern USA (25–28 years). Enough genetic variation must thus be maintained in Scots pine populations to meet the requirements of spatially and temporally heterogeneous environments.

When breeding for northern environments, survival is the most important trait. In line with the large effects on survival of provenance transfers, several breeding zones have been established for Scots pine in northern countries: 11 in Finland and as many as 24 in Sweden where altitudinal variation is much more important than in Finland (**Table 1**). Growth rate has also been an important trait in breeding programs. Furthermore, stem and wood quality, crown shape and size, and pest resistance are other traits that have been taken into consideration in most breeding programs of Scots pine.

Breeding programs of Scots pine in Finland are national and use only domestic material. However, several international large-scale provenance studies have been established and maintained by the International Union of Forest Research Organizations (IUFRO). The first IUFRO trial was established as early as 1907, and it was followed by several other international trials. These experiments have documented the ample genetic variation that exists within and among populations in many quantitative characters. Recently, international provenance trials and progeny tests of Scots pine have been used for studies on resistance to air pollution and adaptation to climate change.

Scots Pine Breeding and Seed Production

Genetically improved material in Scots pine is produced by sexual reproduction. No clonal material

Table 1 Breeding activities of Scots pine in Finland and Sweden; estimates were obtained with permission from Haapanen and Mikola (2002)

	Finland	*Sweden*

Number of planted seedlings in 1999	60 million	124 million
Seed orchards, ha	2000	924

for regeneration purposes is currently available. Cloning by somatic embryogenesis, which succeeds only with immature seed embryos, is difficult in Scots pine, which lowers the efficiency of cloning as a breeding tool in this species. The material of the production populations is generated in seed orchards, where genetically and/or phenotypically superior trees intermate and produce seed. These seeds are used in nurseries to produce seedlings to be planted at 1 to 2 years of age.

Actual breeding takes place in breeding populations. Selection of phenotypically superior "plus" trees has taken place in virtually all countries cultivating Scots pine. These phenotypes have been vegetatively propagated by grafting to establish the first-generation seed orchards. Several criteria have been used in selecting plus trees. Growth rate has been one of the major criteria, others including stem and wood quality and self-pruning. The first-generation seed orchards have been in full seed production already for several decades, and the genetic gain over wild seed has been estimated to be about 5–10% in growth and somewhat lower in quality characteristics.

The performance of plus trees has been evaluated by progeny tests, and the proven best parents with respect to, e.g., hardiness, growth, and stem and wood quality have been selected to establish 1.5-generation seed orchards. This work has started, for example in Finland and Sweden, and some of the 1.5-generation seed orchards are already functional. In Sweden, crosses between most superior trees have already started to produce elite trees for new-generation seed orchards.

The long-term breeding programs of Scots pine try to maximize genetic gain, avoid inbreeding in production populations, and maintain enough genetic variation for potentially changing environments. In Sweden, a multiple-populations breeding approach has been adopted, where double-paired matings produce material for within-family selection experiments. In Finland, breeding will proceed with a rather similar approach where double- and multiple-pair matings produce material for among- and within-family selection experiments. The genetic gain in growth may be as high as 20–24% in the second-generation seed orchards.

Because of the long generation times, these breeding populations are still at a very early stage of development compared to those of *P. radiata* and *P. taeda*.

Genetic Functioning of Scots Pine Seed Orchards

High genetic gain and maintenance of genetic diversity are two demands that clonal Scots pine orchard designs should meet. These aspects have been studied empirically and theoretically by Scots pine breeders.

The loss of genetic variation is not a major problem in present seed orchards of Scots pine. The first-generation seed orchards of Scots pine consist of many clones with a few ramets per clone. In Finland the average clone number in a Scots pine seed orchard is 121 and in Sweden 80. The number of clones will be substantially lower in advanced-generation seed orchards. Furthermore, variation in fertility among clones lowers the effective population size, thus reducing the expected genetic variability in the seed crop. Fertility variation is most pronounced in young seed orchards, reducing effective population size to half of the actual (census) number of clones. However, the loss of genetic variability due to fertility variation is much less serious in seed orchards with full pollen and seed production. Furthermore, the numbers of clones in present-day orchards, and also in the planned advanced-generation orchards, should be high enough to maintain much genetic variability.

The major factor reducing capture of genetic gain of seed-orchard material is background pollination. Orchards producing seed should be spatially isolated from surrounding Scots pine forests. In Finland, the orchards producing seed for northern areas were established in more southern areas to improve seed set, and thus it was expected that they should be genetically isolated from local forests, not only due to spatial separation but also due to temporal separation because of the earlier flowering of northern seed-orchard clones compared to local populations. Long-distance pollen dispersal, however, has been observed to be much more common than was earlier believed. The estimates of background pollination in Scandinavia vary between 6% and 75%, being as high as 25–35% in many old seed orchards with full pollen and seed production. In southern orchards, background contamination reduces the genetic gain expected from the seedlot. The situation is much worse in northern seed orchards, where background pollination (north × south crosses) makes seed lots unsuitable for regeneration in planned areas due to low hardening and high mortality. The area suitable for regeneration with seed orchard material has been estimated to be between the origin location of clones and location of a seed orchard. Suitable areas for different seedlots have also been estimated by freeze tests of the seedlings. Attempts have been made to solve the problem of background pollination with various methods, e.g., by supplemental pollination or selective seed collection, but the problem persists without a clear solution.

Genetic Resources and Gene Conservation

Although large natural populations of Scots pine maintain ample genetic variation, some measures have been taken to assure the maintenance of genetic variability for potentially changing environments, for instance, in planning long-term breeding programs. The Swedish multiple-populations breeding scheme is considered to serve both breeding and gene-conservation purposes. In Finland, several gene-reserve areas of Scots pine have been established in addition to breeding populations. In gene-reserve stands only natural regeneration is allowed, and seed from these stands may also serve as natural-population control material in genetic studies.

Future Aspects

The impending climate change will be an important issue for Scots pine breeding. The core of Scots pine breeding will be the production of seed material that survives for 80 years in the forests. Breeding for climate change has also already started. For instance, all testing is done in several breeding zones, in order to detect genotypes that are preadapted to the future conditions. Recently, more emphasis has also been placed on understanding and breeding for wood physical and chemical properties.

Southern Pine Breeding and Genetic Resources

J P van Buijtenen and T D Byram, Texas A&M University, College Station, TX, USA

The Southern Pines

The southern pines include four major and six minor species. Together, they make up much of the commercial wood production in the USA supplying approximately 56% of the overall wood consumed (**Table 1**). Southern pine is used for both solid-wood products such as dimensional lumber, plywood, and engineered structural beams and panels and for various pulp and paper products of which linerboard is a main application.

Loblolly pine (*Pinus taeda*) occurs throughout the South and ranges from Texas to Delaware, with only one major discontinuity, in the Mississippi River valley (**Figure 1**). It does not occur in the southern part of Florida. It has acceptable wood quality, is widely adapted and grows rapidly.

Loblolly pine seedlings account for over 80% of the annual nursery production in the South.

Slash pine (*P. elliottii* var. *elliottii*) occurs naturally only in the coastal plain east of the Mississippi River although it has also been widely planted as an exotic west of the Mississippi River in the coastal plains of Louisiana and Texas (**Figure 2**). It is popular for its rapid early growth, resistance to fire and tipmoth (*Rhyacionia frustrana*), and adaptability to phosphorus-deficient sites. Despite its rapid early growth and excellent form, it is ultimately outgrown by loblolly pine on most sites. However, its importance has declined primarily because of its susceptibility to fusiform rust (*Cronartium quercuum f. sp. fusiforme*) and its limited geographic range. Although rust-resistant varieties are now available, the species has not regained its former popularity.

Shortleaf pine (*P. echinata*) has the widest natural range of all southern pines. It occurs from New York to Texas, and is better adapted to heavy soils than some of the others. It also is well adapted to somewhat higher elevations, occurring in the Appalachian and Ozark Mountains as high as 1000 m. Very little shortleaf pine is planted commercially, because of its slow early growth and its susceptibility to tipmoth.

Longleaf pine (*P. palustris*) occurs in the coastal plain from Texas to Florida and north to Virginia. It forms a rosette, called the 'grass stage,' after germination. Under natural conditions, the grass stage will persist until a fire eliminates needles infected with brownspot disease (*Scirrhia acicola*), and reduces the surrounding competition and accumulated fuel. It will then grow very rapidly and become tall enough to be fairly resistant to the next fire. The species is difficult to plant, but is making an appreciable comeback with the use of containerized seedlings. It is prized for its straight stems and high-quality wood.

Southern pines are widely planted around the world as exotics. Many of the planting programs are supported by breeding efforts. Continents include South America (Argentina, Brazil), Australia, Asia (China), and Africa (South Africa, Zimbabwe, Swaziland, Malawi). The techniques used are similar to those described for the southern USA, but in slash pine somewhat more emphasis is placed on hybridization.

The minor southern pines include pitch pine (*P. rigida*), pond pine (*P. serotina*), sand pine (*P. clausa*), spruce pine (*P. glabra*), table mountain pine (*P. pungens*), and Virginia pine (*P. virginiana*). There are limited breeding programs to improve Virginia pine, which is widely planted for Christmas tree production. Most of the southern pines are closely related and belong to the subsection Australes

(southern yellow pines) of the genus *Pinus*. The exceptions are Virginia pine and sand pine, which belong to the subsection Contortae. As a result many of the southern pines can be crossed readily.

The Southern Pines as a Genetic Resource

Natural Variation

The southern pines have much natural variability, which is basically intact because domestication has just begun. As a result both natural stands and current breeding programs are rich genetic resources. Genetic variation exists at various levels: regional, stand-to-stand, and among trees within stands. In natural stands, the tree-to-tree variation is most striking, while variation among stands is much less. Regional variation is also of major importance, particularly in species with large natural ranges. Elevational races are only important in species such as shortleaf pine whose range includes mountainous areas. Of the major species, loblolly pine and shortleaf pine are the most variable, while slash pine is most uniform. The variability (**Figure 3**) has been studied extensively, by means of *in situ* studies, geographic variation studies, heritability studies, and progeny tests done in the course of breeding programs.

Since natural regeneration is practiced on much of the public and nonindustrial private land, which comprises more than half of the forest land in the South, a major portion of the gene pool is preserved in its natural condition. In addition the breeding programs are making a concerted effort to preserve a large number of genotypes in test plantations and grafted scion banks.

Geographic Races

Loblolly pine and shortleaf pine, as discussed earlier, have very large ranges and the resulting geographic variation presents opportunities for spectacular successes and disasters. Loblolly pine from Livingston Parish, Louisiana, has done extremely well over a very large area, combining good growth rate with resistance to fusiform rust, while most southern pines from east of the Mississippi River do very poorly in East Texas. A major geographic variation study was undertaken to provide a scientific basis for the geographic movement of seed and seedlings.

The so-called Southwide Geographic Seed Source Study (SGSSS) was the first organized attempt to delineate these geographic trends. This study was

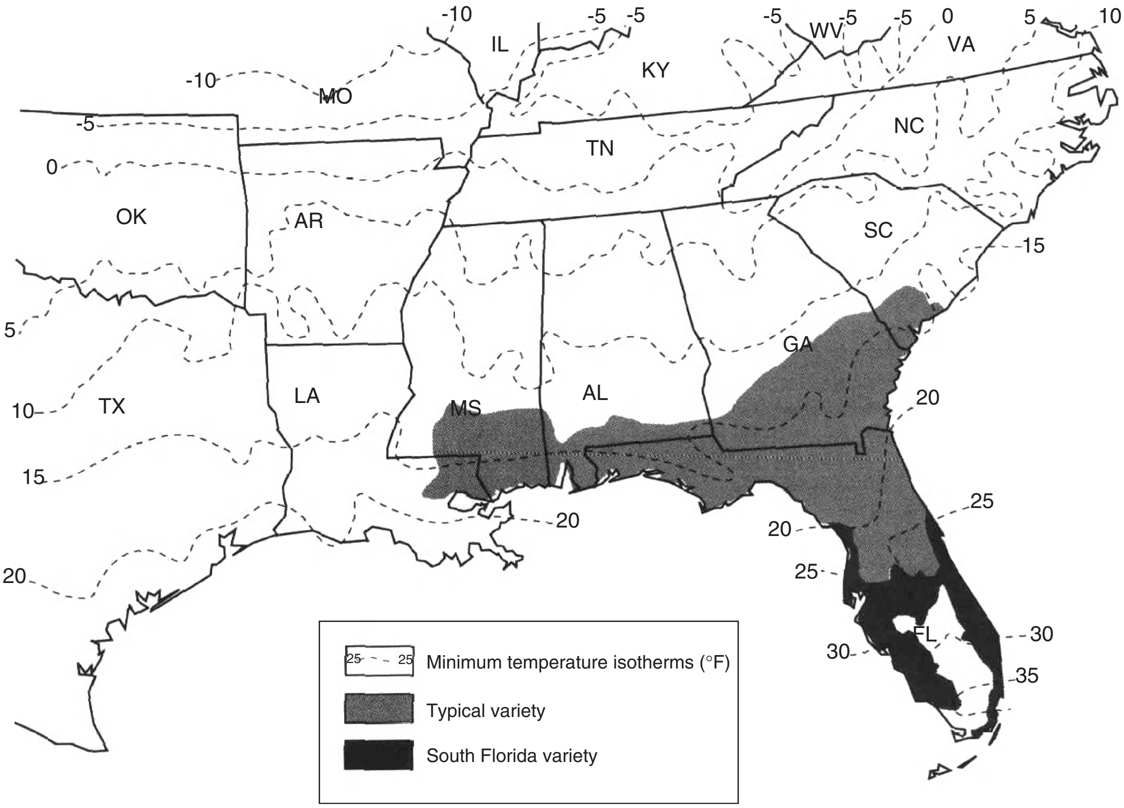

Figure 2 Natural range of slash pine with minimum temperature isotherms. From Schmidtling RC (2001) *Southern Pine Seed Sources*, General Technical Report no. SRS-44. Asheville, NC: USDA, Forest Service.

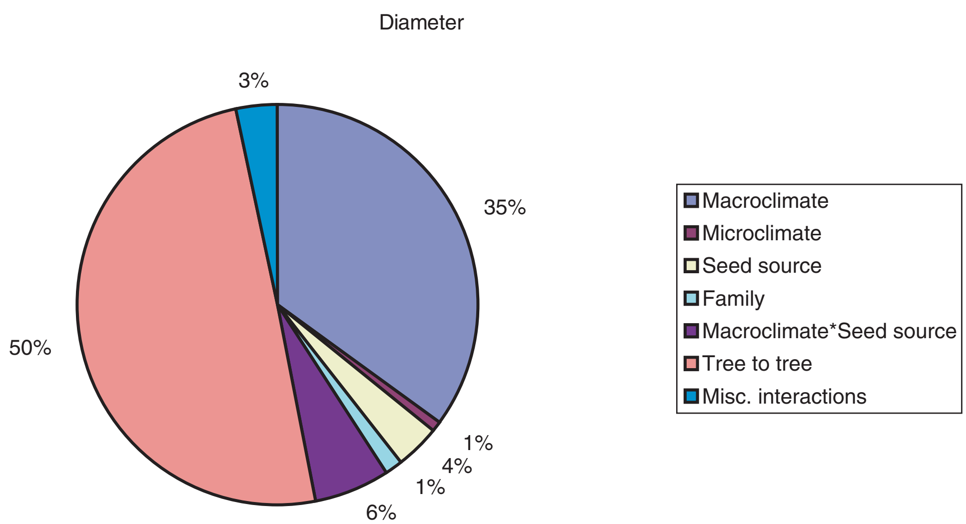

Figure 3 Breakdown of the total variation within the western part of the loblolly pine range into its variance components. Results are based on Western Gulf Forest Tree Improvement Program Geographic Variation Study Series 1.

undertaken in 1951 by the Southern Forest Tree Improvement Committee, with the Southern Experiment Station of the US Forest Service playing a major role. It was a truly cooperative effort with 17 organizations including industries, forestry schools, State agencies, and the US Forest Service participating. The study was nonintensive, with one or two seed collections and a similar number of plantings from each State, but it provided extremely important results that still provide the guidelines for the movement of southern pine germplasm throughout the South (**Figure 1**).

The SGSSS was followed up by individual studies using a finer grid. The most recent general guidelines provided on the basis of these studies are:

> Seedlings will survive and grow well if they come from any area having a minimum temperature within 5°F of the planting site's minimum temperature. Seedlings from an area with warmer winters will grow faster than seedlings from local sources; seedlings from an area with cooler winters will grow slower…. The difference in winter lows can be as much as 10°F, but with increased risk of damage at the cold end of the range and growth loss at the warm end. East–west transfers within districts are usually successful, and in some instances may be desirable if improved stock is available.

History of Southern Pine Tree Improvement

Several factors contributed to the establishment of large-scale breeding programs in the South. The virgin forest had largely been cut over by early in the twentieth century and large scale-planting programs had been undertaken partly in response to the Great Depression and the soil erosion that resulted from drought and poor farming practices. At the same time, research in Sweden, Denmark, and the USA was showing that choosing the right seed source was important for successful regeneration of forest stands.

As told by Zobel and Sprague, one crucial event galvanized the forestry community of the South into action. At that time the Swedes were most advanced in the study of forest genetics. In 1950, Dr Åke Gustafsson gave an inspiring lecture on his accomplishments as a crop breeder, which was attended by the State Governor of Texas, the director of the Texas Forest Service, and a number of forest industry leaders. As a result the Texas Forest Service started a cooperative tree improvement program in 1951, hiring Bruce Zobel to lead the effort, and as they say: the rest is history. About that time, the University of Florida Cooperative Forest Genetics Research Program was started under the direction of Tom Perry. In 1956, Bruce Zobel moved to North Carolina, starting the cooperative at North Carolina State University. At the time, the model of a cooperative tree improvement program was novel, based on some very good biological, economic, and psychological reasons. It allowed the participants to pool their genetic and financial resources and their technical expertise. The free exchange of genetic material and information among the members was crucial to the success of the individual programs. The cooperative spirit of those early days was very different from the competitiveness frequently fostered by the current research and economic climate. Genetic expertise was scarce, the task was too large for the resources of one organization, forests were not seen as profit centers, and the critical mass achieved in the early cooperative programs generated a spirit of enthusiasm.

Approach to Breeding

The Seed Orchard Approach

Most tree improvement programs for the southern pines followed the seed orchard approach to forest tree breeding (*see* **Tree Breeding, Principles**: A Historical Overview of Forest Tree Improvement). This consisted of mass selection of superior phenotypes in natural stands, followed by the concurrent establishment of seed orchards for the production of commercial seed and progeny tests to determine the genetic value of the selected parents. When results of the progeny tests became available, these data were used to 'rogue' the seed orchards (i.e., remove clones of poor genetic value). With this genetic base established, the breeding programs continued as recurrent selection programs.

Major Phases of the Breeding Programs

Initially, a major effort was expended in locating superior trees in natural stands. The selection criteria reflected the breeding objectives with the relative merit of the candidate trees judged by an elaborate grading system that compared their performance to that of their neighbors. Selection efforts were eventually extended to locating candidate trees in unimproved plantations to serve both as infusions and expansions of the original breeding populations.

The breeding objectives differed somewhat depending on the species, the intended deployment zone, and the desired product. Initially, there was great emphasis, particularly in loblolly pine, on the improvement of stem straightness. Rust resistance was a major criterion in areas where rust was a major problem. This was the case for loblolly pine for planting in Georgia, and for slash pine in some parts of its natural range and in all the areas where it was planted as an exotic. Of course, height and volume growth were of major importance in all programs and for all species. In some programs, great effort was also expended on wood quality research, although the selection pressure exerted to improve wood quality was actually very mild.

The grading systems were basically a form of index selection, rating the merits of various traits, but without the benefit of known heritabilities or genetic correlations between traits. The candidate tree was compared to a number of check trees in the immediate neighborhood and given points according to its degree of superiority. After a candidate was identified, a grader employed by one of the tree improvement cooperatives would evaluate the tree to make the final judgment as to whether it should be included in the breeding population. A great many trees were rejected in the process. In any case, hundreds of thousands if not millions of trees were screened to identify the individuals that were ultimately included in the breeding population.

Plantation selections were depended on heavily for the base populations, which caused some concern because the geographic origin of many of the plantations was not known. Fortunately the results of extensive geographic seed source studies of plantation selections have paralleled those of seed source studies from natural stands.

Simultaneously with this tree selection effort a great deal of time was devoted to developing grafting techniques. Grafting the southern pines was not easy, and it took several years before a high success rate was obtained. The most successful types of grafts today are cleft grafts, side grafts and side-veneer grafts. Using these techniques thousands of hectares of seed orchards were established (**Figure 4**). Progeny test procedures also went through a long period of evolution. Initially, mostly open-pollinated or wind-pollinated progeny tests were established as this could be done quickly and cheaply. Gradually these were replaced by control-pollinated tests, as pollination procedures were developed (**Figure 5**). The most popular scheme in the early days was the four-tester scheme in which all clones in an orchard were pollinated with the same four 'males'. This scheme accurately evaluated the genetic quality of the female parents, but it soon became clear that advanced-generation selections from this scheme would be highly interrelated and that inbreeding would be a serious problem in the next cycle of orchards. As a result most organizations shifted to various types of diallel schemes. A complete diallel is the set of all possible crosses among the parents to be evaluated. Since the number of crosses goes up as the square of the number of parents it rapidly becomes unwieldy. A 30-clone orchard, for example, would require 900 controlled crosses. Various types of partial diallel are obtained by systematically sampling the complete diallel to get a good representation of all parents, while keeping the number of crosses within reason.

The field layout of the progeny tests also changed dramatically over the years. Row-plots and block-plots of as many as 100 trees were popular in the 1950s, but it soon became apparent that these tests were statistically inefficient. Also, they took up excessive land, since trees cannot be spaced anywhere near as closely as agricultural crops. The scheme evolved to short rows repeated many times and the whole test repeated at three to four different locations. Currently, many tests are laid out as single tree plots, where each cross in a block is represented by one individual. Randomized complete blocks are commonly used but incomplete blocks where entries are randomized with some restrictions are also used by some programs.

Advanced-generation breeding presented some new hurdles. The age of selection was the first. Ideally, one should select trees at maturity, when all harvest-age characteristics are known. However, this would be an extremely slow process. Theoretical considerations based on available progeny test data showed that genetic gain per year could be maximized by making selections much earlier. The consensus was that selection some time between ages 5 and 10 would be optimal. Considerable research was done to move the selection age even earlier by selecting families based on seedling measurements. At this time it would be very risky to select individual trees on this basis. However, some traits can be measured quite early on seedlings, and

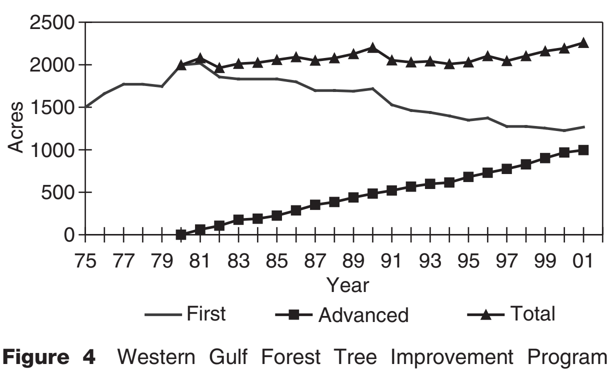

Figure 4 Western Gulf Forest Tree Improvement Program seed orchard acreage from 1975 through 2001.

Figure 5 Bucket trucks are widely used in southern pine seed orchards for pollination (shown here) and cone collection. Photograph courtesy of Texas Forest Service.

one can eliminate some families based on early testing data. Some cooperatives adopted stepwise screening, whereby measurements on greenhouse grown seedlings are used to eliminate poorly performing families before field testing. This resulted in considerable cost savings. Traits that have proven amenable to this procedure include rust resistance in loblolly and slash pine, and growth rate in some provenances of loblolly pine.

Inbreeding and potential inbreeding depression also presented a major problem. This is being managed by subdividing the population into smaller populations called breeding groups or sublines. By limiting crosses made for breeding purposes to matings among members of breeding groups, but designing the orchards so that mating would occur between individuals from different groups, one could confine inbreeding to the breeding population and ensure that seed produced in seed orchards would be largely outcrossed. The approach is somewhat similar to the use of inbred lines in corn, but in corn the lines are purposely inbred and specific crosses are made to combine hybrid vigor (heterosis) with crop uniformity. In southern pines, inbreeding is still avoided as much as possible, even within sublines, while the seed orchards are composed of the best available parents arranged in unrelated groups.

Several organizations have initiated elite breeding populations, or super breeding groups, consisting of only the very best individuals from all the sublines or combinations of breeding groups. These populations are generally a supplement to the mainstream breeding program, being intended to capture additional genetic gain for use in the production population.

Recently increased emphasis is being placed on genetic conservation as an integral part of long-range breeding. The preferred method of conserving genotypes is through grafting into scion banks: a strategy of *ex situ* conservation. Long-term seed storage, commonly used in agriculture, is not very practical for the southern pines. It is not very reliable and would require that stands of trees would be established periodically to replenish the seed. In the absence of inbred lines there is a substantial risk that rare genes would be lost in the process. This approach complements *in situ* conservation through natural regeneration, which is still widely practiced in the South particularly on public and nonindustrial private land.

Accomplishments

The scale at which the tree improvement programs operate is truly staggering. Loblolly pine serves as a good example, since it is the most important species and figures are most readily available. In the initial phase, thousands of selections were made. Over 10 000 have now entered the breeding population (**Table 2**). Individual breeding populations are of course smaller, since breeding is a localized effort, but they are generally of the order of 1000 trees per population (**Figure 6**). Seed orchard acreage increased rapidly in the early years and reached a maximum of about 3900 ha (10 000 acres), leveling off and decreasing after that time because of increased efficiency of seed production as orchards aged. The initial orchards have now largely been replaced by newer selections. Many cooperative member organizations are operating on the advancing-front concept, where every few years an old section is replaced with the best selections currently available.

Southwide, over 1 billion improved seedlings are produced annually. These are sufficient to regenerate about 800 000 ha (2 million acres) per year (**Figure 7**). The genetic gains reported for volume growth range from 10% to 35%. The combined

effect of genetic improvement and more intensive management has far exceeded expectations, to the point that the timber shortages predicted less than a decade ago are not materializing.

The cooperatives are making a concerted effort to preserve all the genotypes included in the breeding population forming a genetic base far greater than the trees included in the production orchards. These so-called scion banks combined with the genetic tests form an invaluable genetic resource in addition to the extensive natural stands.

Tropical Hardwoods Breeding and Genetic Resources

E D Kjaer, The Royal Agriculture and Veterinary University, Hoersholm, Denmark

Introduction

The tropical flora includes thousands of tree species that have proven to be of high value to humans. Products from trees include an almost endless number of goods: timber, fuelwood, edible fruits, medicinal compounds, fibers for clothing, latex, and oils. The genetic diversity of these species represents an enormous biological resource in terms of options for human utilization. Research into the application and conservation of this genetic resource has provided important guidelines on its sustainable genetic management. Tree breeding has focused on relatively few hardwood species considered to have high potential in industrial plantations. However, more recently a broader scope has been applied, and the research and development have focused on a substantially larger number of species including domestication of trees planted by farmers.

Genetic Resources

The term 'genetic resources' refers to genetic variation in trees of potential or present benefit to humans. Variation of genetic origin is due to DNA polymorphisms as such (genes) but the genetic patterns of variation are also of major importance. Genetic variation can thus be seen as organized at different levels: variation between different species, between different populations (forests) within a given species, and between different individual trees of the same species within a given population. The idea of a genetic resource is that this genetic variation – in the broad sense stated above – is of potential value for humankind at present or in the future.

In addition to the genetic diversity as such, a subject of considerable interest is the evolutionary processes (e.g., natural selection in favor of healthy trees) that continuously work within and between populations, and assure continued adaptation to changing climatic conditions, competition with other species, or infections from new pests. This is based on the perception that populations need to be able to respond to changing environments and new competitors in order to maintain their relative fitness. It does hold true that most if not all tree species are exposed to constant competition from other species in a changing environment. Rapid coadaptation and development are thus believed to be necessary for any species in order to maintain fitness and ultimately to avoid extinction in the long run. This perception is sometimes referred to as the 'Red Queen hypothesis' after Van Valen, who chose the name from *Alice in Wonderland*, where the Red Queen tells Alice that 'she needs to run as fast as she can just to stay in the same place.' One can say that the genetic diversity is a dynamic feature of a species being constantly shaped by its environment through ongoing evolutionary forces. Therefore, management of genetic resources of tropical forest trees normally (although not always) aims at protection of the genetic processes as well as the resource itself.

The genetic resource of tropical hardwoods is considered to be especially valuable due to the vast array of potentially harvestable crops from the thousands of species. An important feature of many (although far from all) tropical trees is that they grow in very diverse ecosystems and therefore have a scattered distribution, and/or are found at low densities. This complicates large-scale harvest of the products and therefore in principle favors some kind of domestication of the species through planting activities. However, successful planting programs require planting material in sufficient amount and of high genetic quality. Aspects of characterization, identification, propagation, and breeding of tropical hardwood species have therefore been important research topics for many species for a number of decades.

Provenance Trials and Breeding Programs for Industrial Plantations of Tropical Hardwoods

For practical reasons, the initial focus was on breeding hardwood species with some kind of pioneer characteristics, i.e., shade-intolerant species with fast juvenile growth. Such species are easier to cultivate in plantation regimes compared to the more difficult shade-tolerant, mature-phase species that require shade and exhibit less vigorous juvenile growth. Some of the earliest tree improvement activities focussed on teak (*Tectona grandis*). Teak is considered to be one of the world's most prominent timber species due to its valuable wood but it is also easy to establish in plantation regimes. The juvenile growth rate is high but rapidly moderates with age and more than 50 years are in general required in order to obtain valuable teak logs. Selection and vegetative propagation of superior teak trees on a commercial scale in India, Indonesia, and Thailand go back to the 1950s. Large-scale international provenance tests were initiated in the 1960s as a joint effort between a number of teak growing countries in Africa, Asia, and Central and South America. This comprehensive series of trials has since shown that large differences exist between seed sources and that the selection of the best origin of the seed is therefore important in order to obtain vigorous growing trees (see **Table 1**). Variation in stem form was also found to be important.

Provenance trials have been established for a number of other tropical hardwoods including a number of widely planted species such as *Milicia excelsa*, *Dalbergia sissoo*, *Dalbergia* spp. (rosewoods), *Swietenia humilus* and *S. macrophylla* (mahoganies), *Gmelina arborea*, but also many lesser known species such as *Vochysia guatemalensis*, and *Zeyheria tuberculosa*. The general finding is that variation between populations is important for almost all investigated species.

Breeding in principle consists of continuous cycles of initial selection of superior trees according to their phenotypic performance, testing by growing the trees under relevant conditions in repeated field trials, analysis of the field trials and selection of superior trees or progenies of trees based on these results, crossing of the selected trees (formation of the next generation breeding population), and initiation of the next breeding cycle by selection in the progenies for second-generation testing. Breeding in terms of such selection and testing for tropical hardwoods have in general not progressed beyond the early stages (first generation). Experiences from fairly intensively bred *Gmelina arborea* and *Tectona grandis* have however indicated that at least selection for stem form and insect resistance are likely to provide good response (**Figure 1**). Breeding of rosewood (*Dalbergia sissoo*) in India and Nepal has also shown that a high level of genetic control exists for growth rate and that good response from selection can be obtained from breeding for both growth and especially stem form. This finding has been repeated in a number of species

Table 1 Relative growth rates (basal area at age 17 years) of 12 teak provenances grown in field trials at Aracruz, Brazil

Origin	*Provenance (location of collection site)*	*Estimated annual rainfall*	*Average growth relative to the fastest growing (%)*
Southern India	Mount Start, Tamil Nadu	2032 mm	100
Southern India	Nilambur, Kerala	2565 mm	96
Southern India	Konni, Kerala	2540 mm	91
Indonesia	Ngliron, Java	1200 mm	86
Ghana (African landrace)	Jema	Not available	69
Laos	Khong Island	1925 mm	58
Northern India	Purunakote, Orissa	1350 mm	58
Laos	Vientienne Town	1570 mm	55
Thailand	Ban Pha Lai	1100 mm	54
Thailand	Ban Mae Pam	1200 mm	47
Northern India	Munda Reserve Forest	1350 mm	47
Laos	Savannakhet	1300 mm	44

Note: The trial site at Aracruz in Brazil has an annual rainfall of approximately 1400 mm. Still, the most vigorous provenances at this planting site come from parts of Southern India, where the rainfall is substantially higher. It is a general observation that the genetic patterns of variation often are difficult to predict without proper testing in field trials. Use of planting material from healthy stands of local origin is therefore often preferred when results from provenance trials are lacking. Adapted from Kjær, E.D., E. Lauridsen & H. Wellendorf 1995. *Second Evaluation of an International series of Teak Provenance Trials*. Danida Forest Seed Centre, Humlebaek, Denmark, 117p.

Figure 1 Clonal seed orchard in Northern Thailand. These trees are vegetatively propagated graftings (clones) from so-called plus-trees (very straight trees identified and selected in natural forests in Thailand during the 1960's), and established in order to collect improved seed for planting programs. In front Verapong Suangtho of the Royal Forest Department, Bangkok.

and revealed a pattern that indicates that gains from selection in the early stages are often surprisingly high in many tropical and subtropical species compared to similar findings in temperate species. Over the years, breeding has therefore been accepted as an important means to improve the productivity of plantation species (**Figure 2**).

Propagation

Large-scale propagation of the selected and improved genetic material has proved to be a severe obstacle for large-scale application of many tropical hardwoods. Technically successful breeding programs have in many cases not led to the expected increase in productivity in the plantations, simply because the improved planting material has not been applied at any substantial scale. The problem of effective multiplication is most complicated for species with large fruits, moderate seed, and/or seed that are sensitive to desiccation and therefore difficult to handle and transport. One or more of these features unfortunately characterizes the seed biology of many valuable hardwood species from moist or semimoist tropical conditions, and has by itself limited large-scale application of such species altogether for large-scale planting purposes.

The traditional propagation of improved genetic material is in seed orchards based on seed collection from graftings of the superior trees. However this approach has proven to be much more difficult for many tropical hardwoods compared to the experience from temperate conifers. Thousands of hectares of seed orchards of teak have been established in India, Indonesia, and Thailand, but they have produced only limited commercial seed.

Much research has therefore focused on development of alternative propagation methods to seed. Development of rooted cuttings through application of growth hormones has proven to be a feasible option for a large number of species including several of the difficult dipterocarp species. Development of tissue culture has also been successful for a number of species. Although important findings and important tools for breeding, the vegetative propagation techniques have in general proven to be associated with additional costs that have limited their commercial-scale application with only a few exceptions.

Breeding a Wider Range of Tropical Hardwood Species

Given the thousands of valuable tropical hardwoods, breeding has until recently focused on surprisingly few species. This is probably due to a combination of lack of resources, the partly mythical view that most tropical hardwoods are slow growing (this is often not the case), the preference for growing plantations as monocultures without nurse species, and the fact that many of the species have complicated breeding systems.

Research into Genetics and Population Dynamics of Tropical Hardwood Species

Basic research into the often complicated breeding systems of tropical hardwoods has over the last three decades generated important knowledge for a much larger number of tropical hardwood species. Understanding of pollination ecology is often an important

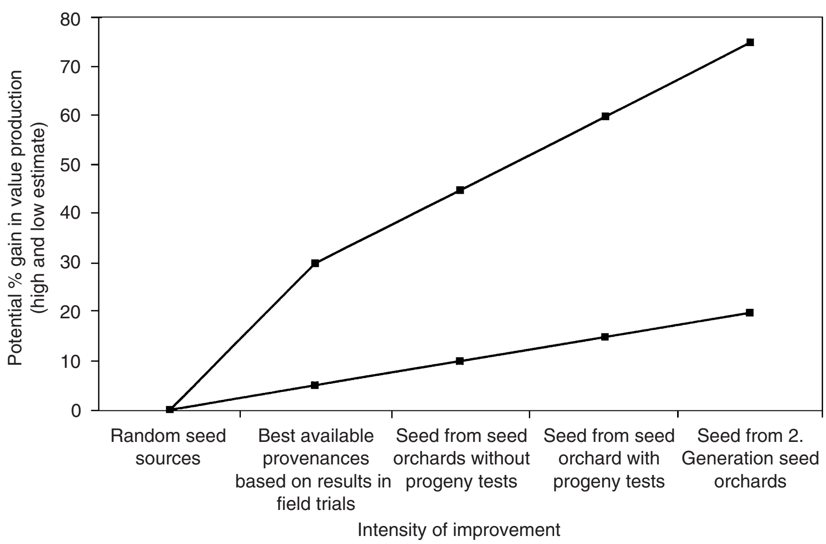

Figure 2 Expected gains from tree breeding. Based on estimates in Foster GS, Jones N, and Kjaer ED (1995) *Economics of Tree Improvement in Development Projects in the Tropics*. In: Environmental and Economic Issues in Forestry: Selected Case Studies in Asia. Edited by Shen S and Converas-Hermosilla A. World Bank Technical Paper no. 281. The World Bank, Washington D.C.

prerequisite for effective breeding programs, and for good management of the genetic resource as such. Formal studies of pollinators and estimation of selling rates and gene flow are time consuming, but results from a number of tropical hardwood species with different pollination syndromes has allowed some important generalizations to be drawn that are valuable for practical management of the genetic resources of tropical hardwoods. These include the recognition that most species are predominately outcrossing and pollen is often dispersed over large distances depending on the pollinators. For example, fig wasps have been found in general to have a pollination radius on the scale of several kilometers whereas beetles often move pollen less than 100 meters. For some species such as some understory woody species, the average pollen movement distance has been found to be only a few meters. The research programs into genetic processes and population dynamics of tropical hardwoods have in most cases been initiated based on concern for their conservation status, where increasing fragmentation of natural habitats is a major concern. However, the findings have also proven very useful for practical breeding and domestication because a basic understanding of the reproductive ecology is important in order to develop effective propagation and genetic management programs.

Breeding of Hardwoods for On-Farm Plantings in Heterogeneous Environments

The large number of potentially important species, combined with the general development towards joint forest management of tropical forest, has in recent years challenged traditional breeding techniques. Further, focus in many forestry programs has moved from industrial plantations to support farmers planting on their own farms in wood lots and agroforestry systems.

Large-scale international provenance trials of dry zone acacias were initiated in the 1980s and these trials have revealed substantial differences in survival and biomass growth according to the origin of the seeds. They indicate that choice of the right seed source is even more important for species growing under dry or semi-dry conditions. Results from domestication of species grown for fodder and fallow (e.g., *Bauhinia* sp. *Sesbaria sesbar*, and *Gliricidia sepium*), gum arabic (*Acacia senegal*), oils (e.g., *Melaleucas*), and other non-wood products (e.g., *Azadirachta indica*) have also proven that these characteristics are often under as high genetic control as growth and stem form. Breeding for non-timber forest products thus seems to be an important option, although often more difficult to select for in practice. On-going research into this issue will contribute important information in the coming years.

New Concepts for Breeding Tropical Hardwoods

The introduction of two important concepts – (1) multiple population breeding and (2) breeding seed orchards – has been an important contribution to development of low-input, genetically diverse breeding programs. The point of departure in multiple population breeding is that a number of smaller, low-input, breeding programs are run in each separate ecologically based breeding zone. This supports local adaptation to ecological conditions and thereby manages the genetic diversity in the breeding program without a number of expensive, repeated tests. The breeding seed orchard is a special planting that serves multiple purposes: it produces seed (seed orchard), tests the genetic entries (progeny trial), and provides the base population of next generation selection (breeding population). This is obtained by establishing a seed orchard based on progenies from selected trees in a repeated block design. The design in terms of plot size, number of progenies and replications, are chosen in breeding seed orchards in ways that accommodate the combined requirements (**Figure 2**).

Interdisciplinary Approaches and Farmer-Based Domestication

Many programs have proven that breeding of tropical hardwoods cannot be done in isolation from the plantation technology and indeed not in isolation from the socioeconomic context. Genetic improvement and propagation remains an academic exercise unless the improved germplasm is distributed and applied by the tree planters. Tree improvement of tropical tree species has therefore gained much in recent years from an interdisciplinary approach that include institutional aspects and participatory methods. Participatory breeding and gene resource management programs for tropical hardwoods enables practical schemes to build on the local knowledge that are essential for breeding for number of non-wood products. Also, participatory breeding is required in order to deal with species cultivated through natural regeneration rather than plantings as is the case in the West African parkland, or species management by farmers at landscape level as is the case with many fodder species in the Nepali middlehills.

TREE BREEDING, PRINCIPLES

Contents

A Historical Overview of Forest Tree Improvement

J Burley, University of Oxford, Oxford, UK

Introduction

Genetic principles have been applied widely in the practice of forest management within the last 100 years although elements of breeding operations were practiced earlier. Various terms have been used to describe the discipline, particularly forest genetics and tree breeding, but a collective term, tree improvement, is useful since it incorporates genetic change, silvicultural improvement, and better use of the end products and services derived from trees.

The twentieth century saw changes in the objectives of forest management and hence of tree improvement, in the species of interest, in the benefits sought, in the nature and number of individual characteristics improved, and in the techniques used. Recently emerging issues include the concept, conservation, and control of the genetic resources that underlie tree improvement, and the application of modern techniques of biotechnology. A number of contributions to this Encyclopedia summarize the state of knowledge of these issues and the progress in genetic understanding and practical improvement of many species.

Concepts of Forest Genetics, Tree Breeding, and Tree Improvement

Forest genetics is generally considered to include Mendelian (traditional) genetics, population genetics and quantitative genetics. Gregor Mendel, an Austrian monk, established the basis for traditional genetics in 1866 with his famous experiments on peas in a monastery at Brno (now in the Czech Republic); these led to his famous laws of heredity (segregation and independent assortment of discrete genes), dealing with the inheritance of traits in relatively small groups of individuals over short periods of time. They concern descendant generation segregation, progeny–parent relationships, linkage of genes and characteristics, and individual gene action (additive, dominance, and epistatic effects).

The implications of Mendel's results were not appreciated by the scientific community until the early 1900s but then agricultural plant and animal breeders effected rapid advances in productivity by the application of these principles. However, they were not applied to forest trees on a significant scale because of the long generation intervals of most trees, especially in commercial rotations; it proved difficult to determine these genetic controls without long-lasting field trials until the development of biochemical methods allowed the identification and tracking of individual genes and character controls. Although some efforts were made earlier, it is reasonable to consider that the start of major tree breeding occurred at the end of World War II (1945) when selective tree breeding began.

Population genetics concerns the genetic behavior, distribution, and changes in large groups or populations of individuals over relatively longer time periods, including responses to natural and artificial selection. It incorporates such concepts as survival, fitness, the Hardy–Weinberg equilibrium for allele frequencies, and polymorphism. Statistical analysis improved dramatically with the enhanced capacity of computers. This is crucial to an understanding of population genetics within a species which itself is essential for guided tree breeding, for comprehending past evolutionary change, and for predicting future responses to political, environmental, management-related, and economic changes.

Many traits of productive and economic importance are controlled by several genes and their interactions (polygenic inheritance). Quantitative genetics deals with the assessment of genetic and environmental parameters including phenotypic and genetic variances, covariances and correlations, the estimation of heritability, and the response to selection.

Tree improvement can thus be taken strictly to include enhancement of silviculture and management systems as well as genetic improvement (tree breeding), together with the enhancement of processing and use of products and benefits derived from trees; however, the Encyclopedia contributions concentrate mainly on the breeding aspects and their underlying genetic principles. Genetic changes must be seen in the framework of appropriate management practices. For instance, a genotype that is good for low-altitude sites with dry sandy soils requiring fertilization or irrigation is not necessarily the optimum for wet clays needing drainage and/or subject to windthrow at high altitudes. Similarly a genotype that has wood structure and properties suitable for newsprint may not be appropriate for fine furniture.

Traditional Tree Improvement

The traditional stages of tree improvement include the following.

Species and Provenance Trials

Many species originate in environments that resemble the conditions of a given planting site and they can be evaluated in comparative (common garden) experiments on a range of sites (homoclimal comparison). For species that naturally occur over a wide geographic range with varying environmental conditions, natural selection may have caused heritable differences to evolve between populations (termed variously, and often loosely, origins, original provenances, or seed sources); some degree of difference may also occur when trees are introduced to a site and seeds subsequently collected from that site (termed provenances, derived provenances, and sometimes landraces, although in a different sense to that used for agricultural crops by Otto Frankel). These different origins and provenances also require evaluation in comparative trials and the interpretation should take into account all available information about the genetic history of each population beginning with the native origin of its parental stock. Many countries have decades of experience of the most suitable exotic species but surprisingly little information on the genetic variability between or within populations of their indigenous species, with the notable exceptions of Canada and the USA where plantation forestry is based largely on indigenous conifers.

Seed Stands (UK) or Seed Production Areas (USA)

When the demand for local seed of exotic species is high (to reduce dependency, risks, and costs of imports from original sources) silviculturists and tree breeders identify phenotypically superior stands and thin or fertilize them to stimulate flower and seed production. Although the phenotypic superiority does not prove genetic superiority, this is the simplest and earliest step that can be taken to obtain some genetic gain and it is successful if the stand identification is careful and the traits of interest are under some degree of genetic control. Such source-identified material costs more to produce and should be saleable by nurseries at slightly higher costs.

Phenotypic Selection of Parent Seed Trees

When sufficient areas of plantation are established the tree breeder screens all trees systematically for individual phenotypic superiority, those chosen being termed plus trees. Again if individual characteristics are under a reasonable degree of genetic control, open-pollinated seed from these selections will yield somewhat improved offspring.

Seed Orchards

Greater improvement can be obtained if the selections are propagated (by grafts, cuttings, or seedlings) into seed orchards. The clonal orchards are special plantations with many copies of each selected phenotype randomly allocated and widely spaced to encourage wide crossing among all possible combinations of the parents and heavy seed production. The seed produced is then genetically superior to forest-collected seed of seed stands or individual plus trees. Seedling seed orchards permit the use of the stock as progeny tests and breeding populations (then known as breeding seedling orchards or BSOs) in addition to seed production.

Progeny Tests

The growth and properties of plants derived from seed stands or from the original parents in the plantations can be compared with commercial seedlots or new imports. However, information about the genetic value of each individual plus tree can only be derived from carefully designed, managed, assessed, and analyzed progeny trials. A wide range of designs and analyses exists and the availability of modern computing facilities makes the use and analysis of unbalanced and incomplete designs possible. The ultimate aim is to obtain information on the breeding value of each individual, the extent of correlations between all traits of interest, and the use of individuals in recurrent selection cycles over successive generations to continue the process of genetic gain while avoiding such problems as inbreeding depression or increased disease risk through narrowing the genetic base.

Use of Improved Material

Genetically improved material arising from seed orchards is usually distributed to commercial plantation agencies as seed, seedlings, or vegetative propagules. Techniques for clonal propagation were developed for many species centuries before genetic principles were understood. A famous Japanese geneticist, Ryookiti Toda, reported in the 1970s on work undertaken in Japan in the seventeenth century on the selection and propagation of sugi (*Cryptomeria japonica*).

Program Sequences

Early tree breeding programs attempted to follow these steps sequentially, often following nearly complete commercial rotation periods to complete each phase; the time required to complete the different stages of tree breeding became the main constraint to genetic advance. However, the gap between these steps progressively shortened as the demands placed by human populations on natural resources increased and as early selection methods, flower induction techniques, sophisticated statistical routines, and modern computing power were developed.

Some breeding programs proved abortive because the steps were not followed adequately; for example, programs with *Pinus sylvestris* in Britain and *Cupressus lusitanica* and *Pinus patula* in Colombia failed because they were essentially the wrong species for the sites. New Zealand efforts with *Pseudotsuga menziesii* failed initially because of failure to identify the optimum provenance whereas relatively little attention was given to the origins of the now hugely successful *Pinus radiata*.

Early Forest Tree Improvement

Tree breeding is not new. It is sometimes argued by botanists that palms are not strictly trees because they do not have persistent cambia and do not therefore technically produce wood; however, if this technicality is overlooked, then the Assyrians and Babylonians can be credited with the first hand-pollination of trees since they improved date palms 3000 years ago. It was not until Hooke's invention of the microscope in the seventeenth century that it was possible to see the pollen grain.

One of the American leaders in the postwar field of forest genetics and tree breeding, Bruce Zobel, published with his coauthor, John Talbert, a widely available list of early forest geneticists and their topics; this list was based on an historical review by the Hungarian–Canadian tree breeder, Oscar Sziklai (see **Table 1**). Beginning with Bradley in England they listed some 30 outstanding individuals who had worked variously from 1717 to 1935 on different components of tree improvement – seed sources, inheritance, hybridization, vegetative propagation, reproductive biology, seed production stands and orchards, and a few specialized characteristics such as stem straightness and wood properties.

Work on provenance variation and self-fertilization of larch was started at the Institute of Forest Genetics in Sweden during 1902. In Placerville, California, in 1924, the Eddy Tree Breeding Station was established largely conducting pine hybridization. However, among the developed countries, the bulk of work related to tree improvement was undertaken in the Southern USA with four major pine species. For instance, also in 1924, Philip Wakely began work at the Southern Forest Experiment Station of the US Forest Service on range-wide seed source collection and testing that was fundamental to all subsequent selective breeding work and he also conducted pine hybridization. In the 1930s, work on poplars was conducted in the US Forest Service North East Forest Experiment Station by Ernest Schreiner and in Sweden by Nilsson-Ehle and coworkers. This work on poplars, especially on interspecific hybrids, precipitated the considerable but often uncritical work on pine and spruce hybridization that took place before and after 1945.

Not all of the work was done in the countries now considered 'developed.' Sir Harry Champion who subsequently became Professor of Forestry at Oxford, published in the 1920s and 1930s on the seed source and genetic control of stem form and wood

Table 1 Some of the early forest geneticists and their areas of interest

Year	*Geneticist and country*	*Area of interest*
1717	Bradley (England)	Importance of seed origin
1760	Duhamel de Monceau (France)	Inheritance: oak
1761	Koehlreuter (Germany)	Hybridization

properties (twisted grain) in the Indian chir pine (*Pinus roxburghii*).

Tree Improvement after 1945

Following World War II, systematic tree breeding programs based on a good understanding of genetic principles were initiated in Europe, Japan, and North America; in Europe the species were both indigenous and exotic while in Japan work was concentrated initially on the indigenous *Cryptomeria japonica*. In both Canada and the USA attention was focused on indigenous Douglas-fir (*Pseudotsuga menziesii*), pines (*Pinus* spp.), and spruces (*Picea* spp.) with some work on timber and nut-bearing hardwood species. Tree breeders were appointed and tree breeding stations were established or expanded in Denmark, Finland, France, Germany, Italy, Norway, Sweden, and the United Kingdom. In Europe and Japan most of the research and development were conducted by governmental and academic institutions. Among the outstanding and most influential pioneers was C. Syrach Larsen in Denmark.

Starting in the 1950s, in the USA Bruce Zobel pioneered not only tree improvement *per se* (in his commercial and academic appointments) but also the concept of tree improvement cooperatives; these facilitated the sharing of research costs, genetic material, and benefits between a number of industrial forestry companies, which were commercial competitors yet which saw the value of precompetitive collaboration. These collaboratives were coordinated by universities notably Florida, North Carolina State and Texas for southern pines. A detailed history of these cooperatives written by Zobel and Sprague was published by the Forest History Society and is a significant, insightful review of the personnel and administrative procedures of these initiatives.

Many other universities conducted forest genetic research and an international tree improvement cooperative was established under the coordination of North Carolina State University and involving countries interested in central American tree species (CAMCORE). In addition to legally constituted cooperatives, throughout the latter half of the twentieth century regional tree improvement conferences were held annually and biennially in several regions of the USA; these brought together geneticists, breeders, nursery and forest managers, and academic staff and students. They provided a valuable forum for the rapid dissemination of findings and practices and they became models for regular associations and conferences in other parts of the world.

In the 1960s tree improvement programs were initiated in Australia (federal and State-oriented), New Zealand (Forest Research Institute, Rotorua), South Africa (De Wet Tree Breeding Station), and Zimbabwe (then Rhodesia) (Forestry Commission); these have become outstanding examples of highly planned, efficiently conducted, and economically effective tree breeding. Subsequently many other countries in the British Commonwealth initiated programs with the initial guidance of the Commonwealth Forestry Institute (now the Oxford Forestry Institute); francophone countries in Africa and the Pacific region were assisted by the Centre Technique Forestier Tropical (CTFT, Nogent-sur-Marne, France). These were all concerned primarily with exotic pines and eucalypts for industrial plantations and in most of these countries they are still fundamental to the forest industry.

The International Union of Forestry Research Organizations (IUFRO) was established in 1892 to encourage collaboration, the sharing of information and material, and mutual support for forest research; initiated by a few countries in Europe, it progressively enlarged and formed several hundred specialist Working Parties, several of which dealt with provenance research on temperate species before and after 1945. However, it was not until 1972 that a specific tropical group was established by Garth Nikles (Australia) and Jeff Burley (UK) to deal with the genetic improvement of tropical species.

Breeders and geneticists from many tropical countries participated thereafter in international provenance trials coordinated by the agencies described above, by the Food and Agriculture Organization of the United Nations (FAO, Rome, Italy, the United Nations Agency created in 1948 with responsibility for forestry activities within the UN), by the Danish Tree Seed Centre (DTSC, Humlebaek, Denmark) and by the Commonwealth Scientific and Industrial Research Organization (CSIRO, Canberra, Australia).

Regular meetings of up to 300 participants from more than 30 countries also shared their experience on all aspects of tree improvement. Advanced breeding programs were developed in several South American countries, particularly Argentina, Brazil, and Uruguay; a team of researchers in the Aracruz Company in Brazil received the Marcus Wallenberg Prize (the most prestigious award related to forestry) in 1983 for their work on the improvement of eucalyptus growth and properties for the paper industry.

The eventual target of these institutions, programs was the clonal seed orchard as the major seed production unit to disseminate the products of the selective breeding effort. These encountered major problems that varied between species. Many early orchards failed to produce significant quantities of seed; sites had to be identified that favored flower and seed production, not necessarily the same as sites that promoted the traditional forester's goal of stem wood production. In grafted seed orchards, late incompatibility between stock and scion caused many clones to be rejected from the breeding program. The behavior of scions after grafting was often influenced adversely by factors dependent on the age of the parent from which the scion was taken (cyclophysis) and the position in the parent's crown from which the scion was collected (topophysis). Gradually these problems were overcome by physiological and management research and sometimes by the use of rooted cuttings rather than grafts; in other cases, seedling seed orchards were adopted to avoid incompatibility problems.

Recent Changes in Tree Improvement Objectives and Methods

There have been significant changes in the policy, institutional, and technical aspects of forestry in the last half-century and tree improvement has changed accordingly. In the 1950s the primary target was simply the production of large volumes of industrial wood. In the 1960s more attention was given to the quality of such wood and this was refined further in the 1970s to address the quality of pulp and paper. These targets continued in the new millennium with increasingly refined techniques for evaluating quality.

However, at the same time as industrial forestry escalated, in tropical and developing countries more attention was given to rural development forestry and the role of trees in supporting agriculture and human welfare. Many research institutions in developing countries and several in developed countries have begun the evaluation of species, populations, and selected individuals for inclusion in breeding programs to enhance the production of human food, animal fodder, fuelwood, construction poles, pharmaceuticals, and chemical exudates. These generally follow the same principles as those for industrial conifers or eucalypts but on the basis of less initial knowledge, more political problems, and fewer resources of finance and skills.

For tree improvement, in the 1950s much work concentrated on the choice of species and provenance with some simple mass selection and occasional species hybridization. Through the 1960s there was considerable debate and practice of different progeny test methods and seed orchard designs; as the sophistication of design and analysis improved, there was also an increased awareness of the need for large numbers of selections and test plantings to obtain precise estimations of genetic parameters and to provide material for recurrent selection.

The 1970s saw the planning and implementation of recurrent selection strategies; in many organizations these replaced the traditional single-generation approach in which individual parents were selected, propagated in seed orchards, and culled on the basis of progeny tests that evaluated their genetic worth; the resulting culled orchards produce seed that Zobel termed '1.5 generation material' although strictly it was still based on selections made in the first generation. The development of recurrent multi-generation plans required the development of intensive recording, maintenance of large databases, and the training and dedication of career geneticists.

The 1980s focused attention on cloning through cuttings and tissue culture. The perfection of cutting techniques led to the ability to propagate hybrids, especially in the eucalypts. Hybridization and cloning together probably led to the biggest increase in productivity of all time because combinations of species' attributes could be put together to match new plantation environments that have never existed in the wild. Outstanding wood production and stem form were obtained in Brazil, Congo, South Africa, and Uruguay and many other countries have emulated these successes. Typical annual yields of eucalypt wood per hectare in Brazil rose from 4 m^3 at the start of the twentieth century to over 40 m^3 by the end; the role of research in integrating selection, hybridization, cloning, and silviculture was recognized by the award of the Marcus Wallenberg Prize in 1983 to a team of four from the Aracruz Company at Victoria, Espiritu Santo, Brazil.

In the 1990s three major sets of techniques and strategies emerged: molecular genetic methods, multiple population breeding strategies (for which Gene Namkoong received the Marcus Wallenberg Prize in 1994), and breeding seedling orchards (pioneered in developing countries by Richard Barnes).

Throughout the 1980s and 1990s terpenoids and isozymes were used for a variety of genetic purposes, sometimes inappropriately; this led to some bad management decisions about optimum breeding strategies. It also identified the need to determine and separate the diversity of genetic markers from functional diversity. The recent development of molecular techniques facilitates several fields of enquiry in ecology, genetics, and tree breeding. These include:

- taxonomic identification and classification
- evolution of species and individuals
- genecology and habitat-related genetic variation between populations of a given species
- population genetic structure
- identification of breeding systems (for breeding, gene flow, conservation, and habitat fragmentation)
- evaluation and prediction of genetic differences among species, populations, individuals, and clones
- genetics and functional genomics of pest resistance, environmental tolerance, growth pattern, and chemical and wood properties
- 'finger-printing' of individual genotypes and verification and reconstruction of pedigrees
- monitoring of biological diversity.

Subject to public acceptance, genetic modification of trees themselves can contribute significantly to rapid and progressive improvement over recurrent generations. The challenge for the future, following a century of traditional tree improvement, is to achieve this technically and politically without reducing the resources for traditional breeding; genetic modification must always be based on the material and knowledge achieved in classical tree improvement.

Dissemination of the results of research and of information on the development of theory and practice was a vital element of the rapid expansion and progress of tree improvement throughout the world. In the postwar era one of the most influential books was written by Syrach Larsen in Denmark; despite some scientific deficiencies, it provoked the rapid growth of interest in the possibilities of tree breeding. Initially one journal, *Silvae Genetica*, was established specifically to cover all fields related to forest genetics and tree breeding. Subsequently the literature related to the subject expanded with innumerable textbooks, journals, and conference proceedings plus many series of committee reports, booklets, and technical notes from national breeding stations and international agencies such as FAO. This literature, coupled with graduate university research and specialized training courses by such institutions as CSIRO, CTFT, DTSC, FAO, and OFI, enhanced the development of the corps of effective forest geneticists and tree breeders throughout the world. Within the academic area, initially principally in the USA, the pioneers in the immediate postwar period who set the standards for academic education included Bruce Zobel in North Carolina State, Francois Mergen at Yale, Jonathan Wright at Michigan State, and Bill Libby at the University of California, all ably supported and succeeded by a large number of scientists and students from many countries.

Genetic Resources

Underlying all forest genetic improvement are the genetic resources of forest ecosystems, species, populations, individual trees, chromosomes, genes, alleles, and all their variation. They include populations and individual genotypes resulting from artificial selection and breeding efforts. They constitute an intergenerational resource for all forest-based demands of products and services. The various benefits sought by humankind are controlled to different extents genetically and information on this variability is fundamental to obtaining genetic advance from selection and breeding. This wide diversity of resources requires a range of methods for its exploration, evaluation, conservation, improvement, and dissemination. Modern tree improvement programs deliberately target the conservation of representative natural diversity in addition to the production of genetically restricted populations for high productivity of benefits.

Conservation of natural forest populations is traditionally undertaken through the establishment of parks and reserves (*in situ*) but it is also effected by exotic plantings (e.g., arboreta, botanic gardens, conservation stands, *ex situ*). Many of the international trials of species and provenances have been used for *ex situ* conservation. Temporary but relatively long-term conservation is also practiced through the storage of seed under appropriate conditions (commonly low temperature and moisture, depending on the species requirements). Tree breeders are now well aware of the values, needs and methods of the conservation of forest genetic resources.

Forest Genetics and Tree Breeding; Current and Future Signposts

R D Burdon, New Zealand Forest Research Institute Ltd., Rotorua, New Zealand

Introduction

The context of forest tree improvement is changing and will continue to change. Upgraded processing technology, the development of new products, global economic changes and associated changes in markets, biotic events, plus changes in crop management systems, will all tend to change breeding goals. The classical breeding methodology is likely to undergo basically incremental changes made possible by a combination of more refined algorithms, upgraded software, and continued increases in computing power. Advances in propagation technology, some more or less classical, some much more radical, will favor updating of both breeding goals and crop management systems. Management of the populations used in total breeding programs will become a more pressing issue as genetic advances continue, with the associated tendency to narrow genetic bases. Novel gene technology, directed at identifying existing genes or at introducing new ones, is being widely explored, yet remains unproven. Genetic modification has many attractions, including reducing lead times and expanding the range of prospective breeding goals, but in forest trees poses some special risks and requires prolonged testing of transformants. While new biotechnology promises much, it is widely seen as a powerful supplement to classical breeding rather than a substitute for it. Institutional and economic changes, along with rapid changes in technology, are changing the ways in which forest genetic improvement is pursued. Collaborative structures are coming under severe pressure, planning horizons are becoming shortened, and field-based work is tending to lapse in the face of stagnant funding combined with a shift towards biotechnology.

At the same time, and counter to the genetic improvement that is a key part of intensive domestication, there is a movement away from interfering with natural genetic processes and towards management of natural ecosystems. Yet to retain this option may require the productive capacity of intensive, highly domesticated plantations; and to implement it effectively may require research information from modern gene technology.

Plantation Crop Improvement

Evolution of Breeding Goals

Breeding goals initially tended to focus on growth rate and tree form, with general health and adaptation as prerequisites. However, the goals have almost always evolved as breeding has progressed, with new information on biotic factors, genetic parameters, market demands, and the underlying wood characteristics that meet those demands. The goals will surely continue to evolve.

Disease and pest resistance Intensive plantation culture, plus increased and more rapid global travel, make diseases and pests more of a risk. So too will the favored status of a few intensively domesticated species that people may seek to grow over extended ranges of environments. Thus increased emphasis on improved pest and disease resistance is likely.

Wood properties Impetus for achieving genetic improvement of wood properties can be expected from several directions. On the one hand, there is greater sophistication among wood processors and in the markets. On the other, there is a widespread tendency for practices that reduce the effective growing costs, notably use of fertilizers and lower stockings in order to shorten rotations, plus genetic gains in growth rate, to militate directly and indirectly against wood quality. Thus there is a call both to tailor wood properties better to market needs and to offset adverse impacts of reducing growing costs, to improve net value.

Portfolio approach Despite the greater sophistication, market requirements will remain uncertain, especially for species that are unsuited to extremely short rotations. One way of addressing such uncertainties is to deliberately grow a 'portfolio' of well-characterized but differentiated breeds in the hopes that one or more may eventually command a high premium in a market niche while the others are all routinely marketable by virtue of being well characterized.

Targeting by hybridization Early on in tree breeding, interspecific hybridization was pursued widely and somewhat uncritically, probably because many poplar hybrids gave strong, often almost unconditional heterosis (superior hybrid vigor) and were readily amenable to mass vegetative propagation. Many species hybrids, however, show no clear heterosis, and/or pose major problems of mass propagation. More recently, it has become appreciated that careful choice of parental populations or genotypes can strongly influence the merit of hybrids, that there are specific situations where heterosis can result from complementarity of site tolerances or pest or disease resistance, and that economic advantages can accrue from certain combinations of attributes even in the absence of actual heterosis, while advances in propagation technology can overcome the historic difficulties in mass propagation. Even with past difficulties, some nonpoplar hybrid combinations have proved successful, and there is likely to be a resurgence of experimental hybridization, both interspecific and interprovenance.

Impacts of new propagation systems and other biotechnology Improved vegetative propagation systems are making possible mass propagation of individual clones in a wider range of species. The consequent clonal systems can change breeding goals in several ways. They will facilitate the selection of ideotypes that may not be strong competitors but can, as pure crops, be especially productive. This would be matching long-term trends in much crop breeding, whereby certain features that can militate against competitive ability can actually favor high economic productivity. Thus some long-term gains in production may stem from exploiting divergences between competitive ability and productivity, although the scope for this is necessarily relatively limited when trees are grown for stemwood production. Yet in future the divergence that exists may become the basis for wringing out further gains in productivity. Moreover, various features of stem architecture that favor competitive ability also represent highly undesirable within-log variation in wood properties. For some traits, like resistance to climatic damage, clonal selection may be much more powerful, since much wind damage may reflect physical interactions among neighboring genotypes rather than the inherent susceptibility of each and every genotype to such damage. Routine screening of large numbers of candidate genotypes for such crop-performance traits is prohibitively costly and time-consuming, so a major challenge is to develop the capability to characterize the appropriate ideotypes for improving such traits.

Less radical is the potential for clonal forestry to target ideotypes that represent intermediate expression of traits, since use of clonal material avoids the variation arising from genetic segregation. This, however, will only be worthwhile for traits of high heritability.

Genetic engineering, which is addressed later, can of course make it possible to address breeding goals that are basically inaccessible when using naturally occurring material. It can also be used as a research tool, to provide information with a range of applications.

Classical Breeding

Quantitative methodology

Selection Algorithms for estimating (or predicting) genotypic values from data are likely to undergo some incremental refinement. However, the limiting factors may remain information on economic-worth functions and genetic intercorrelations, poor economic information being a major problem in the presence of adverse genetic correlations; this calls for good understanding of cost and price structures in production systems, although uncertainty concerning future markets will bedevil longer-rotation species. To some extent, this problem can be finessed by deploying differentiated breeds, which exploit differences between environments and end-uses in the comparative economic weights of different traits. In effect, this is a means of exploiting global nonlinearities in economic-worth functions for different traits. However, with clonal forestry systems there is the prospect of exploiting various nonlinearities to a greater degree.

Trial layout Theoretical efficiency of experimental layouts for selection has been widely studied, but often in relation to fixed total numbers of individuals planted. Optimality in terms of cost-efficiency of genetic gain, however, remains the ideal. While it is almost always the subject of operational guesses, explicit quantitative analysis has seldom, if ever, been published.

Data analysis While experimental layouts can be refined, the efficiency of selection therefrom may remain limited by the inherent effectiveness of block layout schemes for partitioning environmental effects. Another approach is to use the data to estimate both the local environmental effects and the genotypic effects, in order to achieve better estimates of genotypic values. Such neighborhood-adjustment or spatial analysis has already been significantly developed, but guidelines as to optimal algorithms in given situations remain to be established with any high degree of confidence. Establishment of better guidelines and more extensive use of such analysis are foreseen, especially with continued improvements in software and computing power.

As tree-breeding programs progress, population structures are typically becoming more complex, with overlapping generations and multiple classes of relatives. This increases the call for sophisticated data analysis for selection, thus strengthening the traditional affinities with animal-breeding methodology.

Stochastic simulation For general optimization studies, increased stochastic simulation is foreseen, since it is a powerful tool not only for predicting outcomes but also for assessing associated risks by characterizing distributions about the most likely outcomes.

Genotype–environment interaction ($G \times E$) Genotype $\times$ environment interaction, whereby the comparative performance of different genotypes will vary according to the environment, remains an important issue for genetic management of forest trees. It involves: (1) geographic transference rules for deploying material; (2) possibly structuring breeding populations into units to serve different environments; and, (3) even without such differentiation of breeding populations, selective deployment of planting-stock genotypes in different environments. A challenge remains to characterize the roles of environments in generating interaction, so that candidate genotypes can be tested more efficiently by choosing near-optimal subsets of environments for testing. In that way, it should be possible to maximize the efficiency of screening candidates for performance across the range of environments over which the species may be grown. Such an approach will contrast with much of the traditional methodology for studying $G \times E$ in crop plants, which has focused on the interactive behavior of finite numbers of stabilized cultivars and is the subject of a voluminous literature. More specifically, a challenge exists to make joint use of data on both test performance and environmental particulars for characterizing the roles of environments in generating interaction.

Forwards versus backwards selection The term 'backwards selection' is classically applied to selection on the basis of progeny-test performance, as in roguing or reconstituting seed orchards. Forwards selection applies classically to selection of seedling ortets within families created by crossing between superior parents, as in turning over generations in a long-term breeding population. While backwards selection gives high confidence in individual selections, it may sacrifice too much in terms of the genetic gain that can be virtually assured from forwards selection. Moreover, the distinction between forwards and backwards selection can become blurred in clonal selection, where either there can be dedicated clonal trials or seedling offspring in the breeding population can be clonally replicated. The latter case effectively allows forwards selection while reducing exposure to $G \times E$.

Population management

The status of controlled pollination Controlled pollination and the associated control of pedigree have been cornerstones of many existing breeding programs. However, full control of pollination can either limit the number of combinations in which parents can be crossed or incur excessive cost. Full control of pedigree, while it maximizes control of nominal inbreeding, effectively limits the manageable size of a breeding population, which can lead to loss of low-frequency alleles and severely limits the chances of capturing the infrequent to very rare favorable mutations. Sacrifice of full pedigree, however, need no longer be the irreversible step that it has been, thanks to DNA marker technology.

Refining of population structure Management of domesticated genetic resources has not usually reached the stage at which appreciable inbreeding is unavoidable. Neighborhood structures make mild inbreeding a natural feature of the genetic systems of many, if not most, forest tree species, so such inbreeding should be easily enough accommodated. However, there are signs of rekindling interest in some quite close inbreeding as a breeding tool, in order to purge genetic load and to build up frequencies of desired alleles more rapidly — only by selfing is it possible to achieve perfect assortative mating for all traits.

Breeding populations, where programs have elaborated beyond relatively simple variations of mass selection, have basically been structured around the production of seed orchards. However, where clonal forestry systems are the norm, the tendency has been for little to be developed in the way of formally structured breeding populations. In future, we must look to structuring breeding populations in the expectation that they will provide clonal material. Two likely implications are: (1) that individual offspring genotypes may be clonally replicated, particularly across sites; and (2) that some inbreeding may be more readily tolerated, because associated bias in family-mean information may matter less for selection.

In any event, a breeding population with clonal replication allows a closer integration of elements of both forwards and backwards selection.

Allowing for climatic change Since climatic change is a near certainty and, from latest knowledge of quaternary history, an ever-present risk, any management of genetic material should make some provision to accommodate such change. Even without the human influences that are currently driving global warming, recent climatic changes have sufficed to create widespread suboptimality of local populations. While most natural populations, with high rates of natural mortality and the consequent 'soft,' density-dependent selection, are sufficiently heterogeneous to allow considerable natural wastage of maladapted segregants, plantation forestry which is based on low ratios of final-crop trees to trees planted will not accommodate such wastage so readily. It seems logical to anticipate likely climatic change in locating at least some of the breeding-population and gene-resource material.

Deployment Issues

Family and clonal forestry Genetic uniformity has in principle enormous advantages for growing and utilization, although clonal monocultures are subject to notorious biotic and bioclimatic risks. For many species, therefore, single clones cannot safely be regarded as crop cultivars in their own right; rather, they should be components of a composite cultivar population, akin to the multiline cereal cultivars that have been synthesized to provide durable disease resistance in the face of mutation and adaptive shifts in pathogen populations. It remains to be seen what proportions of such clonal assemblages in forest trees will be deployed in mosaic or mixture respectively. For clonal material, management regimes can be precisely tailored to individual clones, or even to mixtures of clones that may be silviculturally similar but diverse with respect to ancestry and cryptic traits such as resistance to new pathogens.

Short of deploying specific clones, specific families are already used in some cases to match the management and utilization of crops to genetic composition but, with the genetic segregation that can even occur within pair-crosses, such matching is likely to fall well short of what is possible with clones.

Application of Molecular Biology

Molecular biology, involving DNA technology, has already reached initial applications in tree improvement. Most of the major potential applications and the basic underpinning science, however, are still being researched. Some of that work is being done with new sources of funding. However, with stagnant funding levels, much of it is being done at significant opportunity costs in terms of gains available from conventional breeding. Yet the successful application of much of the DNA biotechnology will be strongly dependent on the field plantings of the genetic material of conventional breeding programs. Using such biotechnology will intensify the domestication process that begins with plantation forestry and continues with classical breeding, and the essence of domestication is increasing inputs in order to obtain better returns. While biotechnology can substitute for some classical breeding measures, no prospect is seen of satisfactory net overall substitution within the short term.

Markers and expressed sequences

Verification/determination of genetic identity Use of simple sequence repeats (SSRs), also called microsatellites, has enabled verification of both clonal identity and pedigree. It has also revealed an embarrassing rate of errors in genetic identity, such errors becoming more and more crucial as a breeding program advances, on account of the increasing levels of genetic gain that are dependent on correct identity.

Determination of population origins While verifying an intended pedigree may now be relatively straightforward, there can be much greater challenges in identifying population origins of material, because the polymorphisms (presence of different alleles or forms of genes at individual loci within the genome) that differentiate individual genotypes or pedigrees represent noise variation in trying to differentiate populations. Such a capability, however, may be crucial for addressing problems of genetic contamination, which may be acute in the gene resources that underpin breeding populations.

Pedigree reconstruction Pedigree reconstruction, as opposed to the verification of a specific pedigree, has been proposed in respect of paternity as a means of saving on the costs associated with multiple pair-crosses per parent. However, there are likely to be situations where reconstruction of pedigrees, from large numbers of possible parents, may yet be needed, as in a biotic crisis when it may be necessary to select for disease resistance in unpedigreed commercial stands. For that, it appears that much more powerful marker systems will be needed in order to give essentially unambiguous answers.

Use of DNA markers for selection Use of neutral genetic markers to locate and characterize quantitative trait loci (QTL) in the genome (see below), as an aid to selection, has already been the subject of much experimental and theoretical research. Such information may be used in conjunction with phenotypic information on the trait(s) concerned, in true marker-aided selection (MAS) or, if practiced before phenotypes can be expressed, can be done entirely on marker information. Even after some theoretical pitfalls have come to light it appears promising, and it has worked well in some crop plants but not others. However, its efficacy in forest trees remains to be demonstrated. Because forest trees are outbreeders the general linkage disequilibrium (LD) that forms the ideal condition cannot be expected, except perhaps in hybrids between species that are fixed (having zero or 100% gene frequencies) with respect to different QTL and linked markers.

Genomics Genomics, the study of the physical arrangement of genes and noncoding DNA in the chromosomes, and the base sequences and gene functions, has become the focus of major research efforts.

Comparative The close genomic similarities between genomes of various important forest trees will favor collaborative efforts, since findings in one species can often be applied, in various possible ways, to one or more other species. The very high degree of synteny among certain species, e.g., within the genus *Pinus*, with the same genes at the same genetic loci having the same function, allows information to be readily applied from one such species to another. Quite remarkable, however, are the orthologies between very distantly related organisms, whereby very similar DNA sequences can code for closely homologous gene action despite wide differences in general plant structure and organization. Commonalities between the roles of the same genes (or close homologs) in different organisms can provide the basis for what S.H. Strauss refers to as genomics guided transgenes for exploratory use in genetic engineering.

Functional Study of pathways of gene action, based on expressed sequence tags, can, apart from yielding fundamental knowledge, help identify the effects of particular genes, and the feasibility of various prospective breeding goals. Genetic modification can be a powerful research tool, allowing the study of the metabolic and phenotypic impacts of altering the expression of existing genes or introducing alien genes.

Targeting breeding goals While there may arise some conditions that allow general LD in outbreeders, these conditions are often unlikely to obtain. This creates an additional call for the ideal situation of being able to identify readily the genes of interest by the base sequences, which would allow true gene-assisted selection (GAS).

Applications of genetic engineering Genetic engineering, or genetic modification (GM), entails inserting DNA sequences to modify the activity of existing genes, or introduce new functional genes. Much of the research to date has aimed at proving the concept for the species concerned. Several operational applications are being widely pursued, notably pest resistance, herbicide resistance, and reproductive sterility. GM is also being explored as a means of improving certain wood properties. It promises certain gains that may substantially exceed those already promised by the typically high heritabilities of wood properties. However, there remain great attractions in using GM essentially as a research tool, using the insertion of DNA sequences to probe the roles of certain genes and their pathways of action. Indeed, this could yield some information that may eventually be applied in conventional breeding. GM, however, is intensely dependent on *in vitro* culture systems.

While all technologies have their own risks, the risks of GM attract special public attention, and in the case of forest trees they have some special features. They must therefore be addressed as part of the research on developing GM technology for forest trees, and be seen to be so.

Propagation Technology

Seed propagation will remain necessary, at least to produce the genetic recombinants that provide the candidates for the next cycle of recurrent selection. For many species, however, seed production will continue to be needed for mass production of commercial stocks, either directly or as a platform for mass vegetative multiplication. Pending, or failing, the development of mass vegetative multiplication, incremental improvements can be expected in seed-orchard technology, to improve yields and physical quality of seed and to avert unwanted external pollination. Care may be needed, however, in the choice of environment for seed production. In some spruces, in particular, the inherent growth rhythms and climatic tolerances of seedlings have been found to be affected by climatic conditions during a particular phase of seed production. Thus the choice of a congenial climate for producing seed may compromise adaptation to the harsher climates for which the seedlings are intended.

Rooting of cuttings has become a mature technology for mass-producing planting stock in many species, including some that were traditionally propagated as seed. Its development will surely continue in some quarters. Micropropagation, or tissue culture, will be refined further in many cases and developed for additional species, often for initial rapid multiplication to complement cuttings production. Embryogenesis, the other *in vitro* system, offers even higher multiplication rates, and has special promise as a means of providing recipient material for GM. Often, however, *in vitro* systems need to be refined in order to work with any genotypes of choice within a species.

Full control of maturation state in clonal material is extremely desirable, if only to allow clones to be mass-propagated after their merit has been proven. Several technologies exist to check the process of maturation (or physiological aging), with cryogenic storage looking increasingly promising. However, achieving true reversal of maturation, or rejuvenation, in somatic tissue would have enormous strategic significance. Still unrealized for a great many species that do not sprout from stumps, it remains perhaps the biggest single challenge in propagation technology.

Technology Portfolios

New biotechnologies are developing rapidly, and the many prospective technologies for individual steps in the process of genetic improvement can lead to large numbers of potential technological pathways for delivering enhanced genetic gains. Individual technologies typically have risks, of not performing as hoped, at least for the species in question. Even if a technology succeeds in itself, it may fail because it belongs in a pathway that is outflanked by another pathway. The problem is that, while each technology needs a concerted research effort, there needs to be a portfolio of alternative and complementary technologies under investigation in order to spread risks.

Interactions with Other Disciplines

Wood science, processing technology, and product development Increasing emphasis is being placed on genetic improvement of wood properties, for a number of reasons. Easily obtainable genetic gains have often been already captured for traits involving silvicultural performance and tree form. At the same time the pursuit of shorter rotations, fertilizer use, and lower stockings, all to reduce effective growing costs, call for genetic improvement to offset consequent declines in wood quality. Furthermore, wood processors and end-users are often demanding tighter quality specifications. Wood properties often appear to be very amenable to conventional breeding, but can be very expensive to evaluate (especially product-performance properties), while the role of specific basic properties in governing product performance is often little known. Major research efforts are afoot to study wood chemistry and ultrastructure in relation to product-performance properties, and the developmental pathways in expression of genes significantly affecting wood properties, with comparative genomics and genetic modification as research tools. Such work is directed at the full range of existing wood products, and the possibilities of new products.

Pathology Improved disease resistance is often needed for plantation crops, in the face of additional hazards posed by monocultures and growing preferred species over a range of sites. Such resistance often needs to be durable against genetic shifts in pathogen populations. Use of DNA markers promises to detect the various genetic resistance factors in the host, to help aggregate the multiple resistance factors needed to assure durability.

Other disciplines Of note are the overlapping areas of physiology and biochemistry, as essential adjuncts of functional genomics.

Impacts of Institutional Changes

Forest genetics research and tree breeding have historically been done largely under government agencies, or else multiparty cooperatives. Governments have tended to withdraw from such activities, with global pressures to reduce taxes. The development of biotechnology, particularly relating to DNA, has encouraged much more proprietary attitudes towards intellectual property. That in turn, along with many recent changes in forest ownership, is placing tree-breeding cooperatives under pressure. All these factors are also exerting pressure on the long-term strategic management. Also discouraged by proprietary attitudes toward individual technologies, which militate against collaboration, are adequate risk-spreading technology portfolios.

Species for Domestication

The list of forest tree species that have been subject to intensive domestication, including elaborate breeding programs, is relatively short, rather like the main food crops. The cost of intensive breeding will tend to focus domestication on a limited number of forest tree species. On the other hand, the perenniality and lifespan of forest trees make environmental adaptation much less flexible, which may tend to stop the list of domesticated forest tree species from remaining extremely short. Nevertheless, pines, eucalypts, and acacias seem likely to predominate among the intensively domesticated species.

Management for Conservation

Plantation forests have assumed great economic importance, despite occupying only a small area relative to native forests. They also have potentially great ecological importance, in that they may serve to relieve exploitation pressures that might otherwise affect natural forests (although clearance for agriculture is another matter). However, preserving and managing native forests, either for controlled exploitation or pure conservation, is often far from straightforward. Monitoring breeding systems and measures of genetic diversity can help indicate the likely impacts of population size and of cutting and regeneration regimes on long-term viability of populations. For this, information on reproductive biology will be very important. Some indications are being obtained of the impacts of certain exploitation regimes on the structure and diversity of populations. However, the most appropriate measure of genetic diversity is problematic. Diversity reflected in neutral genetic markers is often poorly correlated with the functional diversity that is often crucial to site adaptation and to response to artificial selection, such that common-garden field trials are often needed to relate functional diversity to marker diversity as well as elucidating genecology and within-species taxonomy. Common-garden experiments, however, while they can reveal much, will often need to be complemented by ecophysiological studies. Such studies can identify the specific environmental factors that cause stress, and the ways in which stress arises. As such, they can be powerful tools for applying results of the common-garden experiments beyond the particular environments where they are located. Of interest are indications that major functional diversity can be governed by promoter regions rather than coding regions of genes.

The genetic component of conservation management is likely to depend on the ecological validity of management regimes. Misguided exclusion of fire has often proved very counterproductive. Questions must now arise concerning the appropriateness of trying to impose uneven-aged and essentially continuous canopy structures on each and every species.

Conifer Breeding Principles and Processes

A D Yanchuk, British Columbia Ministry of Forests, Victoria, BC, Canada

Introduction

Conifers or gymnosperms occupy many important forest ecosystems and are some of the oldest known species on the planet. Of the thousands of conifer species known to exist on earth, probably fewer than 100 have received even preliminary genetic studies, and only a dozen or so are under any kind of intensive tree improvement and breeding efforts. Some of these species, such as Monterey pine (*Pinus radiata*), have provided some of the most successful commercial forest tree plantations in the world. According to the Food and Agriculture Organization, of the approximately 187 million ha of forest tree plantations around the world, 31% are coniferous and of these approximately 20% are pine species.

Relative to genetic improvement in agricultural species, forest tree genetic improvement programs are very new. However, many changes to classical breeding approaches used in domesticated plants and animal species have had to be made in order to accommodate the unique biological features of forest trees. The reproductive biology, geographic patterns of genetic variation in the species, preservation of adaptive genetic variation, and the maintenance of wild forest reserves are issues that are unique to forest tree genetic resource management.

Genetic Surveys and Selection in Natural or Naturalized Populations

As far back as the early and mid twentieth century emphasis was placed on range-wide genetic surveys (i.e., provenance testing) using 'common garden' experiments, first established by research ecologists. Samples (seed) were collected from natural populations of interest (i.e., provenances) then raised and planted together in several environments to test performance of the local provenance versus nonlocal.

These studies showed that most conifers have large amounts of genetic variation, both within and among populations, and local populations are generally slightly suboptimal (e.g., adaptational lag can be present, among other factors). However, forest trees, in general, do show that patterns of adaptation are reasonably well associated with the climate from which they originated. More importantly, there are differences among and within species in this type of adaptation. Conifers can be classified as generalists, intermediates, or specialists in their level of adaptation to climatic and environmental gradients. For instance, species such as western white pine (*Pinus monticola*) are considered generalists, i.e., adaptations are not well correlated with climatic or geographic variables, yet others, such as Douglas-fir (*Pseudotsuga menziesii*), are much more tightly adapted; hence, movement of seed in this species needs to be restricted. A few species, such as some of the *Thuja* species, have genetic variation substantially lower than most other conifers, and at the extreme, *Pinus resinosa* shows almost no genetic variation.

Sampling strategies for breeding programs have sometimes been designed to take advantage of natural levels of variation among populations. In some cases, usually where exotic species are used, 'provenance effects' may be available to use, or a well-developed 'landrace,' if present, may also be an effective base population. Several large industries have been established from such introductions of materials, as with Monterey pine in New Zealand, Douglas-fir in France, Sitka spruce (*Picea sitchensis*) in the United Kingdom, and *Eucalyptus* spp. in many tropical and semitropical countries.

Genetic Testing

Genetic testing techniques developed over the last several decades have made it possible for much more rapid genetic improvement. However, the underlying reason for genetic gains is the same: most traits have genetic variation, and these differences can be transferred to offspring or progeny (i.e., they are heritable). Overall, most tree improvement programs have focused on improving growth potential, so selection on individual phenotypes has generally not been very effective because growth is typically a lower-heritability trait. However, a few other traits have been successfully improved by phenotypic selection, such as straightness, form characteristics, some disease resistance traits, and wood properties.

Field Test Designs

As in animal breeding, the past 30 years have seen tree breeders increasingly use techniques that more accurately identify and predict the genetic value or worth of selected parent trees. The use of a mother tree's offspring, whether vegetative (clonal) or seedling offspring, is a powerful technique for examining the genetic value of any parent tree. With many offspring trees per parent, planted across several test sites, some trees will sample better than average (i.e., microenvironments), and some worse, but on average the statistical average or mean of the family will reflect closely the true genetic mean of the family. It is a widespread practice to use about 20–30 offspring per family per site, as including more observations per family tends to be inefficient with respect to our interest in being able to compare more families.

The types of designs briefly discussed above, i.e., all genetic entries in the study are replicated in each replication or block, with multiple blocks, are referred to as randomized complete block designs (RCBs). In the field, blocks or replications are laid out with the hope of 'blocking' out patches of similar microsites, but the weakness with the design has typically been that the blocks are too large and fail to partition off much of the environmental variation that occurs within recognizable patches. With fewer numbers of trees per family in each block, and therefore more blocks on the test site, the efficiency of the design becomes greater.

A typical and relatively robust single-tree plot experiment would be one with 25–30 progeny per genetic entry (which means 25–30 blocks or replicates). It is important to note that if there were no environmental patches or gradients on a test site (which is usually never the case), no test site designs would be necessary. Forest tree test sites are normally quite patchy, with large gradients, even if this is not visible at the time of establishing the test sites. Of late, many breeding programs are considering new designs, such as incomplete block designs (ICB).

One significant problem with progeny testing to identify superior parent trees is that when competitive effects among trees take place, it is effectively no longer useful as a genetic trial to compare all genotypes. Slower-growing families will continually be outcompeted and among-family growth differences inflated. Hence, predicting genetic gain from older progeny tests is biased, as the trees are not in a true plantation situation. In recent decades, many genetic-gain trials in many programs have been established to help verify estimates from replicated progeny trials to volume yields on a per-hectare basis. Many institutions working with fast-growing species, such as Douglas-fir and radiata pine, now have very good measures of yield per hectare, with commercially well-known clones or families.

The Problem of Early Selection

In forestry, it is rare (except with some fast-growing hybrid poplars or *Eucalyptus* spp.) for selection ages to approach the final harvest age. This is particularly true for most conifer tree species bred for timber production, where rotation ages can be 25–80 years, depending upon the species and site productivity. In this situation, if the genes that affect the expression of a trait at an early age change their expression, then errors in selection accuracy and prediction in gain will be made. Family selection ages in forest tree breeding have usually been shown to be optimal (based on growth data) at ages 6–12 years. Tree breeders, then, face the issue of making adjustments to the predictions of genetic gain at rotation, to accommodate the juvenile to mature-age genetic correlation being imperfect. It will take several more decades for forest geneticists to understand the magnitudes of age–age genetic correlations in forest trees, so this is an inherent risk in tree breeding – little else can be done at this stage.

Genotype × Environment Interactions

It is also known that a particular genotype may perform differently, relative to others, in different environments. Thus genetic differences can be expressed differently in different environments. This is usually referred to as genotype × environment interaction (G × E) and has been a very important issue for geneticists to consider for many decades. Most conifer breeding programs use several test sites to look for stability in performance. For the most part, conifer genotypes exhibit reasonable performance across many variable sites, except in extreme conditions (e.g., such as low-elevation selections being tested at high elevations). Therefore, it is important that in initial testing schemes, multiple-site field-testing be used in order to establish the magnitude of G × E in the population and identify specific families of interest.

It is generally accepted now that any satisfactory method of analysis of G × E must allow the breeder the ability to differentiate between true changes in rank among genotypes in different environments, and that of statistical artifact (e.g., scale effects caused by different means and variances among different sites). The quality of the genetic tests, measured by heritability, is one of the factors that must be considered, along with the similarity in averages and variances.

Advanced-Generation Breeding and Testing

If it proves to be economically and biologically feasible to carry on with a genetic improvement program, the best parents identified through the first round of progeny testing (P_1 selection) need to be mated together. With recurrent selection continuing on this basis, the breeders are essentially creating new allelic combinations from which to change the frequency of genes for the trait of interest by selection. The most advanced conifer programs in the world, e.g., *Pinus taeda*, *P. radiata*, *Pseudotsuga menzesii*, and a few others, are at the filial third (F_3) or filial fourth (F_4) generations.

Traits of Economic Interest

Besides the improvements in growth performance, wood density has been studied and has been found to have higher heritabilities than growth rate, typically twice that of growth rate. However, there are often lower coefficients of phenotypic variation so gains are not large in most wood quality traits particularly when growth rate is also selected. As well, there are typically adverse genetic associations between these two traits. Many other traits are also important in conifer breeding and genetics, such as pest and disease resistance, tree form as it would affect log and timber quality, and many other wood properties. Whether these are being directly selected for economic reasons or not, conifer breeders have investigated these traits to establish the genetic and phenotypic relationships that could affect selection on other main traits (i.e., typically growth).

Mating Designs

There are several ways in which conifer breeders have been making controlled crosses (i.e., mating designs) for advanced-generation breeding. Complete matings of all possible desirable crosses is an ideal, but generally not practical and not economically or biologically necessary. Balanced mating designs are preferred in that estimates of general combining ability (GCA) and specific combining ability (SCA) are unbiased, but this has generally been shown not to be overly important. Making as many crosses as possible in the shortest period of time (as long as each parent is crossed a few times) tends to be a more cost-effective approach, as genetic gain per unit of time is generally the most important measure of long-term achievement in forest tree breeding.

A mating design that has been used often is the factorial design. This is where a tree can serve exclusively as a male or a female in some small mating group. This is one distinct advantage of the factorial design; e.g., if the breeder chooses a breeding group of eight unrelated trees, and mates them in the factorial design, four parents only need to provide pollen, and the other four only need to provide female cones for isolation and breeding. The total number of crosses in this situation is therefore 16. In the most commonly used mating design, the diallel, trees are used both as males or females. Complete diallel mating designs are generally not necessary, and the partial half-diallel scheme is usually employed by most tree breeding programs. However, after three to five crosses per tree it has been shown that there is little added benefit for the purposes of family and within-family selection.

Although there has been substantial debate about which approaches are best for advanced-generation field tests and selections (i.e., 'forward' selections), the most effective method will likely be determined by local operational and practical matters more than by theoretical ones. For instance, large homogenous single-family blocks (e.g., 100 full-sibling trees in each block with no replication) have been established, which allow the breeder a much better visual comparison of all cohorts in that family. With homogeneous test environments, this method can be very effective. On the other hand, breeders are usually still interested in applying selection at the family level, before selecting a few individual trees within families. In such cases, the designs, such as those discussed above (i.e., RCB designs), need to be used. Selecting individual trees for the next generation from single-tree plot or incomplete block designs is still possible with these designs (relative to the use of RCBs, or large single-family plots). However, it is likely that more reliance must be put on the family level of selection and therefore the use of more statistical assumptions and methodologies.

Breeding Population Structure

It has been shown that high short-term gains are possible with a relatively small breeding population, without losing much genetic variability (sometimes it may actually increase) even over several generations. If, for example, an aggressive program is considered appropriate, an elite breeding population of about 30 parents could be crossed together for the second generation population. In this situation, however, many of the lower-frequency genes, which may not have strong effects on the trait of interest, will be lost by genetic sampling effects. But including dozens more, or even a hundred, will only slightly reduce the chance of these loses. Moreover, these low-frequency genes do not have much affect on the genetic variation under selection. So other approaches should be developed to accommodate these kinds of genes (i.e., gene conservation programs). Most conifer breeding programs around the world now work with relatively small population sizes in the F_2 and F_3 generations, but maintain larger genetic reserves by other means.

Once this issue of population size has been resolved, it would be important to consider issues of relatedness that will be built up over time in the breeding population. This is inevitable in any breeding program, so tree breeders have to design methods to minimize the effects of accumulated inbreeding as best as possible. Subdividing the breeding population into groups that remain separate from intercrossing, sometimes referred to as sublines, allows the breeder to make matings among trees within sublines over generations but never crossing trees among sublines. This approach is now common in most tree breeding programs, as it allows the breeder the option of making selections among unrelated groups, which will be important for commercial seed production, usually in seed orchards.

Inbreeding Depression

As discussed above, it is inevitable that there will be relatedness among future-generation selections. Inbreeding is generally undesirable, because when related individuals are intermated, the deleterious genes (typically present even in highly selected parents) will be become homozygous at frequencies higher than expected by chance. If too few individuals are selected, or selection is not strong enough to eliminate these homozygous individuals, some deleterious alleles can become fixed in the selected population and overall performance or fitness will be lowered in the population.

Most tree species simply grow too slowly and are too difficult to work with to develop inbred lines, as has been done in some crop species. In forest tree seed orchards, or production populations of trees, as mentioned earlier, a breeder can take one or a small number of trees from each breeding group (subline) and inbreeding is effectively zero and production is maximized.

In the breeding population, mating decisions that minimize crosses among close relatives over time, and generate a large number of offspring per generation, will reduce the risks and hazards of inbreeding depression. With other experimental organisms (e.g., mice, maize) adequate population sizes with strong selection, has, over time, offset these effects and made genetic improvement a long-term possibility.

Genetic Diversity and Risk in Forestry

There are essentially two types of risks that foresters and forest genetic resource managers need to consider:

1. Is there a threat from a currently known pest that may be able to overcome current levels of natural resistance in the species and inflict unacceptable losses in planted forests?

   There are several ways in which this can be addressed, but all will depend upon a good understanding of the genetic basis of the resistance. For instance, several types of resistance mechanisms could be deployed in mixtures to make it difficult for the insect or pest to mutate to overcome all resistance genes at once. Another approach could be to deploy some susceptible genotypes along with resistant genotypes that rely on a single resistance gene or mechanism. The hope is that there is less pressure on the insect to evolve virulence to the resistant gene, while allowing for a commercially viable crop.
2. The geneticist must consider that there may be some future risk of a currently unknown threat (e.g., the introduction of an exotic pest). This is likely the case in which some natural resistance, controlled by genetic variations present in the population, is lost by mismanagement of genetic diversity in the deployment population. Responsible genetic management policy needs to be founded on this basic premise.

   Several research approaches have been considered with respect to this problem. As a general rule it has been shown that a very large number of genotypes, say much greater than 30–40, do not add any additional levels of 'genetic safety' over what natural forest regeneration might be able to provide. In fact, a relatively safe range can be between 10 and 30 unrelated genotypes. This is due to the following: genes at low frequency in the original wild population, which may be able to provide some resistance or increase fitness of the tree, will not be at frequencies high enough to protect even these natural stands. In other words, there would not be enough surviving and unrelated individuals in the wild stand with the resistant gene to serve as parents to regenerate the stand.

In summary, the deployment of genetic variation across the landscape for timber production must balance several factors, but a linear increase in some measure of diversity does not, in itself, provide a linear decrease in risk.

Gene Conservation

Basic measures in most tree breeding and conservation programs are to outline, document, and establish where and how certain classes of genes and genetic variation are best maintained over time and space, in case they are needed. Gene conservation should be viewed as a type of genetic 'insurance,' but the breeding populations, if present, should maintain most of the variation needed for the short and medium term future.

The loss of additive genetic variation in a population can be approximated by the formula $1/(2N_e)$, where N_e is the effective population size, so a sample of 30 trees from an infinitely large population will contain over 98% of the original genetic variation in the population. However, what will not be present in relatively small breeding populations are most of the genes that were at relatively low frequency in the original population. Conservation of these genes, either singly or in some complex of frequencies, is why gene conservation programs are needed and have to be designed to achieve over time. Breeding populations, clone banks, provenance trials, progeny tests, can all be linked, along with *in situ* populations (protected areas, such as parks, or managed forests with natural regeneration) to form the base of material for a conservation strategy.

Climate Change and Tree Breeding

Tree breeders may need to develop breeds today, for climates several decades from now. Assuming climates do change as predicted from global circulation models, it is largely up to the genetic resource manager, with an understanding of genetic variations and patterns of adaptation that the species exhibits, to respond now and generate material that will continue to produce the products we desire. Climate change models, and predictions of changes in biotypes around the world, can only tell us where the problems will be, but do nothing in themselves to offer solutions. The management and movement of the appropriate populations, largely developed and understood by researchers and tree breeders, will be the viable approach for forest managers to consider. Most wild populations of conifers, indeed most tree species, will not be able to migrate enough to maintain much resemblance to current forest ecosystem types. In this respect, climate change research in forest management is first and foremost a problem of genetic resource management.

Biotechnology and its Role in Conifer Breeding

There has been much technical development over the last decade with respect to cloning forest trees and changing the genetics of plants with transgene technologies. Cloning techniques, such as simple grafting, go back as far as the first grape varieties, but with current tissue culture techniques in conifers, such as somatic embryogenesis, genetic transformation using recombinant DNA technology is possible. Still uncertain, however, are the economics and social acceptance of genetically modified trees.

Molecular genetic markers are also becoming more important tools in forest genetics research and breeding, especially as genomes are becoming better understood with more complete molecular analysis. The use of marker technology for marker-assisted selection in applied breeding programs is also possible, but has not yet been applied widely in forestry tree breeding, primarily because of costs. Nevertheless, the information from molecular genetics research is uncovering many interesting aspects of gene evolution and function.

Conclusions

Tree breeding techniques (e.g., modern selection, breeding, and testing methods) are of course of paramount importance in pursuing improved quality of commercial conifers for traits of interest. Important techniques in tree breeding that have developed over recent years mainly revolve around field-test designs, mating designs for advanced-generation breeding, and many specialized procedures to assess traits of interest. New areas of research and program management are required in the areas of conservation of genetic variation, deployment patterns for improved varieties, special traits that require innovative assessment and selection systems, molecular genetics and genomics, multiple population breeding, and genetic management information systems. Of utmost importance, however, is that tree breeding programs consider the simplest and most effective methods that can be handled by the organization in realistic time frames.

Breeding Theory and Genetic Testing

T L White, University of Florida, Gainesville, FL, USA

Introduction

Tree breeding programs, also called tree improvement programs, create genetically improved varieties for reforestation and afforestation. As with breeding programs of agricultural crops and animals, these programs aim to change allele frequencies for a few key traits of a given species through repeated cycles of activities such as selection, breeding, and genetic testing. Today, tree improvement is an integral component of most plantation programs in the world with the ultimate goal being to increase the economic and social value of the planted forest. Unlike annual crops, trees are long-lived and difficult to work with due to their size. This means that, while the concepts of tree breeding and crop breeding are similar, the details differ greatly.

Owing to differences in species' biology, silviculture, product goals and economic considerations, tree improvement programs for distinct species differ dramatically in both design and intensity. Nevertheless, there are basic concepts and activities common to most programs. The aim here is to describe these common activities and the underlying theory on which they are based.

Principles of Recurrent Selection

Recurrent selection means repeated cycles of selection and breeding aimed at gradual genetic improvement of a few key traits in a single species. The benefits of breeding are cumulative in that each cycle or generation of improvement builds upon advances made in prior generations. Genetic gain in selected traits results from changes in frequencies of alleles at loci controlling expression of those traits, with favorable alleles increasing in frequency. Since most commercially important traits are polygenic (i.e., controlled by many loci), gene frequencies change slowly at any single locus and these changes are generally unknown to breeders. Rather, progress is measured by mean performance for target traits (e.g., greater harvest yield, reduction in disease incidence, or increased wood density). Performance for non-target traits should change little, if at all, as long as those traits are controlled by different loci than the target traits.

With the rare exception of programs involving radiation or chemical mutagenesis, tree breeding programs do not create new genetic variation; rather, they utilize naturally occurring variation in starting populations of the species of interest. Then, through recurrent selection and breeding, the existing variation is repackaged into individuals containing higher frequencies of favorable alleles for target traits. Some crop breeding programs began over 10 000 years ago and today's domesticated varieties do not even resemble their original progenitors, thus demonstrating the power of recurrent selection. Tree breeding programs are much less advanced. In fact, for most forest tree species, there have been three or fewer generations or cycles of recurrent selection and breeding. This means that today's genetically improved varieties of forest trees are essentially the native species, and the only changes might be faster growth rate, better disease resistance, straighter stems, higher wood density, or other small quantitative changes in a few key traits.

The oldest form of recurrent selection is called simple recurrent selection (SRS) and each cycle of breeding involves only two steps: (1) mass selection of individuals based solely on their outward, phenotypic appearance; and (2) intermating these selections to produce the offspring for the next generation. This was the method used over 10 000 years ago by ancient farmers to improve their field crops; seed from selected plants was retained for next year's crop. SRS is rarely used in tree breeding programs today, because it is less efficient at achieving genetic gains than forms of recurrent selection that incorporate genetic testing and pedigree control.

Almost all tree breeding programs employ recurrent selection for general combining ability (RS-GCA) in which genetic testing follows selection. This entails planting identified offspring from all the selections in randomized, replicated experiments. Selections with high GCA values for any trait are those that produce top-performing offspring. After genetic testing, selections with low GCA values are discarded, while those with high GCAs (or offspring of high GCA parents) are included in future cycles of breeding. Genetic testing greatly increases the genetic gain above that from mass selection and is especially effective for traits with low heritabilities (as for most traits of trees).

Nearly all tree breeding programs rely on RS-GCA involving recurrent cycles of selection, breeding, and genetic testing. In these breeding programs, only additive effects of alleles (whereby offspring tend to be intermediate to their parents) accumulate in the breeding population, meaning that genetic effects due to dominance and epistasis do not contribute to the cumulative genetic progress in the breeding population. In the early cycles (say the first 10), genetic variability for the selected traits changes little from that in the initial founding population, and genetic gain is similar in each successive cycle given similar selection intensities and breeding practices. That is, it takes many cycles of recurrent selection to lead to a plateau after which selection is ineffective (through fixation of favorable alleles or other causes). Beginning with larger founding populations and infusing unrelated material into the population extend the number of cycles before a selection plateau is reached.

Activities and Populations of a Typical Breeding Cycle

The activities and population types of tree improvement programs are summarized using a model called the breeding cycle (**Figure 1**). The activities of selection (to choose the selected population of genotypes) and breeding (to form the offspring that comprise the next generation's base population) are core activities that must occur each cycle or generation of breeding. The other activities and population types may or may not occur. Programs differ widely in how these activities are implemented, in the size and occurrence of the various types of populations, and in program intensity. Further, the cycles of breeding may not be discrete but rather overlapping with several staggered sets of activities all occurring simultaneously. Here, to stress the concepts, we explain each population type as if it were physically distinct and occurred each cycle of improvement.

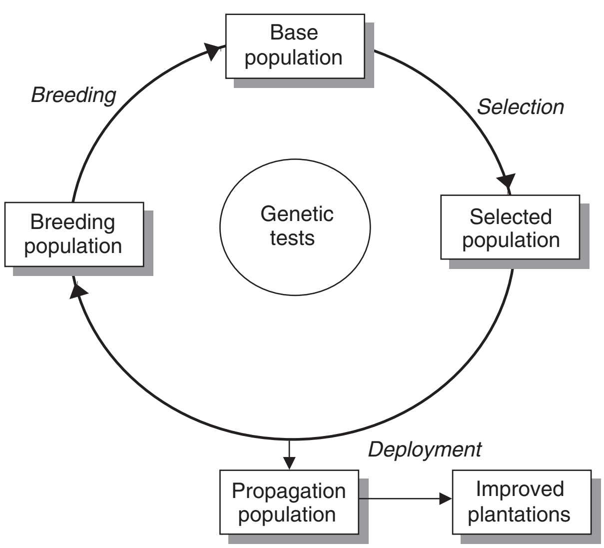

Figure 1 Schematic diagram of the breeding cycle of tree improvement programs showing the population types of genotypes that are formed (inside boxes) and the activities that are conducted (in italics) in a single cycle of improvement. Selection and breeding must be conducted each cycle, while the other activities may or may not occur. Starting at the top, the cycle turns a single revolution for each cycle or generation of selection and breeding in a recurrent improvement program. Adapted with permission from White TL (1987) *New Forests* 4: 325–342.

Base Populations

The base population of a given cycle of improvement consists of all available candidate trees that could be selected. The base population is very large consisting of many thousands of genetically distinct individuals. At the beginning of a program, the base population consists of all trees available for selection growing in natural stands and possibly plantations within the defined breeding zone (i.e., the geographical area for which an improved variety is being developed).

Determining breeding zone boundaries is a critical decision in tree improvement programs, because each breeding zone has a separate improvement program with its own distinct base, selected, breeding and propagation populations. For example, the program for Douglas-fir (*Pseudotsuga menziesii*) in the northwestern USA defined 80 first-cycle breeding zones each with an average size of 40 000 ha of native forests. Thus, there were 80 distinct first-generation improvement programs, each with its own breeding cycle, different set of population types, and improved variety being developed. In contrast, the program for *Pinus elliottii* (slash pine) in the southeastern USA defined one breeding zone consisting of the entire natural range of the species (approximately 4 000 000 ha of timberlands). The differences in size and number of breeding zones between these two programs reflect both the more homogeneous climate in the southeastern USA and differences in breeding philosophy.

Advanced-generation base populations (i.e., after the first complete breeding cycle) consist of genetically improved trees formed by intermating members of the breeding population and planting their offspring in genetic test plantations. All trees in these genetic tests are available to be chosen for advanced-generation selected populations.

Selection and Breeding

Selection and breeding are applied sequentially during each cycle of improvement (**Figure 1**). For most tree improvement programs the selected population in any given cycle contains between 100 and 1000 selected trees for a single breeding zone. In the first cycle of improvement, trees are selected from natural stands and plantations based solely on their superior phenotypic appearance, and this is called mass selection (**Figure 2a**). Advanced-generation selections are made from pedigreed populations growing in genetic tests, and selection effectiveness is increased by using all information available about a candidate's progeny, relatives, and ancestors (**Figure 2b**).

Figure 2 Forming the selected population means choosing superior individuals from the base population. (a) First-generation selection of *Pinus taeda* growing in the base population consisting of natural forests in Arkansas, USA. (Photograph courtesy of E.J. Jokela.) (b) Advanced-generation selection of *Eucalyptus grandis* growing in a base population consisting of pedigreed, randomized, replicated genetic tests of Cartón de Colombia.

Genetic gain in a given trait is achieved only if the selected population has a higher frequency of favorable alleles than the base population from which the selections were made. Genetic gain is greater if the selection is very intensive (only the very best individuals are selected) and if the trait is under strong genetic control (i.e., has a high heritability) with appreciable genetic variation. Allele frequencies differ between the base and selected populations both by intent and by chance. The breeder selects superior individuals and therefore intentionally alters allele frequencies for the target traits. In addition, allele frequencies for all traits (not just those included in the selection criteria) may change by chance due to sampling (i.e., choosing a subset of trees from a larger population). Some very rare alleles present in the base population can be absent from the selected population; however, with hundreds of individuals in the selected population, allele loss or large random changes in allele frequencies are unlikely.

After selection, some or all of the selections are included in that cycle's breeding population and are intermated to regenerate genetic variability through recombination of alleles during sexual reproduction. Intermating to produce full-sib families involves controlled pollination among selections. Female flowers on some selections are bagged (and emasculated if needed) to prevent contaminant pollination, and then pollen from other parents is injected into the bags (**Figure 3**). When two superior parents are mated, not all their offspring are superior, because some offspring in a family receive more favorable alleles from their parents than others. Intermating results in a large amount of genetic variation both among and within the families planted in the genetic tests that form the new base population. Selection of superior trees from among these newly created progeny is the basis for making continuing genetic progress from recurrent cycles of selection and intermating.

Deployment of Genetically Improved Varieties

The ultimate goal of all tree improvement programs is to create improved varieties of trees to use for reforestation and afforestation of new plantations. This represents a tangible economic and social gain: higher-yielding, healthier planted forests. In each cycle of improvement, the propagation population (also called the production population or deployment population) is formed from some or all of the members of the selected population. Usually only a small subset of the very best selections is chosen to produce a sufficient quantity of genetically improved plants to meet the annual needs of the operational forestation program. The trees used for reforestation are a genetically improved variety (also called a breed), and the activity of mass propagation and planting of an improved variety is deployment.

The propagation population is distinguished from the central core of the breeding cycle in **Figure 1**, because core activities focus on maintaining a broad genetic base and achieving genetic gains over many generations of improvement. In contrast, the propagation population produces a commercial variety to maximize genetic gain in operational plantations in the short term. Seed orchards, a common type of propagation population, are often formed by grafting the very best members of the selected population into a single location that is managed intensively for the production of seed (**Figure 4**). The genetically improved seed from open pollination among the grafted trees is then grown by the nursery manager and the seedlings used for forestation.

There are other options for forming the propagation population. For example, clonal forestry can be achieved for some tree species either through rooted cuttings or somatic embryogenesis. With this option, the top performing clones are identified through genetic testing and comprise the propagation population. These 20 or so clones are mass propagated to create enough trees to meet the annual forestation demand. The clones deployed to operational plantations are the improved variety.

It is common to include only the very best selections in the propagation population; for example, the selected population might contain several hundred genotypes, while the propagation population

Figure 3 *Pinus taeda* is monoecious meaning that pollen catkins (a) and female strobili (b) are borne in different structures on the same tree. Controlled pollination of two parents for breeding takes 18 months and entails: (1) collecting catkins and drying them to extract pollen from the male parent; (2) bagging (c) the female strobili in the spring of year 1 to prevent wind pollination by other males; (3) injecting the pollen from the male parent into the bags covering the strobili of the female parent; (4) allowing pollen tubes (d) to begin growing in the first year and effect fertilization in spring of the second year; and (5) collecting full-sib seed in the fall of year 2, some 18 months after pollination.

might consist of the best 20 to 50. This increases the genetic gain expected from the operational variety that is planted, but also reduces its genetic diversity. It is also common to continually upgrade the genetic quality of the propagation population even during a single cycle of improvement. As information becomes available from genetic tests, genetically inferior selections can be removed from the propagation population, while superior selections not originally included can be added. This means that the improved variety being planted may change in its genetic composition and expected gain within a single cycle of improvement. This dynamic, rolling-front nature of improved varieties in forestry may be the reason why varieties are not given names as are cultivars in crops and breeds in animals.

Infusions from External Populations

Most tree improvement programs take advantage of opportunities to acquire new genetic material and infuse it into the breeding population. The infusions can be aimed at improving a specific trait. For example, the *Pinus elliottii* program in the southeastern USA selected nearly 500 disease-free trees in stands highly infected with fusiform rust (*Cronartium quercuum* f. sp. *fusiforme*) to increase the frequency of resistance alleles in the breeding population. Another reason to include infusions is to broaden the genetic diversity existing in the program. For example, the *P. taeda* (loblolly pine) program in the southeastern USA made 3300 new selections to broaden the genetic diversity of several breeding populations spanning multiple breeding zones. In advanced-generation programs, it is often desirable to obtain infusions as proven selections from other programs working on the same species. Breeding programs for *Eucalyptus grandis* in many different countries sometimes exchange material for this purpose.

With infusions, the new material should be evaluated for target traits and adaptability through genetic tests to ensure that gains are not made in some traits with inadvertent losses in others. Tested infusions of sufficient merit are then intermated in the breeding population as part of the regular

Figure 4 Aerial view of a 12-year-old grafted seed orchard of *Pinus elliottii* showing the wide spacing and intensive management (mowing and weed control in the rows) aimed at maximizing seed production. The 50 or so superior selections grafted into this orchard are each represented by many grafted trees (called ramets) and together these ramets from the same selection form a clone (i.e., have the same genotype). Ramets from the same clone are separated from each other and the 50 superior clones are allowed to wind pollinate to produce seed for operational reforestation. This seed is a genetically improved variety with the amount of genetic gain depending directly on the genetic superiority of the clones grafted into the seed orchard.

breeding program. This maintains broad genetic diversity in the breeding population.

Advanced-Generation Tree Breeding Programs

Many tree breeding programs are entering the second or third cycle of breeding. These programs differ widely in breeding strategy, program design, and program intensity; yet, all programs face common challenges and sets of issues. In particular, all programs seek to achieve near-optimal short-term genetic gains in a few traits, while maintaining sufficient genetic diversity in the breeding population to ensure near-optimal long-term genetic gains, flexibility to changing conditions, and gene conservation. Common issues facing all programs addressing these goals are conveniently grouped for discussion below according to the population types of the breeding cycle.

Breeding Zones, Base Populations, and Selected Populations

Most advanced-generation tree breeding programs are opting for relatively large breeding zones encompassing sizeable portions of their plantation estate. Even if there is moderate genotype × environment interaction present within a breeding zone, many programs are choosing to breed for broad adaptability by making selections that perform well across all edaphoclimatic conditions within the zone. Minimizing the number of breeding zones has two distinct advantages: (1) the breeding and testing programs in each zone can be larger and more intensive, thereby achieving larger gains; and (2) costs are reduced, because there are fewer breeding populations and testing programs to manage.

Tree breeding programs with multiple breeding zones for the same species sometimes opt for overlapping zones that share selections among neighboring zones to reduce costs and increase gains. For example, the second-cycle *P. taeda* program in the southeastern USA defined multiple overlapping breeding zones, and each zone recruits new selections from zones on both sides. That is, excellent selections made in one zone are included in the selected populations of the neighboring zones. It is also possible to recruit material from other breeding programs of the same species in other regions or countries. Thus, advanced-generation breeding programs can capitalize on top genetic material from many sources provided the material is well adapted to the breeding zone.

With breeding zones defined, the next steps are to decide on how many selections to make (i.e., the size of the selected population), which traits to select for, and how to make the selections to achieve both genetic gain and diversity. Many advanced-generation tree breeding programs include 300 to 400 selections in the selected population for a given breeding zone in a single cycle. This number is sufficient to sustain near-maximum long-term gains over several cycles of recurrent breeding, even when there are several traits and when intensive efforts are used to achieve large gains in the first few generations. However, quite large populations (1000 or so) are required to ensure that almost all rare alleles are maintained in the population for many generations if the breeding population is also serving a gene-conservation role.

In all tree breeding, it is important to focus on very few traits. Inclusion of too many traits (say more than five) seriously dilutes the gains made on any one trait. Volume growth is almost always one of the important traits because it transcends product goals and technologies. Other important traits often include resistance to important edaphoclimatic stresses or fungal diseases. Finally, wood quality traits have become more important in recent years. When considering the candidate suite of traits, priority should go to those that:

- have high economic importance under a wide variety of future ownership, market, and technological scenarios
- are under moderate to strong genetic control

- are expressed at young tree ages and easily measured
- do not have unfavorable genetic correlations with other target traits.

The next step is to make selections and in advanced-generation programs these usually come from pedigreed genetic tests planted in randomized, replicated designs established on multiple sites in the breeding zone. Very often, data from the genetic tests are highly unbalanced, with not all families planted on all sites, varying test quality among sites and, sometimes, varying mating and field designs. The first step is to analyze the data properly using an analytical technique, called best linear unbiased prediction (BLUP), which incorporates all data from all sources to produce a unified set of predicted genetic values for each trait.

Next, a selection index is developed to weight each trait according to economic or other criteria, such that a single genetic worth is predicted for each pedigreed tree (which aggregates the BLUP predictions for each trait into a single weighted average for each tree). If there are say 50 000 pedigreed trees in genetic tests, and the breeder aims for a selected population with 300 individuals, the process is: (1) all 50 000 candidates are ranked according to their predicted genetic worth; and (2) the breeder begins at the top of list and selects winners subject to penalties for, or constraints on, relatedness. Normally, the penalty for relatedness means that only a certain number of selections can be made within a given family, and more are allowed from better families. Many programs include top performing selections from multiple generations, such as grandparents, parents, and offspring.

Use of a selection index often identifies candidates that are above average for all traits in the index but not outstanding for any single trait. In other words, the index-identified trees are most suitable for maximizing genetic worth of the aggregate index but do not maximize gain for each trait. Therefore, breeders usually include additional selections that are outstanding for each of the target traits.

Breeding Populations

After selection, the chosen trees are usually grafted into a convenient location for breeding (**Figure 3**). If all, say 300 to 400, selections are grafted and bred upon, then the breeding and selected populations are identical. Unlike most first-generation tree breeding programs that employed unstructured breeding populations in which all selections were bred in similar mating designs, advanced-generation programs structure the breeding population for at least three reasons.

First, many programs stratify the breeding population into two or more levels according to predicted genetic value with the top stratum being called the elite population. The elite population might contain the top 10% of the selections in the breeding population (e.g., the top 30 selections if the breeding population has 300 selections). The goal is to make more rapid and larger genetic gains in this small subset of the breeding population through accelerated breeding and more intensive genetic testing. The rest of the breeding population is allocated to the larger main population which is bred and tested less intensively to minimize costs, maintain genetic diversity, and achieve long-term genetic gains. As new selections are made in subsequent generations of breeding, they can be allocated to the elite, main, or both. This gene flow between the elite and main breeding populations increases genetic gain and diversity in the elite population.

Second, when the breeding population is subdivided for the purpose of applying different selection criteria to different segments, the subdivisions are called multiple populations or breeds. For example, the breeding population might be divided into three breeds with one being bred mainly for disease resistance for deployment to high-hazard sites, one as a multipurpose breed for general use, and the third for solidwood, high-value products. There might be some traits in common to all three breeds (such as rapid growth), but others that are only important in one breed or another (such as lumber quality in the solidwood population). The goal is to make more rapid gains for each of the breeds by minimizing the number of traits being improved. There can be few or many breeds, and there is no specific control on relatedness among them. Top selections and their relatives that possess many desirable traits may occur in more than one of the breeds.

The third and final type of structure to the breeding population aims to control the pattern of relatedness in the breeding population and produce noninbred offspring for operational deployment. Use of a single, unified breeding population eventually builds up relatedness among members of the breeding population and, if related parents are crossed to produce offspring for operational plantations, the plantations suffer from inbreeding depression. To avoid this problem, the breeding population is divided into sublines (sometimes called breeding groups). All breeding is conducted among selections in the same subline, and each subsequent generation's selections are assigned to the same subline as their progenitors. There is no breeding or relatedness among groups. All sublines are bred for the same objectives using the same selection criteria. Over generations of breeding, relatedness builds up within each subline; however, members from different sublines are always unrelated, even after many generations of breeding. Therefore, any mating between members from different sublines always results in outcrossed progeny, precluding inbreeding depression. So, by choosing selections from different sublines to form the propagation population, outcrossed offspring are guaranteed for operational plantations.

In real tree breeding programs all three types of structure described above are used simultaneously. In addition, mating designs and field designs vary. This makes for a wide variety of breeding strategies, population structures, and program intensities in advanced generations.

Propagation Populations and Deployment

Most advanced-generation programs still employ open-pollinated (OP) seed orchards, as previously described, in which 15 to 40 top, unrelated selections are grafted into a single location to interpollinate and produce improved seed for operational forestation. Seed is often collected and deployed by OP family; this is called family forestry. For example, if there are 20 to 50 ramets of each of 30 clones in the orchard, then seed from all ramets of each clone is bulked together to produce 30 seedlots, one for each clone. Each seedlot is kept separate for storage, nursery production, and plantation establishment. This approach reduces genetic diversity only slightly, and allows families to be deployed to sites to which they are most suited based on genetic testing information of the maternal parent (e.g., disease-resistant families to high-hazard sites).

Family forestry is sometimes based on full-sib families created by controlled pollination (CP) (**Figure 3**). Top performing parents, based on performance of their offspring in genetic tests, are crossed together. If the CP process is efficient enough, the CP seed can be delivered directly to the nursery for growing seedlings for operational forestation. More commonly, the CP seed is too expensive for this option, and the seed is used to create hedges or stool beds in the nursery. Shoot tips from such plants are then rooted in either greenhouses or outdoor nurseries, and the resulting rooted cuttings from top full-sib families are planted operationally. This technique is being widely used for radiata pine (*Pinus radiata*) in Australia, New Zealand, and Chile.

In addition to family forestry, some intensive tree improvement programs are employing clonal forestry in which 10 to 30 well-tested clones are planted operationally. Clonal forestry means that a single genotype may be planted across many hectares (**Figure 5**). This achieves maximum genetic gain if top performing clones are planted, but eliminates genetic diversity within a single plantation. Several clones are often planted in patches (also called monoclonal mosaics) across the landscape, and most organizations limit the area of land that can be planted with a single clone. Clonal forestry is completely operational in intensive programs planting various species of *Eucalyptus*, *Salix*, and *Populus* that can be propagated easily as rooted cuttings. Conifers have proven more challenging since it is not possible, in general, to produce rooted cuttings from selection-age trees. Tissue culture techniques hold promise for achieving clonal forestry in conifers.

Figure 5 Nine-year-old clonal plantation of *Eucalyptus grandis* belonging to Mondi Forests in South Africa. All trees are a single genotype, a clone, and hence there is no genetic diversity within this plantation. Genetic diversity on a landscape scale is achieved by planting several clones in a patchwork in any one year and limiting the total area in which a given clone can be planted commercially.

Genetic Testing

Genetic tests consist of pedigreed, labeled offspring, or clonal propagules (ramets) usually established in randomized, replicated experiments in field locations on forest sites. Genetic tests are fundamental to all tree improvement programs and a single series of tests can serve any or all of the following objectives:

1. Evaluate relative genetic quality of selections to allow better selections to be favored in breeding and deployment.
2. Estimate genetic parameters such as heritabilities, genetic correlations, and genotype × environment interactions to facilitate programmatic decisions and development of breeding strategies.
3. Plant offspring from breeding to create a base population of new genotypes from which to make the next cycle of selections.
4. Quantify or demonstrate genetic gains made by the program.

Mating designs and field designs, specifying how the genetic material is created and arranged in the experiment, are discussed below for this range of objectives.

Mating Designs for Genetic Tests

Incomplete-pedigree mating designs When many parents are allowed to intermate with no control on pedigree and a single bulk lot of seed is collected, then there is no knowledge of maternal or paternal identity. Bulk collections are most useful for comparing means of different populations such as in realized gains trials (objective 4 mentioned above). For example, consider 200 selections in a selected population with the top 20 being used in the propagation population to produce seed for operational plantations. Two genetic entries (a bulk seed collection from the 200 and one from the 20) could be planted in randomized, replicated designs across several test locations to compare genetic gain differences between the two populations. Unpedigreed, bulk collections are not used for any of the other three objectives of genetic tests.

In OP mating designs, seed is collected from each of the parents in the population and kept separate by parent for planting as OP families. For each tree planted, the female parent is known but the male parent is unknown. If there are 200 parents in the selected population, a test of all parents would involve planting 200 genetic entries or treatments (i.e., 200 OP families). OP mating designs are widely used for a variety of angiosperm and gymnosperm species, and are especially useful when many different male parents pollinate each family (i.e., when the OP families are highly outcrossed). When this occurs, OP families can be used very effectively for ranking selections and estimating most genetic parameters (objectives 1 and 2), and these designs are efficient and cost-effective.

Use of OP mating designs for creating a base population from which to make selections has been criticized on the basis that the male parentage is unknown meaning that two selections from different OP families could have the same male parent. Subsequent intermating of these selections in a propagation population (e.g., if both selections were grafted in the same seed orchard) could lead to inbreeding depression and hence reduced gain in the operational plantations. However, more recently, OP mating designs have been recommended for creating the base population based on theoretical gains calculations, empirical evidence of substantial genetic gains, and logistical ease coupled with low cost. Thus, OP mating designs have a role in some advanced-generation programs. For example, a program could opt to breed the elite portion of the breeding population using full-sib, complete pedigree designs (see next section), but use OP mating for rapid, repeated cycling of the main portion of the breeding population.

In pollen mix (PM) or polymix mating designs, controlled pollination is used to pollinate each female parent with a mixture of pollen from a number of male parents (**Figure 3**). As with OP designs, there is one family for each parent being tested (i.e., 200 PM families for 200 parents in a selected population), and progeny trees from each PM family are labeled according to their female parent. PM designs are very cost-effective for estimating most genetic parameters and for ranking selections based on performance of their offspring but not for making fully pedigreed selections. Disadvantages of PM compared to OP designs are increased cost and time associated with controlled pollination.

Complete pedigree (full-sib family) designs There are various mating designs that employ full-sib (FS) families and hence maintain complete pedigree of all progeny planted. These designs share the following characteristics: (1) controlled pollination is used to create the seedling offspring; (2) identification of progeny trees in the field requires naming both parents; (3) the maximum number of unrelated forward selections is one-half the number of parents assuming parents are unrelated; and (4) each parent should be mated with four or more other parents to assure precise parental rankings.

Some FS designs can be prohibitive to implement owing to the large number of controlled crosses. For example, for a selected population of 200 parents, there are 19 900 possible pairs of matings ($200 \times 199/2$) in what is called a half-diallel without selfs. Even large tree improvement programs limit the number of total crosses for a given breeding zone to no more than several hundred FS families per cycle. The discussion below does not describe the variety of designs available, but rather focuses on one design that is feasible, cost-effective, and efficient for all four objectives of genetic tests listed above.

In a partial diallel mating design only some of the possible pairs of crosses are made, and there are many variants of partial diallels that make more or fewer crosses. More crosses per parent mean more precision for estimating genetic parameters (objective 2), for ranking the parents (objective 1), and for achieving more gain from making selections from the offspring planted (objective 3). Four or five crosses per parent seem optimal for most purposes, if all crosses are successful. For example, if there are 200 parents in the selected population and each parent is crossed with four other parents, there would be a total of 400 full-sib families to establish in genetic tests.

In partial diallels and other mating designs, it is best to create the full-sib families such that there is a genetic linkage, called connectedness, among all parents. Even if two parents are never mated together directly, they can still be connected indirectly (e.g., crosses A × B, B × C, and C × D connect A with C and D). In this way, all crosses provide information about all parents. Disconnected designs with small groups of parents separated from others are less efficient for ranking parents.

Full-sib families are sometimes generated and planted over a period of years in what is called a rolling-front approach. As trees in the breeding population begin to flower, they are crossed with others that are flowering. Instead of waiting for all crosses to be completed and planted in a single series of genetic tests, the crosses are planted as seed becomes available. There are several series of genetic tests planted over a series of years. This creates unbalanced data, since each series contains only a partial set of the full-sib families; however, the data can be analyzed with BLUP if proper connectedness among the series is maintained.

Field Designs for Genetic Tests

Defining the field design of any series of genetic tests means specifying: (1) plot shape and number of trees per plot; (2) statistical design at each location including randomization scheme and number of replicates; (3) number and location of field sites; and (4) inclusion of other seedlings or clones as checklots, borders, and fillers. Specification of an optimal field design involves statistical, genetic, logistical, and economic issues. Most important are the objectives of the tests and, just as for mating designs, some field designs achieve certain objectives better than others. Here two extreme field designs are discussed, one appropriate for simultaneously achieving objectives 1 to 3 and the other suitable for estimating realized gains (objective 4).

Field design for breeding and base population genetic tests Often in advanced-generation breeding programs, a single series of full-sib tests is aimed at estimating genetic parameters (e.g., heritability and genotype × environment interaction for key traits), ranking the parents in the breeding population and making the next-generation selections from the progeny planted (objectives 1 to 3). Nearly always, there are numerous families (50 to 400) to accommodate, and an appropriate field design is: (1) single-tree plots (STP) meaning that each full-sib family is represented by a single progeny tree as its own plot within each complete replicate; (2) an incomplete block design in which each complete replicate is further subdivided into smaller units called incomplete blocks; (3) fifteen to 20 complete replicates at each location (meaning 15 to 20 offspring per family planted at each location); and (4) four to eight field sites (each with this same design) that span the range of edaphoclimatic conditions in the breeding zone. For a test series with 200 full-sib families, 15 replicates per site and five sites, there would be 15 000 progeny trees planted (200 × 15 = 3000 per site) and each family would be represented by 75 trees (15 replicates × 5 sites × 1 tree per replicate).

STPs assure higher statistical precision (i.e., better genetic parameter estimates and better rankings of parents, families, and progeny trees) than do experiments with row plots or rectangular plots that contain multiple trees per family. This is for two reasons: (1) STPs allow more replicates for a given effort, so each family samples more of the microsite variability on a site instead of being clumped together in multiple-tree plots on fewer microsites; and (2) STPs mean that the size of each replicate is smaller for a given number of entries, so replicates are more homogeneous. STPs facilitate testing large numbers of families or clones in many replicates.

Even with STPs, each replicate can occupy a large area. For example, with a typical planting density of 1200 trees per hectare, a test with 200 families in STPs means that each replicate is 0.17 ha (200/1200). In most places, replicates smaller than 0.1 ha are advisable. This is the reason to further subdivide each complete replicate into incomplete blocks. Each incomplete block might contain 15 to 30 trees planted in a more uniform microenvironment than families in the rest of the same complete replicate. The incomplete blocks add another blocking factor used to adjust entry means for microsite differences among incomplete blocks. This reduces the experimental error and increases the precision of the rankings of genetic entries by removing sources of environmental noise from comparisons of genetic entries. Use of incomplete block designs requires special computer programs to design the layout and analyze the data; however, these designs increase precision with no additional costs of test implementation, maintenance, or measurement.

There is a trade-off between the number of complete replicates per test site and number of sites in a test series. The total number of progeny needed per full-sib family across all sites ranges from 50 to 150 depending on several factors. So, with more replicates per site, fewer sites are needed. However, enough sites are needed to adequately sample the edaphoclimatic zones within the breeding zone. For example, a less intensive breeding program with relatively uniform conditions across a small planting zone might opt to plant a test series on three different site locations with 20 complete replicates per site (60 total trees per family), while a more intensive program with a large breeding zone spanning several soil types and climates might opt to establish a test series on eight sites with 15 replicates per site (120 trees per family). These numbers of sites are inflated if the risk of catastrophic loss of entire test sites is appreciable.

Field design for quantifying realized gains Estimating progress from a tree breeding program involves field tests of material of distinct levels of genetic improvement that reflect different stages of program development over time. For example, a single test series might aim to estimate the genetic means of the following nine entries for a few key traits: (1) an unimproved bulk seedlot that represents the operational plantations established before tree breeding began; (2) two bulk seedlots collected from a first-generation seed orchard before and after roguing of inferior clones; (3) three single-family seedlots of families planted operationally; and (4) three operational clones. Tests might also compare first-, second- and third-generation commercial breeds to quantify progress.

Usually, the mating and field designs of realized gains tests (also called yield trials) simulate genetic and stand-level growing conditions of operational plantations so that the estimates of gain are appropriate for subsequent harvest scheduling and economic analysis (e.g., to justify the expenditures on the breeding program). For these reasons, common features of tests to estimate realized gain include:

1. The tested materials simulate operational varieties or breeds from the past, present or future.
2. Unimproved seedlots or unimproved clones are included to have a baseline for comparing newer varieties.
3. Rectangular plots of each genetic entry are used to approximate competitive conditions existing in operational plantations.
4. Tests are of long duration (half to full rotation length) to quantify gains in harvest yield and product quality.

Points 3 and 4 argue for using plots large enough to permit normal silvicultural activities (fertilization, weed control, and thinning) for an entire rotation period. Therefore, square or rectangular plots, each plot containing 25 to 100 trees of the same genetic entry (e.g., same seedlot, family, or clone) are recommended for realized-gains tests. Rectangular plots are preferred because they simulate stand conditions in operational plantations, and so produce unbiased estimates of yield on a per unit area basis. Inter-tree competition intensifies as trees age, and genotypes that start slowly may be disadvantaged. Therefore, means from small plots (e.g., STPs described above) may be biased with results favoring genetic entries that are strong competitors, especially at early ages. Rectangular plots avoid these biases since inter-tree competition is among trees of the same genetic entry (same bulk mix, family, or clone).

The disadvantage of rectangular plots is that replicate sizes are large, so only a small number of different genetic entries can be included (normally fewer than 10 different entries in a given test series) and the number of replicates is limited on a given site. A test series is normally established on several site locations both to accumulate enough replicates to produce sufficient precision for comparing the genetic entries and to ensure that inferences about genetic gains and program progress truly apply to the entire program. Incomplete block designs are very useful to increase precision of comparing the genetic entries, but still the number of entries needs to be small.

Conclusions

Tree breeding programs develop genetically improved varieties for forestation through repeated cycles of activities such as selection, breeding, and genetic testing. Selection aims to increase the frequency of favorable alleles of a few important traits, while breeding re-creates and repackages genetic variation so that still better selections can be made in the next cycle of selection. Nearly all programs rely on a breeding strategy involving recurrent selection for general combining ability, which means that genetic tests are used during each cycle of breeding to rank the parents in the breeding population and increase gains from selection. Thus, designing, implementing, and analyzing genetic tests are critical aspects of tree breeding programs that must be done well to maximize genetic gain per unit time at minimum cost. Tree breeding programs vary widely in design, breeding strategy, and intensity owing to differences in species' biology, breeding objectives, and economic considerations. Nevertheless, tree breeding is an integral part of operational silviculture for most plantation forestry programs in the world. New technologies such as tissue culture to achieve operational planting of tested clones, marker-assisted breeding to increase gain from selection, and genetic modification to insert novel genes all have promise to enhance gains from tree breeding, but must be tested for effectiveness, safety, and public acceptance.

Economic Returns from Tree Breeding

P J Kanowski, Australian National University, Canberra, Australia
N M G Borralho, Forest and Paper Research Institute (RAIZ), Alcoentre, Portugal

Introduction

The economic returns from tree breeding can be estimated over time-frames ranging from the short to the long term, on scales varying from that of an individual enterprise to the entire extent of a species' use, in terms of each individual strategic and technical decision or of their cumulative effect, and in purely financial or in wider economic terms. The gains realized by particular stages or elements of tree breeding can be so dramatic that only the most cursory economic evaluation is necessary to substantiate them; conversely, strategic and technological options may be so complex, and realization of benefits so contingent on particular assumptions, that sophisticated economic analyses are necessary to inform investment decisions.

As for many forestry activities, economic analyses of tree breeding investments are variously complicated by long investment and rotation cycles, uncertainties about costs and benefits over these long time horizons, and by the challenges of accounting for nonmarket benefits and costs. However, there is both a long history of, and an increasing focus on, economic analyses of tree breeding investment decisions, which have contributed significantly to the design and development of tree breeding strategies and programs.

Economic returns from tree breeding are determined by species- and program-specific combinations of the following key parameters:

- the genetic characteristics of the population subject to breeding–reflecting inherent levels of genetic variation in a species, the extent to which that variation has been sampled in the population subject to breeding, and the stage of breeding of the population
- the breeding strategies and technologies employed, and the breeding objectives specified
- the value of the products and services, and the scale of deployment, of improved populations
- the institutional arrangements for breeding and benefit sharing.

Our discussion of the topic is structured around these parameters. In general, they are better characterized for longer-established, advanced industrial tree breeding programs, such as those for loblolly pine (*Pinus taeda*) in the southeast USA, radiata pine (*P. radiata*) in the southern hemisphere, or *Eucalyptus* species in continents other than North America. Industrial tree breeding programs are typically more advanced and data-rich, and have markets and benefit regimes that are generally better defined, than are programs for the breeding of trees for nonindustrial uses. Consequently, while the latter also have the demonstrated potential to make very significant economic contributions to people's livelihoods and to environmental services, they are not necessarily easily evaluated by conventional economic analyses applied to investment decisions.

Realization of returns from any tree breeding is dependent on appropriate silviculture and management of genetically improved trees, and appropriate processing of their products. There are many cases where predicted or potential gains from tree breeding have not been realized because one or more of these technologies has not been optimized or implemented for genetically improved trees or products. An example of the profound impact of silviculture on the capture of economic returns from breeding is illustrated by **Figure 1**.

Figure 1 Economically significant differences due to silviculture in first-generation Caribbean pine (*Pinus caribaea* var. *hondurensis*) performance in coastal central Queensland, Australia. Trial age is about 20 years; the researcher stands in an experimental plot which received neither preplanting site preparation nor postplanting fertilizer application; a plot of the same genotypes, which received both site preparation and fertilizer, is in the background. The experiment was established by the Queensland Department of Forestry. Photograph by Peter Kanowski.

Evaluating Economic Returns from Tree Breeding

Like evaluation of many other forestry investments, the relatively long time intervals between investment and returns both dominate and complicate economic analyses of returns from tree breeding. Historically, most industrial tree growing rotations have been more than 25 years, complicating direct comparisons of more-improved and less-improved material. While many industrial plantations and nonindustrial species are now managed on much shorter rotations, significant practical problems remain in making accurate comparisons. Improved genotypes seldom grow in an environment identical to that of earlier tree crops, as both environments and management practices change. Technological changes in all aspects of tree growing – in the nursery, in silviculture, and in product processing – have profound and interconnected impacts on tree performance and on product recovery, value and economic returns.

Economic returns from breeding may also be evaluated from perspectives of different interests, as follows.

1. Those who have invested, or are considering investment, in tree breeding activities. Typical investment criteria are those such as the internal rate of return, present net worth, or benefit–cost ratio of funds invested, or the minimum scale of deployment of bred material required to break even. These assessments may be applied to whole breeding programs, or to particular separable aspects of them, such as the decision to invest in a new seed orchard or in vegetative rather than seedling propagation.
2. Tree growers, who vary in scale from corporations or public sector agencies with annual planting programs on the order of millions of plants, to small-scale resource-poor farmers who, at the extreme, may be making decisions about individual trees. In both cases, however, decision criteria are likely to reflect an assessment of likely net gain, perhaps including nonmarket values, over the investment period. Criteria may include implicit or explicit assessment of the risks of not investing – for example, in terms of poor adaptation of unimproved material or potential loss of market share – as well as the anticipated direct financial gains from the investment. For those with limited access to financial resources, such as poor farmers, the immediate cost may be a more significant determinant of the investment decision than the ultimate returns on investment.
3. Purchasers of forest products and services, ranging from governments or communities willing to pay for environmental services, to large-scale industrial wood-processing enterprises, to individuals

purchasing individual products (e.g., fruit or poles) at a local market. Ultimately, their decisions provide the market signals on which the decisions of the preceding two groups stand or fall. Their decisions may be expressed through a price differential, or simply through giving preference to particular genotypes, leaving those without such genotypes as residual suppliers with more limited market access.

For these reasons, there is no single economic criterion against which tree breeding investments are or should be judged. The balance of benefits between private interests and public good may also change over time, necessitating evaluation against different criteria. As in other areas of innovation, there is often a phase in which the benefits of tree breeding are captured principally by a few breeders, tree growers, or product processors who have access to new material or technologies. As these materials or technologies become more widely adopted, there is no longer a comparative advantage for the innovators, and the economic benefits from tree breeding will accrue to society more generally rather than to those leading the innovation.

The Genetic Characteristics of Tree Populations

Forests and woodlands are the most biologically diverse terrestrial ecosystems. With some notable exceptions, the tree species which are the defining feature of these ecosystems have been little domesticated relative to the crop plants or animals upon which agricultural production is based. Although their gene pools have been altered, sometimes profoundly, by a wide range of human activities, the genetic resources of most tree species remain rich, a consequence of the longevity of individual trees, their outcrossing breeding system, the extensive geographic distribution of many species, and the high proportion of genes common across most populations in most species. Even for those species that have been the subject of informal domestication or of organized breeding, tree breeders still have – in general – relatively easy access to extensive gene pools which are highly diverse compared to those of other plant species, although some of these genetic resources are now threatened by the unprecedented global rate and scale of forest loss and degradation over the nineteenth and twentieth centuries.

Consequently, there are few tree species for which levels of genetic variation are insufficient to expect significant genetic gains from breeding, although the extent to which these genetic gains translate to economic gains depends on the factors discussed below. *Pinus torreyana* is one such example, as a consequence of a genetic bottleneck in its evolutionary history. Another example is the Australian Gondwanan relic species Wollemi pine (*Wollemia nobilis*), represented by only a few individuals in the wild. Even in such cases, where the species has a commercial value, significant economic returns may be possible simply from propagation. This is the case for Wollemi pine which, although discovered only in 1994, is now being vegetatively propagated on a scale sufficient for large-scale commercial release as an ornamental in 2005, using propagation technologies developed for the related Australian industrial plantation species *Araucaria cunninghamii*. The economic returns from this venture are anticipated to be both commercially attractive and sufficient to contribute significant funds towards conservation efforts for the species.

Stages of Tree Domestication and Breeding

Some tree species have a long history, often of millennia, of informal domestication. These are species important for food and in traditional land use systems: e.g., those of the genera *Artocarpus*, the jakfruits and breadfruits of Asia, or *Mangifera*, the tropically widely distributed mangoes; the leguminous genera *Faidherbia* and *Leucaena* of, respectively, Africa and the New World; or *Fraxinus* and *Quercus*, the European ashes and oaks. The situation of these species, subject to many generations of informal selection and often to induced or spontaneous hybridization, parallels that of other long but extensively domesticated crops, with an often imprecise distinction between natural and naturalized populations. Consequently, the genetic resources available for breeding comprise a highly heterogenous mixture, ranging from highly selected individuals with significant immediate economic value to wild relatives whose value has yet to be established and which may take many cycles of breeding to realize.

Relatively few tree species (around 500 of the presumed more than 50 000) have been subjected to any level of deliberate selection or breeding. The breeding histories of these species are quite contrasting, with contrasting implications for breeding options and associated economic returns.

1. A small group of tree species is of high significance in cultivation in horticultural or estate systems, or in arboriculture. Examples include apple (*Malus* spp.), coffee (*Coffea* spp.), coconut (*Cocos nucifera*), rubber (*Hevea brasiliensis*), and numerous ornamentals. While the principles of assessment of economic returns from these species do not differ

from those for other trees, and tree breeders have much to learn from these industries, the associated body of literature is sufficiently distinct and well addressed elsewhere to not be the subject of this review.

2. Around 200 species have been subject to at least one cycle of breeding (i.e., selection, mating, and testing); a similar number have simply been included in genetic tests. Those subject to the most intensive breeding efforts are the 60 or so species, principally of the genera *Acacia*, *Eucalyptus*, *Picea*, *Pinus*, *Pseudotsuga*, *Populus*, *Larix*, and *Tectona*, that have been improved for industrial wood production (i.e., for solid or reconstituted wood and for pulp) over typically not longer than some fraction of the past 50 years. These populations provide the bulk of our experience and information about the tree breeding and its economic returns, and a few of them provide our only experience of returns associated with advanced generations.
3. Another 60 or so more taxonomically disparate species, amongst them some of the long-domesticated species, have become the subject of breeding for nonindustrial objectives in the past few decades. Examples include species of the tropical and subtropical *Acacia*, *Azadirachta*, *Calliandra*, *Calycophyllum*, *Casuarina*, *Dalbergia*, *Faidherbia*, *Gliricidia*, *Grevillea*, *Irvingia*, *Leucaena*, and *Prosopis*, and the temperate *Acacia*, *Alnus*, and *Salix*. Breeding objectives and strategies, and management regimes, for these species are typically more diverse than for those bred for industrial wood production, and most of the economic returns realized to date are associated with the early stages of breeding.

Figure 2 Economically significant variation in a Douglas-fir (*Pseudotsuga menziesii*) provenance trial, Limousin region, France. Trial age is about 10 years; the student stands between blocks representing an Oregon (background left) and northern British Columbia (foreground and right) provenances. The experiment was established by Office National des Fôrets. Photograph by Peter Kanowski.

Economic Returns from Early Stages of Breeding

The early stages of tree breeding typically involve species and provenance selection, the selection of individual trees within these populations, and the establishment of seed orchards to provide improved material for both production and for further breeding. Given the undomesticated or little-domesticated status and genetic richness of most tree species, substantial genetic gains are possible from the basic first step of species and provenance selection; further substantial gains can be achieved from subsequent individual tree selection and the establishment of seed orchards. The economic gains associated with these genetic gains depend on both the cost of undertaking the breeding activities and on the economic value of the improved material.

The genetic gains achieved at these stages in most tree breeding programs have, almost invariably, been large and cost-effective; they are typified by **Figure 2** which, for a striking but not atypical case, illustrates the extent to which simple provenance selection influences the viability of a species for economic use. Selection on this fundamental basis, for both immediate gain and as the foundation for subsequent breeding, remains the basis of economic returns for new programs, exotic environments, or new breeding objectives. The gains from these early stages of selection can be enhanced by judicious use of any a priori knowledge of patterns of variation and environmental adaptation over a species' range in both natural and exotic environments.

Almost all quantitative data describing genetic and economic gains from this stage of breeding originate from industrial tree improvement programs, many programs now have sophisticated systems for updating breeding and genetic values for individuals, such as Australia's 'Treeplan' or New Zealand's 'GF-Plus' scheme. The gains realized in commercially utilizable stem volume, the initial focus for most industrial programs, from provenance and the first generation of individual tree selection have typically been at least 10% (where provenance differences are small), and often up to 30–50% (where provenance differences are great), over unimproved population means. Gains realized have reflected, to varying extents, selection of well-adapted provenance(s), effective within-provenance selection, and in some cases the release from inbreeding depression associated with natural or small populations. In the most straightforward and historically typical case, where growers' returns for a particular industrial species were dependent simply on the value of wood produced in large-scale afforestation, these genetic gains corresponded to very favorable returns on investment; benefit–cost ratios greater than 5, and internal rates of return of 10–15%, are commonly reported.

Data for nonindustrial species are scarce, reflecting the more recent origins of formal improvement programs. However, nonindustrial tree species appear to be no less genetically variable than industrial species, suggesting that expectations of realized gains should be comparable. The attribution of costs and benefits does, however, differ significantly between many industrial and nonindustrial species; in the former case, benefits typically accrue to an industrial-scale enterprise, whereas in the latter, the intended beneficiaries are typically resource-poor small-scale farmers. The increasing scale of 'outgrower' schemes, under which small-scale farmers grow industrial tree crops under contract to forest products enterprises, blurs this distinction and provides another perspective on the evaluation of economic returns. Where outgrower schemes are well established and offer the option of access to genetically improved material at additional cost, such as for some eucalypts in South Africa, high levels of uptake of advanced material suggest that growers judge the additional cost per plant to be a good investment.

Economic Returns from Advanced Cycles of Tree Breeding

Economic returns from advanced (i.e., later) cycles of tree breeding are founded on the populations established and selections made in the initial stages. As breeding advances from initial stages to subsequent cycles, strategic objectives and breeding options have generally become more focused–for example, through the clearer definition of breeding objectives, more efficient approaches to genetic testing and selection, the better use of genetic information and advanced statistical methods, and sharper analysis of the options amongst various mating designs and multiplication options. Each of these has implications for economic returns, as we discuss below.

In general, the evidence from 'advanced' generations of tree breeding, represented by only a small number of species to date, suggests that it is possible to continue to achieve high rates of economic return over at least a few generations. The capacity to deliver continuing genetic gains and economic returns depends on:

- the clearer definition of breeding objectives and their relation to economic returns
- the better understanding, as a result of accumulating species-specific genetic information over generations, of the genetic structure and parameters of populations
- the efficient design and conduct of breeding activities, to optimize investments amongst alternative breeding strategies, and amongst the elements of tree breeding activities such as selection, mating, and multiplication
- advances in technologies, ranging from simple propagation methods to advanced biotechnologies, and including forest management and product processing technologies
- the optimization of forest and tree management regimes and product processing systems.

Each of these advances helps the breeder, grower, and processor improve the efficiency of and return from their efforts. Economic analyses of returns on investment for various individual elements of advanced generation breeding are encouraging, but analyses of actual gains realized from the overall package of advanced breeding activities await the further progress of these programs.

Breeding Strategies, Technologies, and Objectives

From the 1990s, tree breeders began to follow the lead of their animal-breeding colleagues in defining breeding strategies and objectives more explicitly and formally. Increasing sophistication and competition in markets for forest products and services, and in those for growing trees, have encouraged breeders to focus more sharply on maximizing value gain and optimizing investments – a process that requires both explicit definition of the breeding objectives and assessment of strategic options to achieve them. Technological advances in many aspects of the biological sciences and breeding operations have allowed options that were not previously possible, or enhanced the efficiency of existing options. At the same time, the large scale of deployment in some plantation forestry systems has allowed levels of investment in breeding that would otherwise not be possible, and has helped develop and prove new technologies with wider relevance, such as those for cuttings production of species previously propagated only by seed, or the many applications of molecular genetics.

Breeding Strategies and Technologies

Breeding strategies provide both the conceptual and operational frameworks for tree breeding activities, and comprise both an overall plan and its particular elements – principally selection methods, mating and testing designs, and multiplication processes. They are enabled, and constrained, by technologies relevant to breeding activities. Breeding strategy options are determined principally by the breeding objectives specified, the species' biological and genetic characteristics, the available technologies, and the human and financial resources invested. These factors depend at least in part on the value of products and services, and the likely scale of deployment, of improved populations. Strategies and technologies that deliver outcomes more quickly, by reducing the time associated with breeding activities, are generally most appealing in terms of economic criteria.

An array of breeding strategies, from simple to sophisticated, is available to the breeder. Experience in tree breeding demonstrates the economic importance of designing and implementing strategies appropriate to the species, its scale of deployment, and the production system. In general, simple strategies and technologies, such as those based on mass selection and seedling seed orchards, can be very cost-effective for species for which only limited resources can be found or justified. As the level of available investment increases, reflecting the relative economic importance of a species or judgements about its potential, more sophisticated strategies and technologies become economically accessible and justified.

Decisions to adopt, or not adopt, particular strategic options and technologies reflect an economic assessment of their benefits relative to their costs; there are many examples of how such decisions, ranging from the use of biotechnologies to the choice of propagation system or the decision to incorporate a particular trait in a breeding objective, have been informed by various forms of economic analysis. Estimation of break-even thresholds, in terms of the extent of deployment or level of gain required to justify an investment, or of the investment's likely internal rate of return, are common means of economic analysis of strategic and technological breeding decisions.

Specification of Breeding Objectives

A breeding objective is the specific combination of traits that a breeder seeks to improve, weighted according to their relative economic worth. In the first phase of tree breeding, breeding objectives were typically defined (often necessarily) subjectively and imprecisely. However, both theoretical and empirical evidence demonstrate that, as in plant and animal breeding more generally, progressing to less subjective and more accurate definition of breeding objectives is one of the most significant means of enhancing economic returns from tree breeding. Even preliminary economic information about particular production systems can considerably clarify breeding objectives, which also depend on genetic information generated by a breeding program. Consequently, the refinement of breeding objectives usually proceeds in conjunction with the progress of breeding into advanced generations.

Definition of breeding objectives has to consider both costs and income associated with the production system under consideration, which may vary for example from that for multipurpose trees grown on small-scale farms for fodder, fuelwood, and fruit to that for industrial-scale pulpwood plantations. In terms of the breeding objective, economic returns can be maximized by increasing income (e.g., from achieving higher growth rates without prejudicing wood quality), decreasing costs (e.g., reducing processing costs by altering wood properties), or both. Retirement of the breeding objective for eucalypt pulp production in Portugal offers a typical example; two generations of selection were expected to increase income by 1.5% and decrease production costs by 16%, saving $US7.2 million per annum for a 250,000 tonne pulp mill.

The economic returns associated with clearer definition of breeding objectives are dependent on the characteristics of the species being bred, the costs and income associated with particular production system and suite of products, and the scale of deployment. Notwithstanding this heterogeneity, empirical results over the past decade suggest that investment in the clearer definition of breeding objectives generates substantial economic returns to both the breeder and grower of forest products.

The Value and Scale of Deployment of Improved Populations

The economic returns from tree breeding are ultimately dependent on the value of the products and services, and the scale of deployment, of improved populations. As each of these increases, so do the capacity for investing and the potential for generating returns from investments in breeding. The value of improved populations has historically depended only on their physical wood and/or non-wood products. However, value might also be reflected in terms of the opportunity costs avoided, and expanded by the services as well as the products of trees. Breeding for disease resistance exemplifies the former, and has been demonstrated to generate very favorable benefit–cost ratios; an example is that of fusiform rust resistance in southern pines in the USA, which is expected to return benefits at least four times greater than costs. The emergence of environmental services markets, such as those for carbon or ecosystem restoration, offers additional opportunities for the definition and delivery of breeding objectives, and consequent income generation.

The scale of deployment of improved populations is a significant determinant of the income stream against which the fixed costs of breeding will be offset. For these reasons, assessment of threshold levels of deployment or uptake are a common means of economic evaluation of breeding options. The role that many governments assume, of helping to foster new industries, is one reason why many tree breeding programs worldwide began with significant public-sector involvement, often transferring progressively to the private sector as industries became established on a scale sufficient to support commercial ventures. It is also one of the reasons that the public sector retains a substantial role in breeding of many nonindustrial species.

Institutional Arrangements for Breeding and Benefit Sharing

Institutional arrangements for breeding and benefit sharing impact on the distribution of costs and benefits associated with tree breeding. Historically, access to genetic resources of tree species has seldom been restricted; more usually, access has been facilitated by strong cooperation between countries and between public and private sectors. For reasons outlined above, most tree breeding programs began, and many remain, in the public domain, and have been judged against broader economic, rather than narrower financial, criteria. However, tree genetic resources and breeding activities are becoming increasingly proprietary, mirroring more general trade and intellectual property regimes. These changes challenge some of the important assumptions on which public investments in tree breeding have been made, and are likely to make breeding of some species more economically attractive and that of others less so.

Public-sector entities investing in breeding are likely to have different performance criteria than private investors, leading to different forms of economic evaluation. They may, for example, be willing to incorporate consideration of externalities, such as the potential for industry development or employment generation, the maintenance of rural livelihoods, or the delivery of environmental services, into evaluations; they are also likely to have access to lower-cost capital, and have a longer time horizon, than private sector investors. Where the investment is part of a development assistance program, as has been the case for both industrial and nonindustrial tree species, economic criteria may be very broadly defined, for example, the potential to contribute to sustainable livelihoods, or to address environmental degradation. However, in such cases, it is likely that investment in tree breeding will still need to be justified against alternative investment options.

Conclusions

Prudent investments in tree breeding offer the prospect of good economic returns, frequently greater than those from alternative forestry investments. Their realization is, however, contingent on good silviculture and management and appropriate product processing, which themselves also demand astute investments. High returns can be achieved most easily in the early stages of breeding, but evidence suggests that they can be sustained over subsequent generations through more focused, informed, and efficient breeding. Simple breeding strategies can yield relatively good returns, and may have advantages over more sophisticated strategies in terms of lesser risk and opportunity cost. However, more sophisticated strategies are likely to be necessary to optimize returns from advanced generations of breeding. The value of forest products and services, and the scale of deployment, of improved populations have significant influence on the magnitude of economic returns from tree breeding. The institutional arrangements for breeding and benefit sharing impact on the distribution of costs and benefits associated with tree breeding, and thus on the economic returns to different parties. The criteria against which the economic returns from tree breeding are assessed are also likely to depend on whether the evaluation is undertaken from the perspective of the breeder, the tree grower, or the purchaser of forest products and services.

Published by Elsevier Ltd., 2004

Introduction

Physiology is the study of how plants function. Ecophysiology is the study of how a community of plants, animals, and microorganisms function together. Environmental ecophysiology is the study of how factors such as light, temperature, atmospheric carbon dioxide concentration, wind, relative humidity, soil water, and nutrients affect community function. Silviculture is the science and art of using environmental ecophysiology, wittingly or unwittingly, to manage forests.

The physiological processes observed in trees are common to most plants. As with other species in the plant kingdom, trees are found across a range of environments and therefore display a very wide range of adaptation to environment. In this article we examine the basic physiological processes that govern tree function and indicate how this information can be applied to silviculture.

Silvicultural practices are directed towards a management objective. These include ensuring adequate regeneration, promoting some species over others, making trees grow faster, improving the quality of wood, protecting the trees from pests and diseases, sustaining water supply and soil chemical and physical properties, and conserving biodiversity. Many traditional silvicultural practices were developed before there was little physiological awareness of how trees grow. However, there is ample evidence that an understanding of environmental ecophysiology can assist in improving current, and developing new, silvicultural practices.

For convenience we consider the relationships between physiology and silviculture in the context of (a) the aboveground (aerial) environment and (b) the belowground (soil) environment.

The Aboveground Environment

The leaves, their structural properties and display, and their interaction with environmental variables determine photosynthesis, the process that drives all plant growth and therefore all biological systems. The environmental variables include quantity and quality of light intercepted by the foliage, atmospheric carbon dioxide concentration, air temperature, vapor pressure deficit, and wind. Based on an understanding of the relationships between photosynthesis and environment, silviculturalists manipulate the forest to achieve a particular management objective.

Leaves

The leaves of trees vary considerably in their size and shape. There are well-defined differences in the period of time that they remain functional. This is in part related to the architecture of the tree including whether the species is evergreen or deciduous. Size and longevity of leaves are affected by environmental stress. These properties are concerned with leaf expansion, retention, and senescence, and determine the size and extent of the canopy. Leaf structure and angle vary with depth in the canopy. These properties are dynamic and driven by the immediate light environment, and related to the physiological activity of the leaves (*see* **Tree Physiology:** Canopy Processes).

Leaf growth Leaves grow by expanding their surface area and increasing their mass. Their potential for expansion is determined by the extent of cell division and their size by the capacity of those cells to expand. In the absence of stress, rates of growth and leaf size at maturity are primarily determined by temperature and nutrition. Cell expansion is a function of leaf turgor (see Water relations below) and quite sensitive to water stress. Cell division and the rate of emergence of leaves are less sensitive to stress but have a large demand for the products of photosynthesis (assimilates). Growth requires an irreversible increase in cell volume that occurs above a threshold or critical value of turgor. Foliar nitrogen (N) has a large effect on final leaf size.

The period as well as the rate of expansion of leaves can vary considerably within and between species. In tropical species, rates of leaf extension can be as high as 18 mm day^{-1} and growth can be completed in 2 weeks. In conifers, needle extension can continue for several months. In eucalypts, a genus with a naked bud habit that allows continuous growth if conditions remain favorable, leaf size will be reduced while water stress develops or at the end of the growing season where low temperatures limit growth.

Leaf longevity Leaf longevity is the period that a leaf remains functional between initiation and fall. The period can vary up to three orders of magnitude between species. Longevity is often related to patterns of growth and levels of stress experienced by species in their native habitats. In the very slow-growing and long-lived bristlecone pine (*Pinus longaeva*), leaves have a lifespan of up to 45 years; in early-successional rainforest species lifespan may be just 50 days. Coniferous leaves have a longer lifespan than evergreen broadleaves while that of deciduous species is largely dictated by the length of the growing season. In tropical deciduous species, leaf longevity is strongly seasonal and largely determined by the levels and intensity of water stress that induce earlier leaf senescence and leaf fall.

Leaf longevity affects fluctuations in the extent of the canopy. However, the physiological activity of leaves across a range of species is closely related to their longevity. For example, a coniferous needle over a 5-year lifespan can fix two to three times the amount of CO_2 in photosynthesis than a deciduous leaf in one growing season, but at a lower rate of photosynthesis per unit leaf area. Leaf longevity is associated also with adaptation to stress. Plants that have leaves with a long lifespan minimize investment in new foliage but the leaves are suited to survival, for example through being structurally and chemically more robust in order to deter herbivory.

Photosynthesis

Photosynthesis converts solar (light) energy into dry mass and occurs in the leaves. The biophysical and biochemical processes that constitute photosynthesis are located in the mesophyll tissue, layers of cells that contain chlorophyll and other pigments, and enzymes. These processes involve both light and dark reactions. In the light reactions, solar energy in the spectrum between 400 and 700 nm is absorbed by chlorophyll and converted to chemical energy which is stored as phosphorylation potential (ATP) and as reducing power (NADPH). The dark reactions then lead to the reduction of carbon dioxide (CO_2) and its conversion to simple carbohydrates (CH_2O, sugars). The biochemical cycle that drives photosynthesis is the Calvin or photosynthetic carbon reduction cycle. Trees use this cycle only for photosynthesis and are C_3 plants. The enzyme (that catalyzes a reaction between two substrates, ribulose 1,6-*bis*phosphate and CO_2; see **Figure 1b**) involved in the first reducing step is ribulose 1,6-*bis*phosphate carboxylase, commonly referred to as Rubisco. It is present in leaves at high concentrations but these vary widely according to incident levels of light on the leaf, and the availability of nutrients (as Rubisco, a protein, has a high demand for nitrogen-based resources) and water. Photosynthesis is commonly measured as the amount of CO_2 fixed per unit leaf area per unit time. The photosynthetic capacity or maximum rate of photosynthesis varies widely between tree species, from <5 to around 25–30 μmol $CO_2\,m^{-2}\,s^{-1}$. Species with higher photosynthetic capacity are usually associated with higher rates of growth. Leaf photosynthesis is commonly measured using gas-exchange analysis; micrometeorological techniques are used over whole canopies (*see* **Tree Physiology**: Canopy Processes).

Gas exchange In order to absorb CO_2 for photosynthesis, leaves expose a wet surface to a drier atmosphere. The evaporative loss of water that occurs results in cooling that assists maintaining equable temperatures for photosynthesis. To prevent dehydration, the epidermis has a relatively impermeable cuticle and turgor-operated valves called stomata. Changes in turgor lead to the opening and closing of the stomata. This regulates the diffusion of water vapor out of, and of CO_2 into, the leaf in a process referred to as gas exchange. The driving force in gas exchange is the concentration difference between the external atmosphere and, for CO_2, the concentration within the leaf; for water it is the saturated vapor pressure at the leaf temperature. The (stomatal) conductance is a measure of the degree of opening of the stomata.

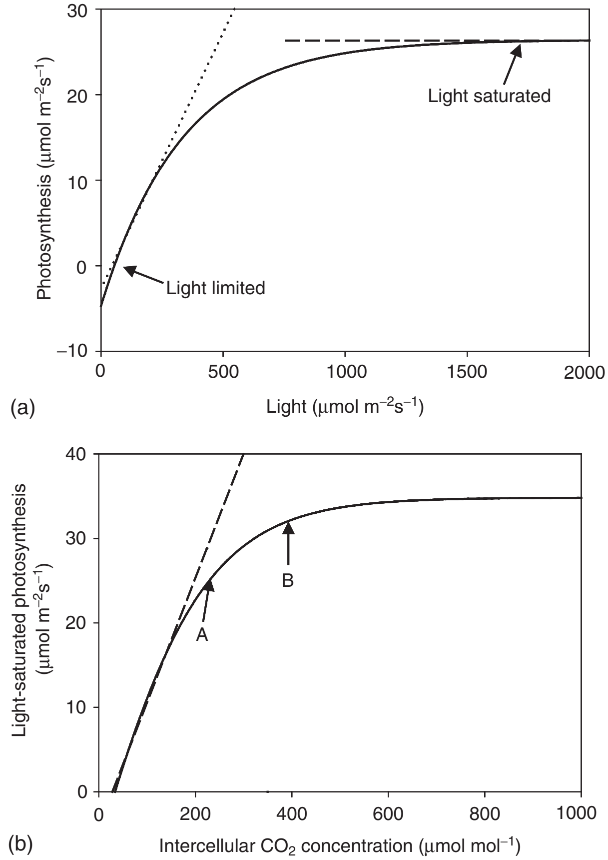

Figure 1 (a) The response of photosynthesis to increasing levels of light. At very low light levels, photosynthesis is negative as the rate of dark respiration (which results in the release of CO_2) is greater than the rate of photosynthesis. Photosynthesis then increases rapidly, the dotted line representing the initial slope of the response or quantum yield (μmol CO_2 fixed per μmol incident or absorbed light). At high light levels, photosynthesis becomes light saturated (broken line). Full sunlight varies with season but is approximately 2000 (μmol $m^{-2}\,s^{-1}$). (b) The response of light-saturated photosynthesis to intracellular CO_2 concentration, a measure of the concentration in the internal spaces of the leaf that is available to be fixed in the mesophyll cells. The broken line measures the carboxylation efficiency and indicates that photosynthesis is RuBP (ribulose 1,6-*bis*phosphate) saturated. As CO_2 concentration increases, photosynthesis becomes limited by the regeneration of RuBP in the Calvin cycle. Point A represents the rate of photosynthesis that occurs at atmospheric CO_2 concentration; point B the rate if there was no stomatal limitation.

Environment and photosynthesis Light and CO_2 are essential to photosynthesis as explained above. Light varies both diurnally and seasonally, and in a tree canopy the levels of light incident on a leaf will vary with position and orientation of the leaf. Leaves adapt to their incident light environment but have a characteristic light-response curve (**Figure 1a**). When light levels are low, photosynthesis is limited by light. When light levels are high in C_3 plants, photosynthesis is light-saturated.

Carbon dioxide and water (see below) are the essential substrates of photosynthesis. Photosynthesis is CO_2 limited at low levels of CO_2 concentration but the process becomes saturated at high concentrations (**Figure 1b**). The average atmospheric CO_2 concentration today (in 2004) is approximately 370 μmol mol^{-1}. Thus rates of photosynthesis will continue to increase if anthropogenic release of CO_2 into the atmosphere continues at current rates. This will lead to further increases in photosynthesis assuming no change in other factors that affect the rate of photosynthesis, for example temperature. As trees are the major terrestrial global sink for CO_2, this has environmental as well as biological significance.

Temperature is closely associated with photosynthesis as we are dealing with a biochemical process where rates of reaction increase with temperature, approximately doubling with each 10°C increase in temperature. Thus photosynthesis varies both diurnally and seasonally. However, as pointed out above, leaf initiation and shedding are also driven by the availability of water. Thus photosynthesis tends to be most active over the middle range of temperatures, that is the response curve is parabolic, and decreases at very low and very high temperatures that are often associated with stress. Extremes of temperature are often associated with photoinhibition and photorespiration (see below). Seasonal shifts in temperature result in adaptive changes that are defined by the slope of the line relating the optimum temperature for photosynthesis and the acclimation or ambient temperature. Species from a continental climate and a more variable diurnal temperature range tend to have a broad temperature maximum to maximize uptake of CO_2 in photosynthesis whereas in species from a coastal environment, where diurnal changes in temperature are moderate, uptake of CO_2 has a more dynamic response to changes in temperature.

Rates of photosynthesis are also limited by nutrient and water stress (see below). Given that nitrogen and phosphorus are essential components of the photosynthetic process (Rubisco, ATP, and NADPH) positive associations between photosynthetic capacity and leaf nitrogen and leaf phosphorus are observed. However the effects of atmospheric and soil water stress on photosynthesis are primarily caused by changes in response to leaf water status and vapor pressure deficit on stomatal conductance.

Stomatal conductance Stomata are powerful regulators of gas exchange and linear relationships between rate of photosynthesis and stomatal conductance are often observed in trees. This relationship may become nonlinear at high conductance as the rate limitation may no longer be diffusion of CO_2 into the leaf but reside in the activity of photosynthetic processes in the mesophyll. As with rates of photosynthesis, there is a considerable variation in maximum stomatal conductance between species where low conductance is often associated with low photosynthetic capacity and vice versa.

Stomata open and close as a result of increases and decreases in turgor, respectively, of guard cells that surround the stomatal pore. However these changes in turgor are driven by active mechanisms that involve the transport of ions, in particular potassium. The regulation of stomata is complex but in general they open in response to light, have a parabolic response to temperature and close in response to atmospheric (vapor pressure) and leaf (soil) water deficits (**Figure 2**). The sensitivity of stomata to these variables varies between species, and as with photosynthesis, there is adaptation of stomatal conductance to the ambient environment. Trees are tall crops and the leaves are closely coupled to the atmosphere (*see* **Tree Physiology**: Canopy Processes). As a result, stomatal conductance of trees is often observed to be quite sensitive to vapor pressure deficit.

Effects of age The photosynthetic capacity and maximum stomatal conductance of leaves changes during their development, maturation, and senescence. On tree species that have several cohorts of leaves, for example conifers, there may be considerable stratification of physiological activity, the lowest being associated with the oldest leaves. Trees are perennial crops and some are very long-lived. There is evidence that tree aging is associated with a decline in photosynthetic capacity though this is linked to changes in other areas of physiological activity.

Photoinhibition Photoinhibition is associated with the absorption of light by plants in excess of that required for photosynthesis and is manifest in a reduced photosynthetic capacity. Photoinhibition occurs when leaves are under stress, for example during conditions of low temperature or water stress, such that the rate at which enzymes function in the Calvin cycle is limited. Sustained decreases in the efficiency of photosynthesis and quantum yield, a measure of the efficiency of conversion of light to biomass, are observed that can be detected by chlorophyll fluorescence and are associated with prevention of damage to the photosynthetic system. If light is absorbed in excess but not dissipated, oxidative damage occurs. Prevention of damage is associated with the xanthophyll cycle, an interconversion of carotenoid pigments that results in the harmless dissipation of light as heat energy, and a range of other potential mechanisms, some unproven.

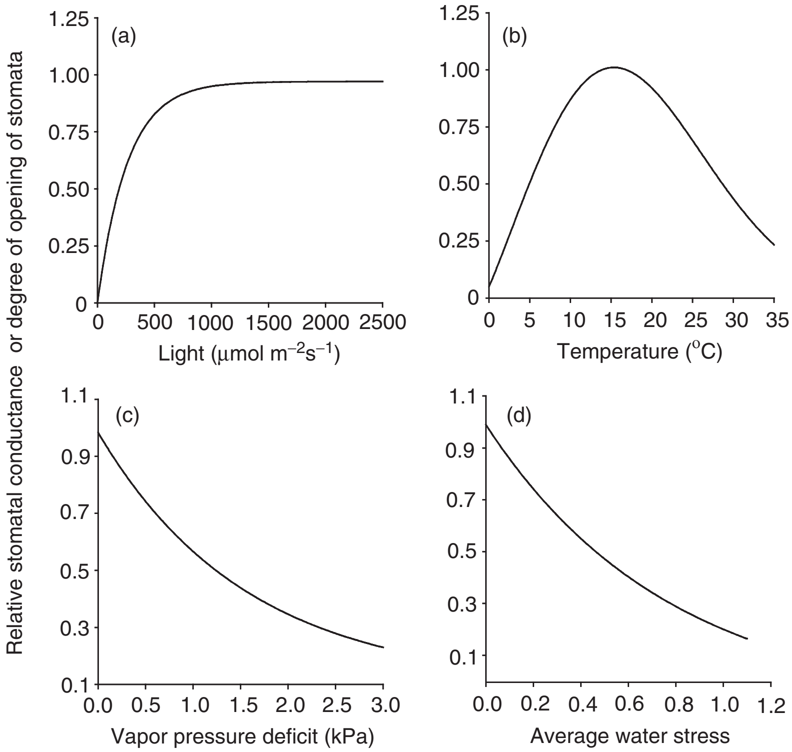

Figure 2 Stomatal respond to their environment. Stomata open rapidly in response to increasing light levels (a). Stomata also open in response to increasing temperature but are observed to close at high temperatures (b). However this is often because the stomata are sensitive to increasing vapor pressure deficit (the difference between the saturated vapor pressure at the air temperature and the actual vapor pressure) (c) and vapor pressure deficit increases with temperature. Stomata are also responsive to the water status of the leaf (d); this is measured by considering the water stress history (measured as the pre-dawn water potential) that the leaf has experienced. The stomata of tree species differ in their response to these environmental variables.

Respiration Respiration is a process that consumes oxygen and releases CO_2, water, and energy. Most respiration is independent of light and produces energy to support growth. However, photorespiration occurs only in the light and competes directly with photosynthesis in a process where both oxygen and CO_2 compete for ribulose 1,6-*bis*phosphate and Rubisco. This reduces the efficiency of utilization of CO_2 in the Calvin cycle and causes photosynthesis of C_3 plants to saturate at lower values of light and photosynthesis than in C_4 plants. (C_4 plants can largely overcome the negative effects of photorespiration by using anatomical and biochemical mechanisms to deny access of oxygen to Rubisco.) Photorespiration is most active at high light intensities and temperatures and acts, along with photoinhibition, to reduce photosynthesis.

Silviculture

Several tools are available to silviculturalists to manipulate the aboveground environment. Choice of species, stocking density, the use of monocultural or mixed-species plantings, shelter belts, pruning, and thinning are some. Application of fertilizer and irrigation, although altering the belowground environment in the first instance, change growth rates and canopy size, thereby altering also the aboveground environment. Some of the ways these actions affect physiological activity will now be explored.

Light The classical silvicultural systems in natural forests are single-tree selection, group selection, shelterwood, and clear-cut. This series represents a progressive increase in the amount of light reaching the forest floor to promote regeneration. The appropriate system is determined to a large extent by the photosynthetic properties of the trees. Although clear-cuts are considered by many to be environmentally unfriendly, there are circumstances in which this system is the most appropriate. In native forest, many 'clear-cuts' that arise from natural disturbance (e.g., by fire) are essential for regeneration and replacement of the same forest type. For example, *Eucalyptus regnans* is a major forest type in southeastern Australia which often occurs as a single species of the same age. This age is determined by the timing of the fire event that destroyed the previous forest and provided a large seedbed out in the open. Physiologists call *E. regnans* a 'sun' or 'shade-intolerant' plant. Conversely, in the rainforests of northeastern Australia, *Alocasia macrorrhiza* grows as an understory species and regenerates and persists under low light. *A. macrorrhiza* is a popular indoor plant. Physiologists call it a 'shade' or 'shade-tolerant' plant. The photosynthetic properties of sun plants and shade plants are shown in **Figure 3**.

It can be seen that sun plants (e.g., *E. regnans*) typically grow faster than shade plants (e.g., *A. macrorrhiza*) but only if there is plenty of light reaching the leaves. *Eucalyptus regnans* grows very poorly under shade and indeed will only regenerate and grow satisfactorily in the open. *Alocasia macrorrhiza* grows much slower than *E. regnans* but it can establish and persist at lower light levels. The light compensation point (the light level at which net photosynthesis is zero) is considerably less in *A. macrorrhiza* than in *E. regnans*. Thus use of a silvicultural regime that shades *E. regnans* regeneration is likely to fail. Pioneer species that are intolerant of shade (like *E. regnans*) are usually very productive and readily establish on bare sites. Successful plantation trees are often pioneer species that occur naturally as even-aged monocultures. By contrast species with photosynthetic properties adapted to growth under shade are not suited to being regenerated in the open and attempts to use these species in plantations often fail.

The manipulation of light in forest plantations through stocking density at planting and thinning during the rotation are used to optimize the amount of light intercepted by an individual tree and therefore its size, at the same time maximizing the quantity of wood produced per unit area, and the quality of the wood required for a particular end-use. High initial stockings in all types of forest promote height growth, straight and single-stemmed trees, and prevent the development of large branches. Thinning reduces between-tree competition and allows increased growth of remaining trees. Pruning reduces the size of the knotty core and allows the development of knot-free clear wood by removing the lower branches, often in a series of progressive lifts.

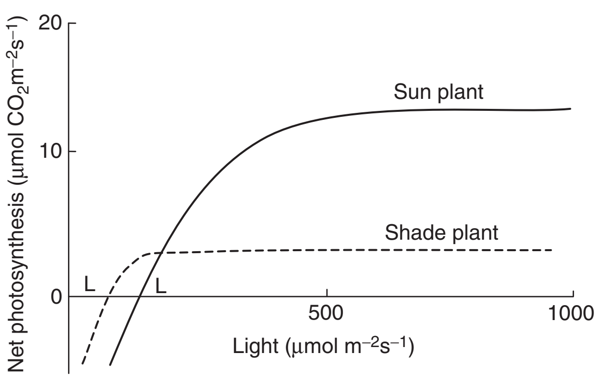

Figure 3 A typical relationship between net photosynthesis and light for single unshaded leaves of sun plants and shade plants. L is the light compensation point.

Pruning and thinning are associated with changes in the photosynthetic activity of leaves. Green pruning that removes live branches reduces the total number of leaves per tree; thinning changes the distribution of light incident on the leaves of the retained trees. A quantitative understanding of the physiological responses to both practices is used as a basis for management. The reduction in canopy size with green pruning significantly increases the rate of photosynthesis of the residual leaves throughout the crown. There is also an increase in the rate of leaf development and delayed senescence of existing leaves. The magnitude and duration of these responses is related to the severity of pruning. Thus an increasing capacity for photosynthesis at tree level is offset by an increasing reduction in crown size. The balance point is the pruning severity beyond which reduction in growth is observed. The enhanced levels of light-saturated leaf level photosynthesis observed following thinning are related to the increase in the fraction of incident light penetrating to the middle and lower parts of the canopy compared to that in unthinned stands. The magnitude of this response increases with time from thinning and is associated with increased levels of leaf nitrogen concentration and changes in its distribution commensurate with its allocation according to the prevailing light environment. Thinning is also associated with increases in tree-growth efficiency, the amount of stemwood produced per unit leaf area.

Carbon dioxide As CO_2 is a primary reactant of photosynthesis, increases in its concentration in the atmosphere have the potential to increase growth rates. Indeed, artificial enrichment of CO_2 concentrations in nurseries has been used to that effect. The concentration of CO_2 in the atmosphere has been increasing exponentially for over 100 years, mainly from burning fossil fuels but also from the clearing and burning of vegetation, including forests which historically have been very large sinks for CO_2. If not already occurring, it is expected that climates will change as a result of increased CO_2 concentrations in the atmosphere and that the consequences of this will be largely negative for human welfare. Forests, however, all other things being equal, may be more productive, though any increase in average temperatures and the distribution and quantity of rainfall will change species boundaries.

While changes in atmospheric CO_2 concentration are beyond their control silviculturalists can manipulate CO_2 to their advantage by increasing the stomatal conductance of CO_2 from the atmosphere into the leaves through the stomata. Silviculture is used in a broad sense to maximize photosynthesis in this way. For example weed control, the removal of competition for resources, i.e., light, nutrients, and water, ensures that these are used to support uptake of CO_2 by the tree crop only. This is particularly important when any one resource is a major factor limiting plant growth.

Air temperature Very low temperatures can 'damage' the physiological integrity of plant tissue. This is, in particular, a silvicultural issue in nurseries where seedlings are raised under conditions that are mild compared to those at the planting site. Two types of damage may occur. Physical frost damage is caused by the freezing and expansion of intracellular fluid that result in cell breakage. Photodamage associated with photoinhibition is caused when more light is absorbed than can be dissipated harmlessly. This leads to reactions that destroy cell membranes. Silviculturalists impose 'hardening' in the nursery to make the seedlings physiologically more resistant to frost and low temperature after transplanting. These include progressive exposure to lower temperatures that leads to improved resistance because the seedlings increase the osmotic concentration of cell contents, thereby decreasing their freezing point. Low temperature and nutrient starvation increase resistance to photodamage by stimulating the activity of physiological processes that dissipate light energy. In addition, shadecloth is used to reduce the levels of incident light on seedlings. The pattern of regeneration of tree seedlings in native forest is affected by the degree of cold-induced photoinhibition and greater exposure increases the intensity of a frost event. Shelterwood systems reduce exposure and increase average minimum temperature, thereby supporting seedling survival.

Wind A boundary layer of relatively still air at the leaf surface contributes to the resistance to transfer of CO_2 into, and water vapor out of, the leaf. However forests with high canopies are aerodynamically rough and the atmospheric climate comes very close to the leaf surface. Consequently boundary-layer conductance is very high and reinforced by wind mixing up the air close to the leaf surface. Photosynthesis is increased in gentle to moderate winds but severe winds can accelerate water loss, promoting stomatal closure and a reduction in photosynthesis. Strong winds can also cause mechanical damage to trees. Planting patterns are used to promote shelter within a stand, and belts of trees planted strategically to reduce wind speed across the stand.

The Belowground Environment

Plants require water and nutrients for growth and these are obtained in the main by absorption through roots. Thus the physiological condition of the aboveground parts of the plant are reliant on soil properties, and processes that control root development and the exploration of the soil (*see* **Tree Physiology**: Root System Physiology) and the acquisition, translocation, and storage of nutrients (*see* **Tree Physiology**: Nutritional Physiology of Trees). Conversely root systems are reliant on the translocation of assimilates from leaves for their growth and energy requirements. Changes in soil water content can have a profound effect on physiological activity and are associated with reductions in water potential and water content throughout the plant.

Water Relations

The amount of water used directly in the biochemical reactions of photosynthesis is very small compared to that transpired by leaves. Changes in water status strongly influence tree growth through their effect on leaf expansion and shoot and root extension. As water status decreases, turgor is reduced, stomata close, and direct effects of water stress on chloroplast processes reduce the rate of photosynthesis. There is evidence that hormonal signals transmitted between the root surface and leaves can trigger changes in stomatal conductance in response to the current level of water supply.

Water content, water potential, and water transport Water status can be measured gravimetrically as tissue water content, most often relative to its saturated or turgid weight. Water moves along gradients of water potential (that has units of pressure) which is defined as the potential energy per unit volume of water with reference to pure water at zero potential. Water in most biological systems and in soil has less potential energy than pure water. Consequently values of water potential are negative and water moves along negative potential (pressure) gradients. A key measurement of leaf water potential is made pre-dawn to determine the minimum level of water stress. This value is taken when there is little or no net flux of water through the tree and therefore estimates the water potential at the soil–root interface.

The water potential of a leaf (shoot or root) is the sum of two components, a negative osmotic potential arising from the presence of dissolved solutes in the cell and a positive turgor potential arising from the pressure exerted on the cells by their walls. These variables, and a measure of the elasticity of the cell walls, can be derived from the relationship, referred to as the pressure–volume curve, between water potential and water content.

In response to the demand for water at the evaporating surface, leaf water potential becomes more negative to increase the potential gradient. As the soil dries and soil water potential becomes more negative, a strategy for maintaining the same flux of water through the plant is to further lower leaf water potential to maintain the potential gradient. Trees are observed to adopt a range of strategies to deal with water stress including an inherently low osmotic potential, lowering of leaf osmotic potential that is referred to as osmotic adjustment, and elastic tissues that allow the maintenance of turgor over a wider range of tissue water contents. Trees with high osmotic potentials and inelastic tissues that promote rapid loss of turgor are associated with a high stomatal sensitivity to leaf water status and drought avoidance. Conversely, trees with low osmotic potential and elastic tissues are associated with a low stomatal sensitivity and drought tolerance.

Sapwood The major conducting pathway for water between the roots and the leaves is the stem sapwood. The sapwood consists of a network of interconnecting pipes which in trees is made up of xylem vessels or tracheids. This 'pipe model' link between sapwood and leaves implies a causal relationship although the direction of causation remains unclear. Thus stem sapwood area can be an accurate scalar for estimating leaf area due to its role in supplying water to the transpiring foliage (*see* **Tree Physiology**: A Whole Tree Perspective).

Silviculture

The growth and function of roots is influenced by soil water, soil nutrients, soil air, soil strength, soil temperature, soil salinity, soil acidity, soil sodicity, and soil toxicity. Silviculturalists can manipulate these environmental factors to their advantage, using techniques such as cultivation, including mounding and deep ripping, or by species selection. A soil environment that promotes root development does not necessarily mean that the growth of roots will be greater than that of the stem, branches, and foliage. Indeed it is usually the opposite. Thus if the soil has plenty of water and nutrients but the aboveground environment is in some way deficient, e.g., there are low levels of incident light, then the tree will partition more assimilates to aboveground growth in a bid to capture more light.

When dealing with an interface between soils and roots, there is a knowledge boundary and exploitation of a physiological understanding of root behavior requires close cooperation with soil scientists as well as silviculturalists.

Water Irrigation is not usually an option for the silviculturalist, except in nurseries or in disposal of treated sewage effluent (*see* **Soil Development and Properties**: Waste Treatment and Recycling). However there are silvicultural strategies that can conserve scarce soil water and ensure that it is used most efficiently in growth. The most fundamental is avoidance of dry sites but as these are often unsuitable for activities other than forestry, an option is a tree species that will grow and survive at such a site. Trees vary in their response and ability to adapt to soil water stress. They also vary in their ability to close their stomata in response to the dryness of the atmosphere (measured as the vapor pressure deficit). Water-use efficiency, a term that measures biomass produced per unit of water transpired varies a limited amount and is not commonly used as a selection tool in forestry. In environments that have higher levels of water supply but where water stress is still the major factor limiting tree growth, one strategy is to deliver the soil water to the crop trees only. This can be achieved by reducing the evaporation of water directly from the soil by using mulches or retaining litter. In addition, spacing and thinning the tree crop reduces the total transpiring area. Besides increasing tree survival, this option can be used to maximize the growth of the retained trees and provides a basis for the sustainable use of available soil water across rotations. As pointed out above, weed control is an essential part of management on dry sites.

Eucalypts provide an example of where insufficient knowledge of tree physiology has resulted in poor silviculture and created a potential environmental weed. Australia is a large and predominantly dry country dominated by genus *Eucalyptus*. This genus includes some very fast-growing species and the inference was made that some of these species might be successful on sites with low rainfall. However the fast-growing species are native to wetter sites and are not physiologically well adapted to severe water stress. Thus many early plantings of eucalypts outside of Australia on dry sites failed because of inappropriate species selection. When these same species escaped to sites with higher water supply, they became aggressive weeds and suppressed the growth of more desirable species. An understanding of the physiology of water use would have foreseen these eventualities. A general strategy among plants for conserving soil water is to close stomata, but this will also reduce growth rates because photosynthesis will also be reduced. However several eucalypt species tolerate drought and do not close their stomata so much as the soil dries or as the vapor pressure deficit increases (**Figure 4**). This means that when eucalypts are grown in competition with more conservative and slower-growing species, they transpire more water and exhaust the soil water supply faster. Eucalypts often survive by dropping their leaves and then regenerating their foliage from dormant buds when the conditions are again favorable for growth, a strategy that also makes them highly competitive species in some exotic environments.

Nutrients The elements essential for growth were established by physiologists in the early twentieth century and mineral nutrition is now relatively well understood in the context of the processes that drive plant growth. Application of fertilizer to forests is an established silvicultural practice. For example rates of canopy development and canopy size are strongly dependent on the supply of nitrogen. Fertilizers are also used to correct nutrient imbalances which can impair the functioning of processes that are crucial to acceptable growth and form. However, there are other ways of managing forest nutrition. Cultivation, residue retention, elimination of burning, organic matter maintenance, prevention of erosion, use of legumes, application of treated municipal wastes, and the promotion of mycorrhizal infection of roots are all forms of management of nutrition, and in all of these cases a knowledge of the underlying physiological processes helps in defining the most appropriate regimes.

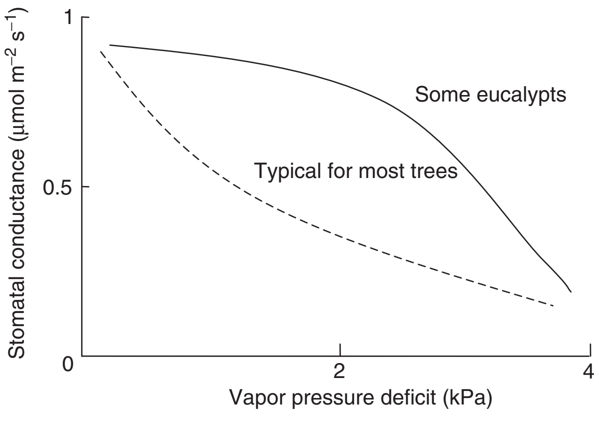

Figure 4 The typical relationship between stomatal conductance and vapor pressure deficit for most trees compared to that of some eucalypts.

Small amounts of nutrients can also enter foliage and soil through atmospheric deposition and this can be critical to the welfare of certain ecosystems. However, nutrient inputs from air pollution can be significant. Soils in southern Sweden have been estimated to receive approximately 30 kg ha^{-1} of free nitrogen from the combustion of coal and other fossil fuels in Germany. This, combined with increased CO_2 concentrations in the atmosphere, has resulted in higher growth rates. However, air pollution is not recommended as an acceptable silvicultural practice!

Soil air and soil strength Roots need oxygen for respiration and growth. Oxygen can be reduced to critical limits in situations where the air-filled pore space in the soil is reduced, such as in clay soils, in waterlogged soils, and in compacted soils. Reduced soil air will impair membrane function and therefore can reduce the uptake of water across the root endodermis. This means that a soil with too much water can actually cause water stress in the tree. Waterlogged soils can be mounded and compacted soils can be ripped.

In order for roots to grow they need to overcome the mechanical resistance offered by the soil. This mechanical resistance or impedance is related to the strength of the soil. Root growth rates decrease exponentially with increasing soil strength (**Figure 5**). Ripping the soil can reduce soil strength but it is better to have soil management regimes that do not cause soil compaction in the first place. The strength of a particular soil increases with soil bulk density (a measure of soil compaction) and decreases with soil water content. This means that root growth in a drying soil will be reduced because of both the lower water potential in the soil and the increased soil strength. Thus soil cultivation can alleviate water stress in plants in compacted soils to some extent.

Cultivation Soils are cultivated (by plowing, mounding, ripping) as part of plantation establishment to control weeds, to release nitrogen, to improve access to soil water and drainage, and to reduce soil strength. Cultivation regimes are usually based on empirical trials. Silvicultural practices informed by empirical trials or trial and error must by their very nature be blunt tools. The tendency has been to assume a worst-case scenario and

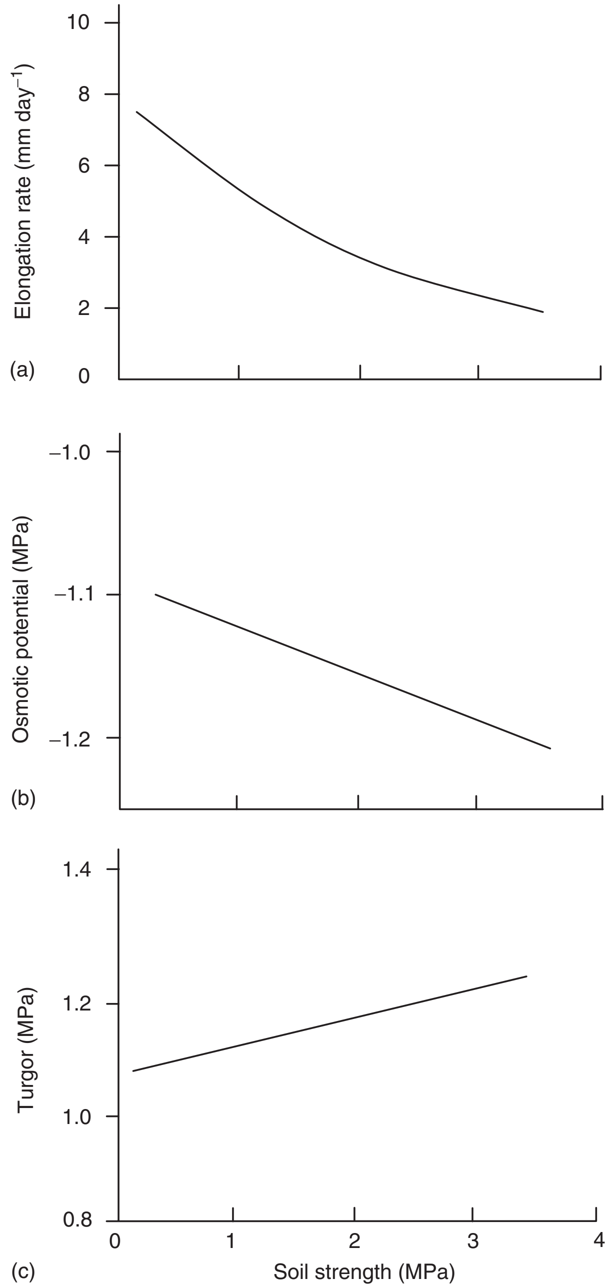

Figure 5 The effect of soil strength on (a) the rate of elongation of roots of radiata pine, (b) the osmotic potential of the cells in the root elongation zone, and (c) the turgor of the cells in the root elongation zone. Part (a) shows that the rate of root elongation decreases exponentially with increasing soil strength; (b) demonstrates that elongating cells reduce their osmotic potential (osmoregulation) in response to increasing soil strength which results in an increase in turgor (c) which can compensate in part for the increasing mechanical impedance of the soil. Adapted with permission from Zou C, Sands R, and Sun O (2000) *Tree Physiology* 20: 1205–1207.

consequently to overcultivate in order to be sure that an effect is realized. Thus knowledge of root physiology can assist the silviculturalist in making a more informed decision.

Process-Based Models: A Synthesis and Conclusion

There has been considerable effort in recent years to inform silviculture through process-based models. These are complementing and extending the use of empirical models. Empirical models can only be used to predict growth for the sites, environments, and conditions on which they are based, i.e., they are site specific.

Physiological relationships of the type described in this article form the basis of process-based models that can describe forest growth. These models are ‘process-based’ because growth is predicted from a knowledge of how physiological processes respond to environment and to silviculture. The advantage of these models is that they can be used across a range of environments where a species is grown although the parameters of the model, for example light-saturated photosynthesis or resistance to uptake of water by roots, may change with species. These models are becoming very sophisticated and dynamic such that they can now be used for predicting responses to silviculture and growth in future rotations based on an understanding of the resources used to support the current rotation.

The lines of communication between physiologists and silviculturalists have been improved but there is still a long way to go. It is essential that Schools of Forestry teach tree physiology in order for silviculturalists to be able to communicate with physiologists. It is perhaps equally important that silviculture be taught as applied environmental ecophysiology in an economic and social context.

A Whole Tree Perspective

T M Hinckley, University of Washington, Seattle, WA, USA

Introduction

Trees are spectacular organisms (**Figure 1**); they can accumulate an incredible amount of biomass, they can live for long times, they can grow in extraordinarily stressful environments, they are globally important because of their historic roles in providing fuel and fiber and their more recent and emerging roles in providing chemicals including pharmaceuticals, providing habitat for a diverse array of organisms, and sequestering carbon. Although any organism is the sum of its parts, changes in the function of a part (e.g., leaf herbivory as the result of an insect outbreak) are not always reflected in changes in the whole organism (i.e., a scaling issue). As a consequence, knowledge about the growth, development, functioning, and morphology of the parts enables one to understand the mechanisms behind how a tree grows, develops, functions, and, ultimately, appears, but this knowledge alone often fails to predict accurately the response of the whole organism (i.e., issues of scaling and context). Therefore, an article focusing on the integrated whole organism has merit. Other articles in this Encyclopedia have either viewed a part of the whole tree or a particular process or property of the tree. In contrast, this article will take an integrated approach and focus on the entire tree.

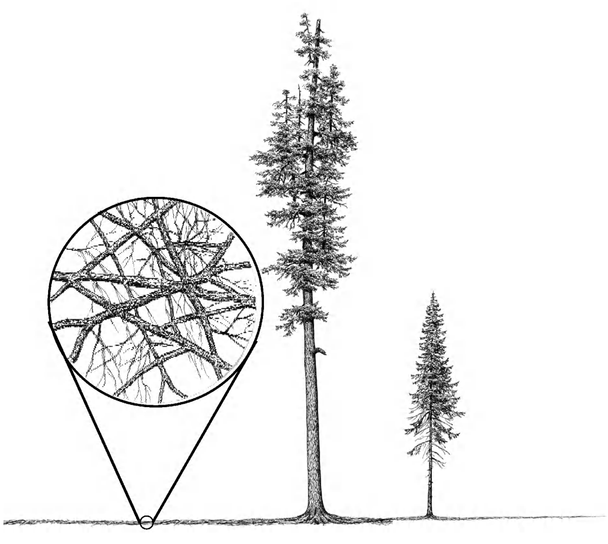

Figure 1 Two *Pseudotsuga menziesii* trees, one an old-growth, the other 80 years old, are shown with their 'root' systems. Emphasized in this drawing is the change in crown complexity, as well as size, with age and the horizontal and interconnected extent of the root systems. Drawn by Dr Robert Van Pelt.

Five topics will be developed here. First, the nature and definition of the individual organism will be explored. Second, the current status of understanding at the whole organism level about one of several key physiological processes associated with carbon, water, and nutrient acquisition and their use will be presented. Third, 'perception' of internal and external changes, and then the transmission and 'interpretation' of this 'perception' are critical for tree survival. The whole area of biophysical and biochemical signaling has become a major topic and research area at the tissue and cell levels of biological organization – what is known at higher levels? Fourth, there are a number of scaling issues that need additional discussion; for example, over the last 10 to 15 years, branches have been defined as an appropriate, intermediate scale of biological organization for the study of large, complex trees – there may be significant weaknesses in this assumption. Fifth and finally, major human social and cultural development was set in motion between 8000 and 10 000 years ago by the domestication of a few critical crop species and now we are totally dependent upon these. Over this same period of time, comparatively little genetic selection has occurred with forest trees. Because of advances in molecular biology and genetics, opportunities to domesticate trees over vastly shorter time scales are now possible.

Definition of the Whole Tree

The whole tree (i.e., the organism) might be defined as a system of relatively fine organs (i.e., foliage and fine roots) acquiring resources (i.e., carbon, nutrients, and water) then linked via a coarser system of roots, stems, and branches to create a particular form. Architectural form, trade-offs between structure and function, and optimization of carbon 'investment' in the construction and maintenance of support and transport tissue vs. tissue involved in resource acquisition are widely discussed in the literature. Therefore, the visible form that a tree takes is the result of architectural and process rules (i.e., the hardwired or genetic component) and their interplay over time with the combined abiotic and biotic environment. This interplay has been examined in a number of ways: (1) efforts to seek general rules of form and function, (2) documentation under natural and experimental conditions of changes in form and function with abrupt changes in the environment, (3) common garden studies involving many different genotypes and at least two very different 'gardens,' and (4), most recently, the use of a wide range of molecular tools. Emerging from these studies are a number of generalizations. First, trees, within a prescribed genetic framework, respond to a set of environmental conditions and this response can be described morphologically (e.g., sun–shade), physiologically (e.g., quantum efficiency), and allometrically (e.g., root:shoot ratio). Second, trees, in contrast to most plants and animals, may harbor tremendous genetic variation (however, it is not certain whether this translates to higher levels of adaptive genetic variation). Third, the individual tree often has a very large capacity to acclimate to new or different environmental conditions. Fourth, large differences in morphology or function between one genotype and another may be due to only a few genes; unfortunately, there is insufficient evidence at present for this to be unequivocal.

Trees are large, sessile organisms capable of long life and capable of living in extraordinarily diverse environments. These attributes place special restrictions on the form and function of trees. The desiccation properties of woody angiosperms and gymnosperms versus other photosynthesizing plants have been compared and a major difference in the two groups' ability to tolerate or function at low water potentials was noted. The inability of woody angiosperms and gymnosperms to tolerate low water potentials means that water loss must be strongly (and rapidly) regulated. How then do stomata 80 m from the root system perceive decreases in soil water potential (or cessation of root growth)? In addition, competition for resources, particularly light, has favored two very different life history traits and these are often found together in the same organism. Height growth, whether to gain competitive advantages for light or reproduction or both, means that transporting resources becomes increasingly difficult and, as trees become taller and bigger, potentially carbon maintenance costs increase. Finally, as a result of increases in tree height, foliage is always being added at the top (i.e., in relatively high light environments) and lost at the bottom (i.e., in low light environments). In sum, a tree's response to competition is carbon-costly and mechanically risky and, therefore, establishes one of the first goals of domestication; that is the elimination of continuous height growth (discussed below).

Although the aboveground portion of one tree can be readily and visually separated from another tree, where one organism stops belowground and another begins is not clear. Root grafts, known for a long time, represent one means by which one organism and another may be connected positively (resources) and negatively (disease). However, belowground connections may be far more complex and extensive – evidence suggests that mycorrhizal roots of an individual of one species are connected with other individuals of the same species. In fact, mycorrhizal roots of one species may be connected to another species. For example, in 1997, Simard and others found that stable ^{13}C moves from the deciduous hardwood *Betula papyrifera* to the evergreen conifer *Pseudotsuga menziesii* and vice versa via a common, interconnected ecto-mycorrhizal species. These experiments indicated that belowground carbon sharing is of sufficient magnitude that it may help ensure the coexistence of these two species in mixed communities.

More recent work using radioactive ^{14}C demonstrated bidirectional carbon exchange, depending upon phenological state, between the spring ephemeral *Erythronium americanum* and sugar maple (*Acer saccharum)* saplings via the mycelium of arbuscular mycorrhizal (AM) fungi. It was also noted that the exchange via the AM fungi was specific because there was no uptake of ^{14}C in associated yellow birches (*Betula alleghaniensis*) (an ecto-mycorrhizal tree species). Such studies illustrate how, via interconnected AM or ecto-mycorrhizae, individuals of the same species and of different species can positively influence each other. Implied then is that the absence of this connection could negatively affect the remaining organism – this suggests that the individual's performance is more than the combination of its genetic background and the environment or that the definition of either the 'individual' or the 'environment' must be made more comprehensive.

Fungal endophytes are fungi growing asymptomatically on stems and leaves. They have been found in every species of plant examined to date, including marine macroalgae, mosses, ferns, 'gymnosperms,' and herbaceous and woody angiosperms. Research more than two decades old on species-specific endophytes and the 'extended phenotype' in grasses has demonstrated the close relatedness of this mutualism where the endophytic fungi lives on the host species and, as a consequence, deters herbivores and enhances the physiology of the host. For several species of grass, the endophytic relationship may be necessary for survival. In a 2002 study of *Dichanthelium lanuginosum* plants from geothermal soils in Lassen Volcanic and Yellowstone National Parks, Redman and others noted that the beneficial effect of a fungal symbiosis increased with soil temperatures. In contrast to grasses, the newly discovered relationship between endophytes and trees is different – many endophytic species coexist on leaves and stems, they are highly diverse within and among host, they are transmitted horizontally (vs. within the seed or clonally) and they may not defend the host against herbivores. However in spite of the uncertainty about whether tree endophytes provide benefits to the host or not, a number of researchers are beginning to examine both natural and genetically engineered endophytic relationships with host trees (e.g., white pine blister rust and *Pinus monticola* and *P. albicaulis*). If fungal diversity mimics the noted enormous diversity of prokaryotic organisms both above and below ground, then there could be several important consequences to our consideration of the organism (and, therefore, groups of organisms in stands, communities, or ecosystems). First, it may be, except under experimental conditions, difficult to study the individual organism separated from its associated microflora. As a consequence, we have an 'extended phenotype' to consider. Second, because evolutionary change occurs rather slowly in long-lived organisms, evolutionary changes in the associated microflora may play a significant role in 'assisting' the host organism to deal with, for example, historical and projected climate change. Third, any consideration of domestication must also consider opportunities with the associated or introduced microflora. As this section concludes, our definition of the whole organism has been greatly extended. In addition, we have seen how trees, perhaps because of their size and longevity, may have temporally and spatially a vastly more diverse and complex relationship with other organisms.

Key Structural–Functional Relationships

A number of important structural–functional relationships might be presented (e.g., carbon allocation, crown and root architecture, and hydraulic architecture). It is important to note that these can be treated as separate topics; however, they must be ultimately integrated when considering the whole organism. Although all three of these have been extensively covered elsewhere (*see* **Tree Physiology**: Canopy Processes; Nutritional Physiology of Trees; Shoot Growth and Canopy Development), I have chosen plant hydraulic architecture both because of personal interest, but also because it provides clear evidence of structural–functional integration that spans from fractions of a minute to the lifetime of the tree and because it is a subject that supports and links well with subsequent sections.

Plant Hydraulic Architecture

Hydraulic architecture has been for the last 25 years and is still a dominant theme in plant and tree water relations. In a recent comparison of leaf-specific hydraulic conductance to transpiration or whole-plant hydraulic conductance to plant leaf area over vastly different life-forms, strong support was found for function–structure integration. Further, it was suggested that there is considerable flexibility in these relationships depending upon the availability of resources. In a very careful analysis of the water conducting system in *Laurus azorica* trees, it was found that there was a strong relationship between petiole hydraulic conductivity and whole tree or stand transpiration; however, it was noted that stem hydraulic capacity exceeded actual water movement by almost a factor of 45. This could perhaps be a safety feature where the stem can transport all the water needed using only a small fraction of its vessels – the remaining vessels may serve in a capacitance role. Somewhat similar results were found when the hydraulic conductances of fine and coarse roots of *Prunus* were compared: coarse root capacity was not the limiting factor.

Hydraulic redistribution of water within the root system is now well documented. Perhaps even more noteworthy have been the recent observations on giant, coastal *Sequoia sempervirens* trees. Unlike work published on large, old-growth *P. menziesii* that demonstrated a considerable lag between xylem water movement at 50 m vs. 2 m, the new observations indicate no lags and even reverse flow where the source of water is either from dew on the foliage or from pools of water in large branch crotches. The presence of roots in these pools means that the hydraulic gradient to the foliage should be thought of in terms of meters vs. tens of meters. Clear, general structural–functional relationships with regard to tree hydraulic properties may exist, but considerable variability appears also to occur. Although the quantitative nature of science tends to focus on means and patterns, variation and outliers may be equally important to understand and document.

Integration also implies that the water system within a tree forms an integrated network; however, a number of investigations of insect activity and herbivory within the crown of trees suggest otherwise. In addition to clear within-plant heterogeneity in growth, morphology, and chemistry, due to differences in tissue age, light availability, or previous damage by herbivores, some of these studies indicated that heterogeneity originated in the soil environment (experimentally demonstrated via split-root studies) and can be modulated or accentuated by the pattern of water transport (e.g., sectoral vs. nonsectoral). Hydraulic architecture provides a wonderful framework to understand tree function and structure; however, large gaps in our understanding of how the entire system might be integrated (e.g., reconciling the segmentation theory to the limiting role that root xylem hydraulic conductivity plays or cavitation as an early warning system vs. a source of water or refilling as a diurnal vs. seasonal process) still exist.

Signaling

Because of the massive size of trees and the lack of a central nervous system, long-distance communication would seem to be both critical and mechanistically interesting. For example, sudden damage to the root system or rapid changes in soil oxygen, temperature, or moisture could have a profound effect on water supply. Because water loss is only regulated at the stomatal-leaf level, until stomata were to close, a 5-m or 65-m tree would continue to lose water and would soon reach critical leaf and xylem water potentials. During a typical day, leaf water potentials decline to near critical, but rarely less than critical levels. That is, a tree functions near the point of catastrophic xylem failure (i.e., runaway cavitation). Critical leaf water potentials have long been known to cause stomatal closure; however, this might be a case of 'too little – too late.' Without adequate short- and long-distance 'communication,' xylem water potential could easily exceed this critical point.

For a long time, plant growth substances (or regulators or hormones) have been recognized as important controls over plant growth and function, including stomatal control. The timing of the onset and cessation of growth and dormancy, for example, appears to be under a number of different controls. Changes from juvenile to mature, the onset of reproductive activity, and reproductive activity itself are under strong control. Plant form, as manifested by apical dominance and apical control, is controlled by plant growth substances. Watching the initiation and spread of vegetative growth in the crown of a tree would certainly suggest that various chemicals, transported in the xylem or phloem, could be largely responsible. Herbaceous plants, tree seedlings, and tree saplings have all been shown to transport various substances (e.g., K^+, Ca^{++}, abscisic acid (ABA), and zeatin riboside (i.e., a cytokinin)) from the root to the shoot in response to changes in the rhizosphere. Flooding, root damage, and cessation of root growth due to temperature or compaction have all been shown to elicit a group of growth inhibitors (e.g., increases in ABA) and suppress growth promoters (e.g., cytokinins) – these then result in stomatal closure and cessation of leaf growth. The response of trees to wounding suggests that wound-induced (win) mRNAs are transmitted in the same manner and direction as currently produced photosynthates (e.g., acropetally in leaves and branches near the apex of the tree, both acropetally and basipetally in leaves and branches found in mid positions, and largely basipetally in lower leaves or branches). Clearly, biochemical messages or signals can be moved in both the phloem and xylem; however, their movement, except in ring-porous species, will be relatively slow (less than 8 m and $1\,\mathrm{m\,h^{-1}}$ for diffuse-porous and gymnosperms, respectively).

Present opinion is that long-distance transport of a biochemical message would be too slow to provide timely stomatal closure in *Pinus sylvestris*. There is limited (controversial and shaky) evidence that small changes in water potential, due to a few cavitation events, may be propagated close to the speed of sound within the microfibrils of the cell wall – this biophysical message then results in the release of Ca^{++} or ABA at the stomata. Even studies of herbaceous plants such as *Ricinus communis* have suggested that initial changes in stomatal conductance were not due to ABA transport from the roots to the foliage, but due to changes in root hydraulic conductivity. Unfortunately for large trees, the transmission of gradual changes in root hydraulic conductivity is likely not fast enough to cause stomatal closure and avoidance of runaway cavitation. Evidence, albeit again controversial, has been provided for very rapid responses in large (35 m plus) *Nothofagus* trees in New Zealand. Therefore, there is limited evidence for a mechanism for rapid signaling within a large tree; however, as attractive as this might be, there is still too little evidence.

Over relatively short distances (i.e., within a cell, between cells, and even within a tissue), there has been a recent explosion in information on signaling. Whether one is reviewing an organ or a whole organism level study of plant growth substances and their role, one is impressed with the difficulty of elucidating mechanism and particular an integrated, *in situ* view of biophysical and biochemical mechanisms responsible for signaling. What is needed is an understanding of rapid, long-distance signaling in very large trees.

Scaling

The ecological and physiological literature is filled with studies from 0.1-ha plots or from chloroplasts or leaves and then extrapolated and discussed at much larger scales. The process of scaling has been discussed, reviewed and used extensively. Because of this article's focus on the organism and the comments under the section on the definition of the organism, it is worth reviewing an important point and presenting some current aspects of scaling that might be useful to take from this article. For me, what continues to be an important lesson of scaling is the following observation. One should always be concerned with three scales in any study. The scale below that of the study provides an understanding of mechanism and the scale above that of the study provides the context – for our present purpose, the parts of the tree are critical for mechanism and the stand (or population), community, and ecosystem are critical for context.

Scaling in physiological ecology appears to focus on a number of specific issues. First, can one scale one's readings at, for example, the leaf level to the whole tree. Second, scaling from a seedling to a tree involves understanding how morphology and process change with stage of development. Finally, for large, complex organisms, is it possible to use an intermediate scale (i.e., between the leaf and the tree) for study and, therefore, scaling? The branch has become a favorite example of this latter issue. Recent research has highlighted ways in which branch autonomy may fail and, therefore, the reliance on branches as an intermediate step in scaling may also fail.

Of the diversity of different invasive and noninvasive techniques that have emerged over the last two decades, perhaps the use of stable isotopes has proven the most useful for whole plant studies of (1) carbon allocation and movement within an individual, from parent to offspring via seed, between individuals, and within ecosystem(s), and (2) water movement. Techniques to measure water flow, especially those that can be used to develop depth profiles and can detect both zero flow and flow in either direction, have also been invaluable in an understanding of the parts and the whole.

Domestication

Around 10 000 years ago, people living in the Fertile Crescent (in what is now the Middle East) began to rely increasingly on domesticated grains such as rye. Domesticated corn appeared about 9000 years ago in Mexico and rice in China around 8000 years ago. These events had a profound influence on humans. As an increasing number of crops (and animals) became domesticated, there was a transformation from hunting and gathering to agricultural cultivation and associated settlements. In terms of social evolution, this was extraordinary. Today, we recognize the absolute dependence of most human societies (and all developed societies) on domesticated crops and animals. For plants, we also understand the genetic changes linked to domestication. There appear to have been three features associated with the domestication of most crop plants: (1) there was a radical transformation of the wild plant in terms of structure and function (often the domesticated plant shows little or no resemblance to the original progenitor), (2) this transformation typically involved a few key mutations and these had huge effects, and (3) the initial transformations occurred very soon in the process, that is, they were rapid. It is important to note that the first mutation(s) associated with domestication were likely very rare and were probably noted because of either intensive observation (via gathering) or early cultivation. Since these first large steps, refinements using conventional breeding methods have come much more slowly, have represented much more subtle changes in structure and function, and have involved a greater number of genes.

Over this same period of time, why were trees not domesticated? A number of reasons may exist for this and they include: the relatively long generation cycle in trees, the lack of edible products from most trees, the high inherent genetic and phenotypic variability within populations and between populations of trees, and the difficulty of both observing and capturing useful mutations. Clearly some selection and partial domestication has occurred (e.g., *Olea europea* and *Pinus caribaea*); however, in comparison to say the domestication of corn, trees are still analogous to the original teosinte.

Having this background and now having the platform provided by molecular biology and genetics, it should be possible to domesticate trees. What specific attributes might one seek? The following is a potential list:

1. A high rate of biomass accumulation.
2. Strong apical control (i.e., a single axis).
3. A narrow, confined crown with minimal branching.
4. Maximum light interception by the foliage and high quantum use efficiencies.
5. Apical meristems, buds, or shoots insensitive to the presence of neighboring trees (i.e., competition insensitive).
6. Reduced height growth after some initial, rapid minimal gain in height (i.e., a platform on which biomass is added).
7. Greater carbon allocation to the stem.
8. No reproductive activity (unless elicited).
9. Low cell lignin content.
10. No 'juvenile' stemwood (assumes the stem is the site of biomass accumulation).
11. More efficient resource acquisition especially by roots and associated microflora.

Many of these, as happened with crop domestication, represent dramatic changes in the structure of a tree and how that structure functions. Our ability to visualize this 'new' tree is extraordinarily difficult as we are so used to incremental changes. Modeling, including the use of 'virtual plants,' offers one approach. However, there are large segments of society who, for one reason or another, will find such a transformation of a tree unacceptable. Relying on either conventional silviculture or further increases in a CO_2 fertilizing effect to meet future fiber and fuel needs may not be realistic. Given continued population growth, increased consumption, the relatively low carbon costs of using wood and wood products (vs. other products for construction, for heating, for chemicals), it would seem unwise not to explore this opportunity. Had the same constraints been placed on the original progenitors for our current agricultural crops, I would not be writing and you would not be reading.

Summary and Conclusions

Understanding how the whole organism functions, and that it is not merely the sum of its parts, that it can be represented as an 'extended phenotype,' and that an untapped potential for change in its phenotype exists are the key messages developed within this article. It is also clear that there are very large unknowns: what are the controls on age- and size-related declines in productivity, how is 'information' transmitted through an organism, and how is transport in the phloem and the xylem controlled and integrated? Finally, what changes in structure and function would accompany domestication and how does our current understanding of whole tree physiology aid or impede domestication?

Xylem Physiology

J R Barnett, University of Reading, Reading, UK

Introduction

Secondary xylem, or wood, is a product of the activity of a secondary meristem, the vascular cambium. Those plants which possess one can be very long-lived, their life span being only limited by catastrophic events such as gales and lightning strikes or disease. More wood is added each season, with the result that it is the most abundant natural product on earth. The cambium and xylem differentiation have been the subjects of a number of monographs and it is not the purpose of this chapter to précis these works. Rather, some important aspects of the way the structure of wood is related to its behavior and properties postdifferentiation will be considered. Only a brief overview can be presented here and the reader is recommended to the list of further reading for more comprehensive reviews.

The structure of wood differs between tree species as a result of local evolutionary pressures and each has its own wood properties. This was exploited intuitively early in human history and is one of the factors that make wood such a variable and useful raw material. The long life span and generation times of trees meant that many also developed the ability to survive the significant changes in environmental conditions which occur from time to time. This is evidenced by the fact that arboreta, botanic and private gardens, city parks, and streets are furnished with tree species which evolved in regions whose climate and range of day lengths were markedly different from those in which they are now growing successfully. Sometimes the trees are more successful in terms of growth in an alien environment than in their native home. *Pinus radiata*, a native of the Monterey peninsula, where it is slow-growing and of poor form (from a forester's viewpoint), has become the linchpin of the New Zealand forest industry, where it is fast-growing and of good form (*see* **Tree Breeding, Practices**: *Pinus radiata* Genetics).

The evolutionary process has thus resulted in selection of trees which may be considered overdesigned for survival in their environment as it is today. A 500-year-old oak tree growing in the UK will have experienced the mini ice ages of the seventeenth and nineteenth centuries, and periods of global warming in between. It is often only when trees are growing at the limits of their geographical range where environmental conditions are limiting that the value of some morphological and anatomical adaptations can be understood.

The Biological Functions of Wood

Wood has two major functions: firstly, to support the crown of the tree, enabling the leaves to compete for light, and secondly, to provide a conduit for water and nutrients between the roots and the crown. It also incidentally supports the phloem which comprises the inner bark and conducts nutrients from the leaves to other parts of the tree. As the crown moves higher and enlarges, the stem must thicken to support the extra mass. Eventually the wood at the base of the stem may support hundreds of tonnes. The wood must also be able to maintain the tree stem in a vertical posture, and the branches at appropriate angles, while being able to absorb any physical stresses imposed by the environment without breaking.

Wood also has to conduct water efficiently and safely in conditions which may vary from extreme drought to flooding or freezing. In some cases, different species have adopted different anatomical strategies to cope with similar environmental conditions. Scots pine and silver birch live side by side in the boreal forests of Scandinavia and northern Europe, yet their wood anatomies are quite different. However, their strategies for coping with winter drought and freezing conditions are equally successful.

If wood were simply dead material it would be unable to deal with many of the stresses encountered by the tree during its life. In fact, the wood of young trees and the outer or sapwood of older trees may contain as much as 50% of living parenchyma cells. These cells have been regarded as being mainly for storage and, in the case of rays, for radial transport of water and raw materials. As will be described below, however, they are also involved in defense and in controlling water movement. Wood is thus far more active in its own interests than appears at first sight.

The Cellular Structure of Wood

The anatomy of wood has been amply documented in the literature. It is made up of two cellular systems, the axial system, responsible for structural support and vertical water movement, and the ray system, which provides a pathway for radial movement of water, nutrients, and other materials. A few woody species, for example, members of the genus *Hebe*, lack rays, but this is comparatively unusual. The wood anatomy of coniferous trees (gymnosperms) is fundamentally different from that of broadleaved trees (angiosperms) in that the axial system comprises a single cell type, the tracheid, which is responsible for both support and water conduction (**Figures 1** and **2**). Angiosperms have evolved a system in which the water-conducting elements are aligned to form tubes (vessels). These are interspersed among other cell types, predominantly fibers and parenchyma cells (**Figures 3** and **4**). There are a few exceptions to this in primitive families such as the Winteraceae, Pseudowinteraceae, and Trochodendraceae, which have an anatomical structure superficially similar to that of gymnosperms.

Vessel Distribution and Function

The wood of angiosperms is commonly classified into two types based on the distribution of vessels. In the diffuse-porous type, vessels have a more or less uniform diameter across an annual ring and are dispersed more or less evenly throughout the wood (**Figure 3**). In the ring-porous type, large-diameter

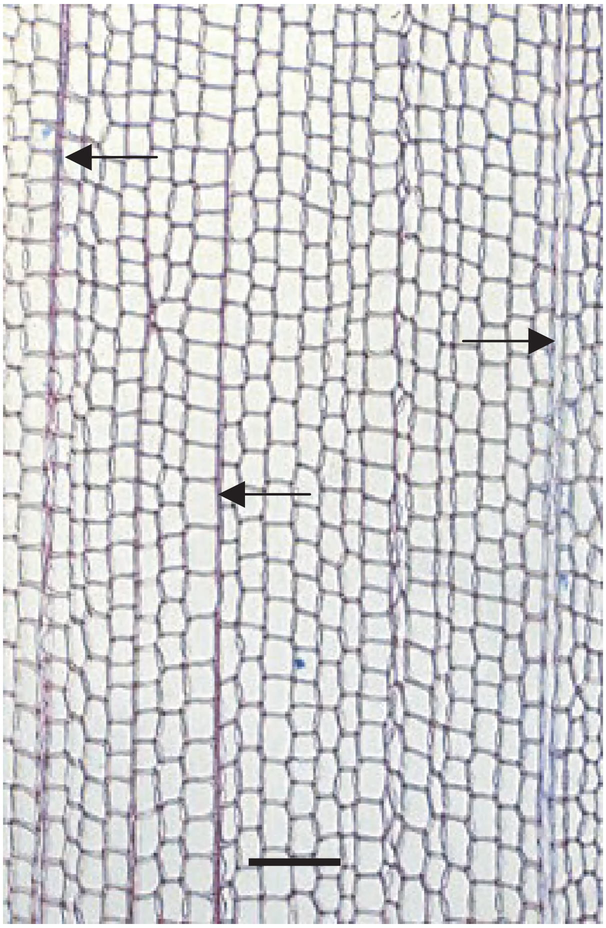

Figure 1 Transverse section through earlywood of *Pinus sylvestris*. The axial elements are all of one type (tracheids), giving the wood a homogeneous appearance. Rays are visible running at right angles to the long axis of the tracheids (arrows). Scale bar = 100 μm.

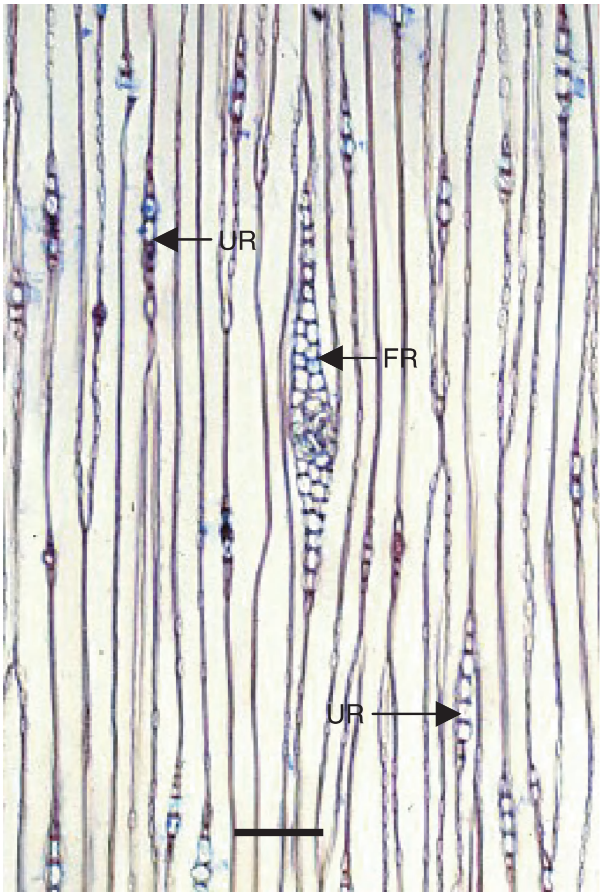

Figure 2 Tangential longitudinal section through earlywood of *Pinus sylvestris*. The tracheids are longer than the section, although a few ends may be seen. The cut ends of uniseriate rays (UR) and a large fusiform ray (FR) can also be seen. Scale bar = 100 μm.

vessels, often visible to the naked eye, are formed in spring at the beginning of the growing season while smaller vessels are formed during the main period of growth (**Figures 5** and **6**).

Hydraulic Conductivity and Safety

The size and arrangement of vessel elements have evolved to optimize hydraulic conductivity. Ring-porous species conduct water in sufficient quantities to supply the needs of the crown through their outermost growth ring. They are able to do this because the diameter of their springwood vessels is large. Since the conductivity of a tube is proportional to the fourth power of its radius (Poiseuille's law), a ring-porous species such as *Quercus robur* in which earlywood vessels typically have a diameter of 400–500 μm is theoretically 625 times more efficient than a vessel in a diffuse-porous species like *Liquidambar styraciflua*, in which vessel diameter is 80–100 μm, and 10 000 times more efficient than a tracheid in a conifer with a diameter of 40–50 μm. Diffuse-porous species and gymnosperms therefore require far more actively conducting elements than ring-porous species and conduct water through several of their outer growth rings. The situation is more complex than this, however. While oak vessels can be considered as relatively unobstructed pipes whose simple perforation plates hardly obtrude into the lumen of the vessel, they have finite length and closed ends. This means that water has to move to adjoining and overlapping vessels through the membranes of the numerous pits between them. Conductivity may also be restricted in some species by the presence of scalariform, reticulate or foraminate perforation plates between the cells which make up the vessels. Measurements have shown that in vessels of *Betula pubescens* axial conductivity is about a third of that in an unobstructed capillary.

In gaining an advantage in terms of efficiency, ring-porous trees have compromised their hydraulic

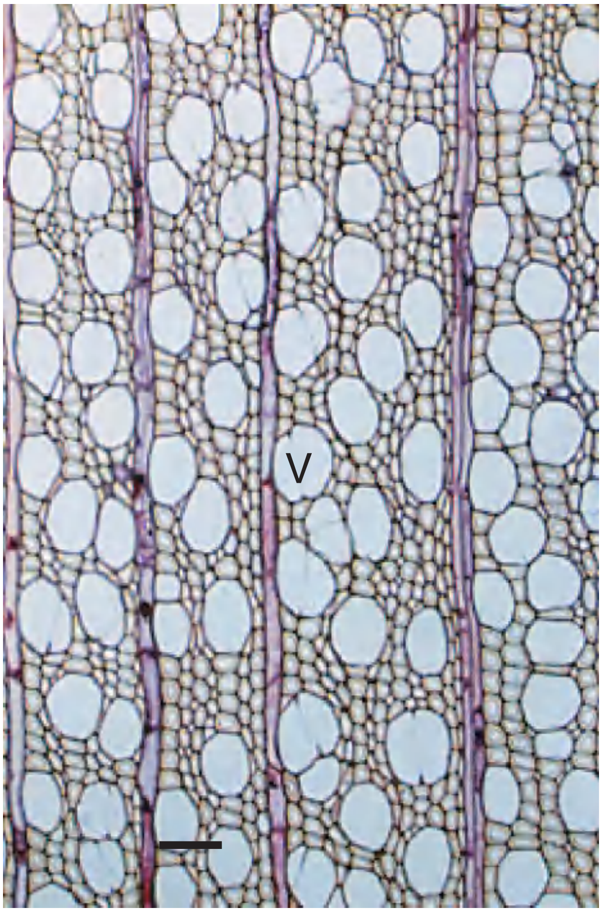

Figure 3 Transverse section through wood of *Liquidambar styraciflua*. Water-conducting vessels (V) are interspersed among smaller-diameter fibres and parenchyma. Scale bar = 100 μm.

Figure 4 Tangential longitudinal section through wood of *Liquidambar styraciflua*. The cut ends of rays are seen interspersed among the fibers and vessels (arrows). The vessels (V) contain some tyloses (T). Scale bar = 100 μm.

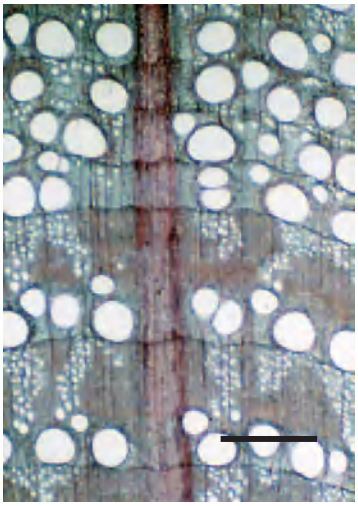

Figure 5 Low magnification of a transverse section through wood of *Quercus robur*. The ring-porous nature of the wood is clearly seen in the two growth rings at the bottom of the figure. At the top, the ring width in four successive years has been reduced by adverse growing conditions. Although the large springwood vessels have been produced in each year, the summer wood is much reduced. Scale bar = 1 mm.

safety. Damage to a single vessel is much more serious than damage to a single vessel in a diffuse-porous species. This was clearly demonstrated in the case of Dutch elm disease, in which the tree responded to a toxin secreted by the fungal pathogen *Ceratocystis ulmi* by forming tyloses in its vessels, blocking them and starving the crown of water.

In diffuse-porous species, the diameter of vessels increases markedly from juvenile to mature wood and from the top of the tree towards the base in any growth ring. As vessel diameter increases, their number per unit area of cross-section decreases (**Figure** 7). An explanation for this lies in the fact that, as the tree grows, there is a need for a larger proportion of fibers for support. To accommodate this while maintaining water flow to the larger crown, the tree produces fewer vessels of larger diameter.

Calculations using Poiseuille's relationship and compensating for the reduced area occupied by vessel elements suggest that the wood in outer growth rings in *Betula* has a conductivity three to

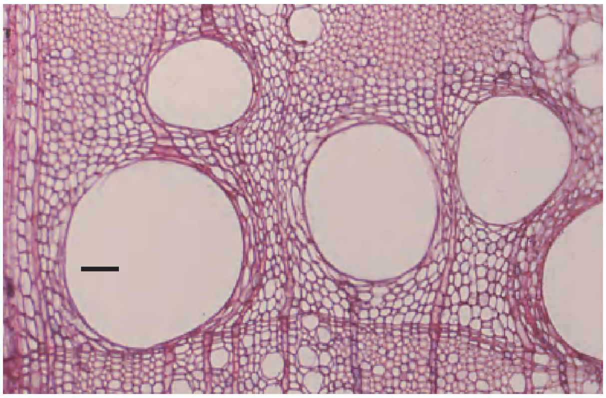

Figure 6 Greater magnification of springwood in *Quercus robur* showing the large diameter of earlywood vessels. Small-diameter latewood vessels are visible at the end of the previous year's growth (bottom of the micrograph) and at the beginning of the summerwood (top of the micrograph). Scale bar = 100 μm.

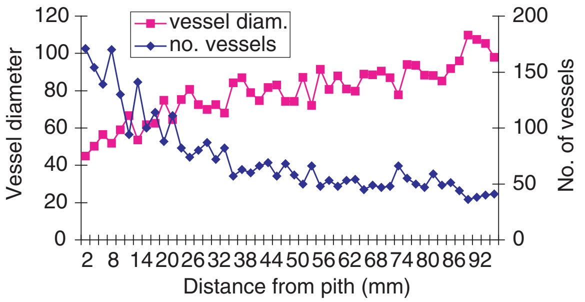

Figure 7 Number of vessels per mm^2 and vessel diameter in *Betula pendula* plotted against distance from the pith. There is a clear inverse relationship between vessel number and diameter.

five times greater than that in the innermost growth rings. The real difference is probably less than this owing to the restrictions on movement imposed by scalariform perforation plates and pit membranes, although the effect of this would be the same for all vessels, regardless of diameter.

Freezing

Trees in boreal regions must be adapted to cope with low winter temperatures which may freeze the water in their conducting elements. During freezing, air comes out of solution and forms small bubbles which in vessels or tracheids of trees will necessarily be small, and provided the water thaws before the sapstream goes into tension in spring, will be redissolved. If allowed to coalesce with other bubbles before redissolving, however, there is a possibility that embolisms could form. Scalariform perforation plates in the vessels of boreal angiosperms preclude this by preventing movement of small bubbles between vessel elements, while bordered pits do the same for conifer tracheids.

It has been suggested that, since conifers show almost no loss in xylem conductivity following freezing, the vesselless condition of the Winteraceae may in fact represent an evolution from a form possessing vessels. The loss of vessels and the return to a system of tracheids for water conduction enabled the retention of leaves and photosynthesis under freezing conditions.

Xylem Parenchyma

Students are often taught that wood is a dead structure resulting from terminal differentiation of cambial derivatives. As far as the sapwood is concerned, nothing could be further from the truth. In some species 50% or more may comprise living parenchyma. As parenchyma contributes little to the physical strength of wood, and is to some extent undesirable as fines in pulp, its functions in the wood have not been thoroughly investigated. It is, however, certain that it provides storage for materials such as starch and proteins, and secondary compounds such as tannins. It is also certain that it forms the pathway for transport of raw materials from the phloem to the cambium, its differentiating derivatives and developing heartwood. In the latter case they may also be involved in synthesis of the secondary compounds deposited in heartwood.

In addition to the axial parenchyma cells, the ray system is made up entirely of parenchyma cells in all but a few members of the Pinaceae, which also have ray tracheids. Individual parenchyma cells do not exist in isolation but all are interconnected by plasmodesmata, their protoplasts thus forming part of a great symplasm running throughout the living tissues of the tree. Recent work has shown that a system of microtubules and microfilaments, which is continuous with the system present in the axial parenchyma cells of the xylem and parenchyma cells and companion cells of the phloem, runs through the ray system via the plasmodesmata. In view of the known transport functions of these cytoskeletal components it is likely that they provide the system for moving materials around the developing and mature secondary tissues in the stem.

Parenchyma cells actively assist water movement, particularly when transpiration is not possible. Deciduous trees need to build up internal turgor to swell their buds and developing leaves in the spring. They do this by breaking down starch in their parenchyma cells and transferring the sugars to the lumens of adjacent vessels. This creates an osmotic potential, increasing internal pressure and providing turgor for growth. Humans have exploited this phenomenon in the collection of maple syrup and birch sap, both of which are collected in late winter before budbreak. It is a common misconception that the sugary solution is produced by the phloem, when in fact it is the wood which is tapped to obtain the liquid. Trees in cloud forest, where relative humidity may approach 100%, appear to use the same technique to move water when significant transpiration is not occurring, switching back to transpiration for this purpose and restoring starch levels when the relative humidity falls.

In addition to these functions, the parenchyma system plays a key part in protecting the tree from pathogen attack. Its role can range from blocking damaged vessels by producing tyloses to repairing small cavities caused by the activity of insect pathogens such as cambium miners or by removing bark by accidental damage or herbivore activity. It is also involved in creating barrier zones to resist the spread of decay fungi through the wood.

Tyloses

Tyloses form in some ring and diffuse porous species when embolisms arise in vessels either during drought or in response to wounding (**Figure 8a–d**). In normally conducting sapwood, the tendency for net water movement from vessels through pit membranes into adjoining living parenchyma cells by osmosis is countered by the tension in the sapstream. When the sapstream is broken, this balance is destroyed and there is a net osmotic flow of water into the parenchyma cells. The resulting pressure increase causes the pit membranes to swell into the vessel lumen (**Figure 8a**). To prevent rupture of the membrane, the protoplast actively consolidates the membrane and may even move into the tylosis thus formed. An individual tylosis takes on the appearance of a balloon blown into the vessel lumen (**Figure 8c**). More usually, however, numerous tyloses arise simultaneously from all or most of the vessel/parenchyma pit membranes in the vicinity (**Figure 8b**), resulting in a network of cell wall material which may become lignified, blocking the vessel (**Figure 8d**). The blocking of vessels in this way, while locally useful in preventing water loss and pathogen entry, may have fatal consequences for the tree, as in the case of Dutch elm disease.

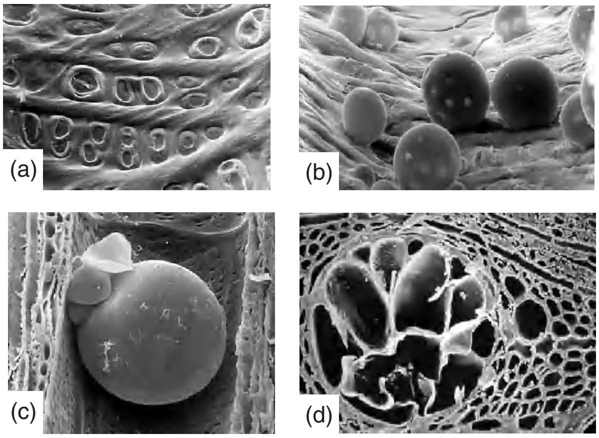

Figure 8 Stages in the formation of tyloses in *Quercus robur*. (a) Pit membranes beginning to bulge into the vessel lumen ($\times$350). (b) Young tyloses ($\times$250). (c) Older tyloses almost filling the cell lumen ($\times$80). (d) Multiple tyloses completely blocking the vessel ($\times$80).

Tylosis-like structures have been described as forming in *Fraxinus*, although these structures are not true tyloses. They are in fact formed by extrusion of material into the vessel lumen through the pit membrane from adjacent parenchyma cells. The membrane itself does not grow and bulge into the lumen as in the case of tyloses.

Callus Formation

It is only by having living parenchyma cells that the sapwood can respond to damage caused by phenomena such as branches breaking and removal of bark by herbivores. On release of the constraining pressures by which they are normally surrounded, parenchyma cells dedifferentiate to form callus which eventually differentiates, forming new periderm or meristematic tissues. The role of parenchyma in repairing the damage caused by mining insects is illustrated by the case of *Phytobia betulae* which lays its eggs below the bark on young shoots of *Betula pendula*. The larva tunnels downwards through the layer of cambium and young, differentiating xylem cells. The tunnels are repaired and blocked by the production of callus from xylem ray parenchyma and eventually the cambium itself is restored in the wounded region.

Defense Against Fungal Pathogens

In the case of fungal penetration into the xylem by wood-rotting fungi, the response to infection is the production of a discolored zone of sapwood known as a barrier zone in an attempt to restrict further penetration of the pathogen. Microscopy has shown that vessels in the sapwood in the discolored areas are blocked either by tyloses or by vessel plugs made up of fibrillar material and so-called accessory compounds. In *B. pendula*, the protective layer disintegrates following wounding and it is possible that it is incorporated into the fibrillar deposits extruded into the vessel lumen. These changes, however, are not a specific response to fungal invasion; they can also be induced by simple wounding and are a normal response in branch and stem tissue close to pruning wounds.

Some tree species defend themselves by exuding resins or gums, produced by and stored in parenchyma cells associated with resin canals or gum ducts. Wounding stimulates activity of parenchymatous cells which form the epithelium of these canals and ducts and large quantities of resin or gums are moved to the wounded surface. This prevents or inhibits the penetration of pathogens into the wood through the wound.

The Role of Fibers and Tracheids

The fibers of angiosperm wood and the tracheids of gymnosperm wood are the load-bearing cells in the tree, and are thus the main determinants of the properties of timber in use. In angiosperms the morphology of fibers shows a gradation from cells which are superficially similar to the tracheids of conifers (and which are consequently referred to as tracheids), to libriform fibers, which are shorter and have very little pitting. Intermediate cell types are usually referred to as fiber tracheids. Although these cells are normally dead, the conditions being experienced by the tree when they are formed affect the way the cell wall is laid down, adapting them to their role in helping the tree to survive.

Remarkably, but perhaps unsurprisingly, the structure of the secondary cell wall (apart from some variation in pit size and form) is similar in all of these cell types. The cellulose of secondary walls is laid down as lamellae of parallel cellulose microfibrils. In fibers and tracheids these are clearly arranged into three layers known as the S_1, S_2, and S_3 layers, with the suffixed numbers referring to the sequence in which the layers are laid down, the S_1 being the first-formed and therefore outermost layer, the S_3 being the last-formed and innermost layer. The S_1 and S_3 layers have microfibrils arranged at a large angle to the cell axis, while the S_2 microfibrils are arranged at a smaller angle. This structure explains the ability of the cell to withstand, without collapsing, vertical and lateral compressive forces, and in the case of tracheids which are conducting water, the internal tension, to which it is subjected. The angle of microfibrils in the S_2 layer is responsible for many of the physical properties of fibers and tracheids. In the center of a tree where the wood was formed when the cambium was young (juvenile or corewood), the microfibril angle is large (45° or more is not uncommon in conifers). In later-formed wood (mature or outerwood), the microfibril angle is small, typically less than 10°.

A large microfibril angle confers flexibility on the young stem, enabling it to withstand high winds without breaking, while the small microfibril angle in mature wood confers the stiffness needed by an older tree to support large weights. This has survival advantages for the living tree but creates problems in utilization, where juvenile wood is insufficiently stiff to be used for high-value purposes such as construction. This was of little consequence when old trees were harvested and the majority of the wood in the tree was mature. As demand for timber products and pulp has increased, so has pressure for short-rotation cropping of fast-growing trees. Harvesting trees at 35 years of age, for example, means that 50% or more of the tree may comprise juvenile wood and be of low commercial value. This has led to an upsurge of interest in microfibril angle and whether it can be reduced in juvenile wood. The consequences of reducing the juvenile wood microfibril angle for the living tree, where it may make it susceptible to breaking in the wind, will have to be borne in mind by breeders and molecular biologists in deciding how far it is possible to go along this route.

Most interest in microfibril angle has centered on coniferous trees. Measurements on silver birch, however, have suggested that in this species the large microfibril angles associated with corewood in pines are not present. In fact, the angle rarely exceeds 20° in any part of the trunk. Those results that have been reported for hardwood species such as eucalypts and *Liriodendron tulipifera* suggest that microfibril angle in hardwood fibers is lower than that in conifer tracheids. It may be that the presence of vessels interspersed among fibers in a hardwood confers flexibility on the young stem that has to be countered by a smaller microfibril angle in the fibers.

In addition to cellulose, lignin has a major role in increasing the compressive strength of fibers and tracheids, typically comprising some 20% of the walls of fibers in angiosperms and 35% of the walls of tracheids in gymnosperms. It is laid down between the cellulose microfibrils to which it is bound by hemicelluloses. Without the evolution of lignification, trees could not have evolved as tall, massive organisms. Lignin is, however, a major problem for the paper industry where its removal in order to separate fibers and enable production of bright, white paper is expensive. Disposal of the extracted lignin also poses major problems. Genetic modification has been explored as a way of solving these problems, although the essential role of lignin in the successful life of trees means that improvement will have to be limited to producing trees whose lignin is easier to remove, rather than trees without lignin.

Reaction Wood

Trees can modify the structure of the walls of tracheids and fibers during their differentiation to deal with imposed stress. In gymnosperms, the tracheids formed under a compressive load on the lower side of branches and leaning stems, or the leeward side of the tree with respect to the prevailing wind, have a larger than normal microfibril angle and extra lignification. In this case the wood is known as compression wood. In angiosperms, fibers formed under tension on the upper side of branches and leaning stems and the windward side of the tree develop a special wall layer, the gelatinous layer, which comprises almost pure cellulose with a very small microfibril angle. Wood containing these fibers is known as tension wood. Collectively these two types are known as reaction wood and they are essential to the tree to maintain an upright main stem, correct branch angles, and prevent branches drooping under their own weight. However, reaction wood is a serious problem for the timber and pulp industries and has been the subject of intensive research. As with microfibril angle, however, any attempts to modify reaction wood production must also consider the consequences of doing so for the tree.

Tropical Tree Seed Physiology

E M Flores and J A Vozzo, US Department of Agriculture Forest Service, Starkville, MS, USA

Introduction

Forest trees are a renewable natural resource. Understanding forest dynamics, trees, seeds, and seedlings as indisputable factors and basic units of regeneration has become important in developing effective techniques to promote conservation, management, and rational use of remaining forests. These are significant rudiments to implement successful reforestation programs.

The Angiosperm Seed

Seed Development

The fruit is the structure containing the seed. It develops from the gynoecium of the flower, which is frequently associated with other floral organs. The ovary wall forms the pericarp (fruit wall), and the fertilized ovule forms the seed. Fruit ripening is followed by senescence and, sometimes, dehiscence and abscission.

The process of seed development has three functional phases:

1. Cell divisions to produce the seedcoat, the endosperm, and the embryo (embryogenesis); this stage is characterized by an enhanced increase in fresh weight. Embryo development includes establishing a precise spatial organization of cells derived from the zygote (pattern of formation) and the generation of cell diversity inside the developing embryo (cytodifferentiation). These processes are coordinated to develop a recognizable morphological structure, regulated by the embryogenic pattern of the species (**Figure 1**).
2. Storage of reserves leading to an increase in dry weight.
3. Maturation drying leading to a stage of metabolic quiescence, interpolated between the end of seed development and the beginning of germination.

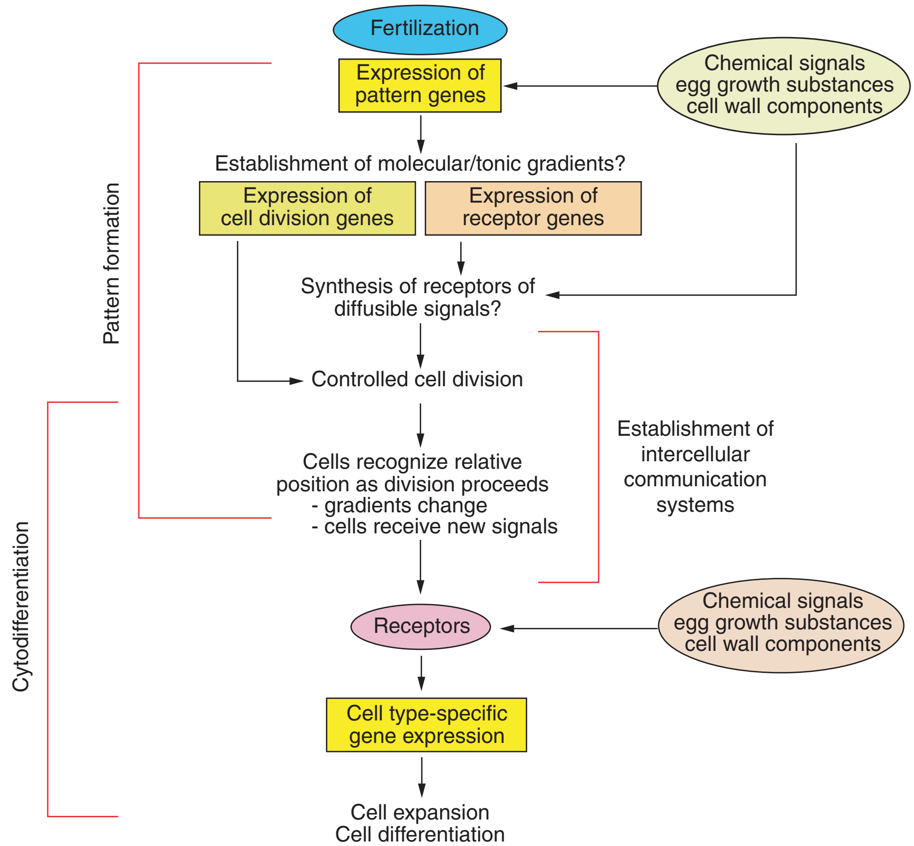

Figure 1 Gene expression during embryo development. Redrawn with permission from Lindsey K and Topping JF (1993) Embryogenesis: a question of pattern. *Journal of Experimental Botany* 44: 359–374.

> Seed inactivity is promoted by reduction of water content in the tissues, seedcoat impermeability, and inhibitors. Seed drying also reduces the synthesis of storage proteins.

Ovule, embryo, and endosperm development are coordinated and have contributions from both sporophytic and male and female gametophytic genes. Growth regulators present in the tissues of developing seeds (indol acetic acid, gibberellins, cytokinins, and abscisic acid) are active in seed development; accumulation of the storage reserves; development of the extra seminal tissues; and physiological changes of tissues and organs surrounding the developing fruit.

Many tropical and temperate seeds do not undergo drying, do not experience reduced cellular metabolism, and do not exhibit a clear end to seed development. During fruit dehiscence and dispersal, seed development is followed by germination-seed development without interruption. In some species, the seedling develops when the seed is still inside the fruit and is attached to the parent tree. These seeds are called viviparous (**Figure 2**). Mangroves growing on protected tropical coasts are the best-known examples of viviparous seeds. Overgrown seeds, which have a continuous embryo development limited by a hard and indehiscent pericarp or a late dehiscence pericarp (e.g., *Dipteryx*, *Prioria*) (**Figure 3**) may represent an intermediate type.

Figure 2 Viviparous seed of *Inga paterno*. Reproduced with permission from Vozzo JA (ed.) (2002) *Tropical Tree Seed Manual*. Agricultural Handbook no. 721. Washington, DC: US Department of Agriculture Forest Service.

Embryo development in seeds without maturation drying is similar in its early stages to that of seeds with maturation drying; however, variations

appear in late embryogenesis. Many seeds without maturation drying are large, with well-developed embryos (e.g., *Aesculus*, *Calophyllum*, *Dipterocarpus*, *Hevea*, *Quercus*, and *Sclerocarya*). Other seeds are large but have a small, rudimentary embryo (e.g., *Calatola*) (**Figure 4**). All these seeds increase in dry weight until fruit dehiscence, with insignificant loss in fresh weight. Embryo growth may continue (increasing in dry weight) after dehiscence in the absence of enough water to promote germination. However, in the tropical forest with very high rainfall the seeds or fruits (diaspores) fall down on very humid soils, sometimes inundated, and continue hydrating.

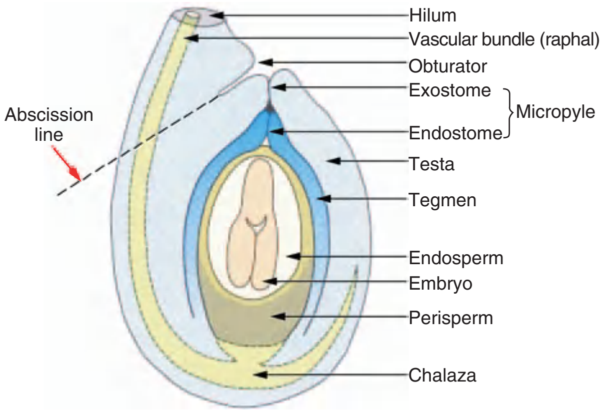

Figure 5 Diagram of typical mature seed. Reproduced with permission from Vozzo JA (ed.) (2002) *Tropical Tree Seed Manual*. Agricultural Handbook no. 721. Washington, DC: US Department of Agriculture Forest Service.

Some embryos have a suspensor. It seems to accomplish an active and dynamic role in nutrient absorption from the surrounding somatic tissues and transportation to the developing embryo as well as a source of nutrients and growth regulators for the developing embryo. The suspensor contains gibberellic acid, auxins, and cytokinins; the concentrations of these substances follow a fluctuation pattern.

The Mature Seed

The mature seed generally has a seed coat (product of one or both ovule integuments), an endosperm, and an embryo (**Figure 5**). Some mature seeds retain a remnant of nucellar tissue called a perisperm. The degree to which these structures continue their development, are reduced or reabsorbed, or disappear during the late stages of seed development leads to distinct structural patterns associated with physiological differences.

Storage of reserves Seeds store lipids, carbohydrates, and proteins to nourish the embryo (before and after germination) and to develop the early stages of seedling development. They are a source of precursors for carbon skeletons and provide energy when assembling precursors. Reserves may be stored in cell walls of different tissues, perisperm, endosperm, cotyledons, hypocotyl, and chalaza. The endosperm does not have a significant role at the proembryo stage, but it is important during embryo development and seed germination. The formation of the endosperm, its reabsorption, and the transference of reserves to the embryo are controlled genetically.

Lipids, which appear as lipidic bodies in the endosperm and the embryo, are a greater source of nourishment than the carbohydrates. The seeds without maturation drying are rich in lipids (e.g., *Virola koschnyi* ≥41%, *Calophyllum brasiliense*

38–39%). Carbohydrates are stored as starch or in thick cell walls rich in hemicelluloses.

Nearly all seeds contain proteins as reserve. They are found as aleurone grains and supply the nitrogen in early stages of plant development. In addition to the homogeneous protein matrix, aleurone grains contain crystals of proteins, minerals, and calcium oxalate. Several cations (K, Mg, Ca, Fe, Ba, Mn) are also found as globoid crystals. Seeds with maturation drying accumulate disaccharides, such as the saccharose and oligosaccharides, in the form of stachyose and raffinose. It has been suggested that these sugars are associated with tolerance to desiccation; however, some seeds sensitive to desiccation also accumulate sugars and saccharose (e.g., *Avicennia marina*) or saccharose and raffinose (e.g., *Quercus robur*).

Relationships between Seed Structure and Storage Behavior

Seeds losing water during maturation drying gradually acquire tolerance to desiccation; others maintain a high water content, do not reduce cellular metabolism, and are sensitive to desiccation and temperature decreases. The tolerance/intolerance to desiccation shown by these seeds in their natural environment is also seen in their storage.

Sensitivity to desiccation limits seed storage potential, genetic conservation, and use in trade. Two types of seeds based on sensitivity to desiccation are recognized: orthodox seeds (those that undergo maturation drying) and recalcitrant seeds (those that do not undergo maturation drying).

The ability to tolerate desiccation by orthodox seeds is associated with metabolic changes such as respiration decrease, increase of some carbohydrates or oligosaccharides, and accumulation of dehydrines (late embryogenesis abundant (LEA) proteins). During germination, seeds lose this tolerance several hours after radicle protrusion. Dehydration at this stage leads to irreversible damage, in which the peroxidation of lipids and free radicals has an important role. However, mature orthodox seeds can be dehydrated without damage to very low levels of moisture (1–5%) and in a variety of conditions. Bound water (structural) is less easily frozen than free water. Bound water seems to be a crucial component to tolerating desiccation, and in the orthodox seeds all water is bound. In storage, the longevity of seeds increases with a reduction of the water content in a predictable and quantifiable manner. These seeds may be subdivided into (1) true orthodox, which can be stored for long periods at seed moisture contents of 5–10% and subfreezing temperatures, and (2) suborthodox, which can be stored under the same conditions, but for shorter periods due to high lipid content or thin seed coats.

Recalcitrant seeds are rich in free water and neither tolerate nor survive desiccation. The dehydration of tissues provokes membrane deterioration (plasma membrane and mitochondria), protein denaturation, and reduction of both the respiratory rate and the adenosine triphosphate (ATP) level. The oxidative processes and the free radical seem to be involved in cellular and molecular deterioration. Seeds show a strong resistance to rehydration and the loss of cellular integrity leads to a loss of viability. Recalcitrant seeds are present in at least 70% of tropical trees. Their sensitivity to a low temperature is due to the high water content.

Because some seeds do not fit readily into either orthodox or recalcitrant categories, they have been clustered in a third category: the intermediate seeds. These seeds survive desiccation at intermediate moisture levels but not to the degree of orthodox seeds. This last category can be considered arbitrary, and the existence of a recalcitrance gradient throughout the different species has been suggested.

Variations in the sites of water storage and the gradual damage observed in the seed tissues when it dehydrates can be illustrated by the seeds of the following species: *Calophyllum brasiliense*, *Otoba novogranatensis*, *Minquartia guianensis*, *Caryocar costaricense*, and *Lecythis ampla* (**Figures 6–10**) (**Table 1**).

How does dehydration affect seeds? In *Calophyllum brasiliense* the hard seed coat resists desiccation; water loss is slow. Once the seed coat dehydrates, the water loss directly affects the embryo, with the exposed radicle being the most rapidly affected. The small plumule enclosed by thick cotyledons dehydrates last. *Otoba novogranatensis* and *Minquartia guianensis* have minute rudimentary embryos. The sequence of dehydration is seedcoat → peripheral endosperm and radicle → remaining embryo → inner endosperm.

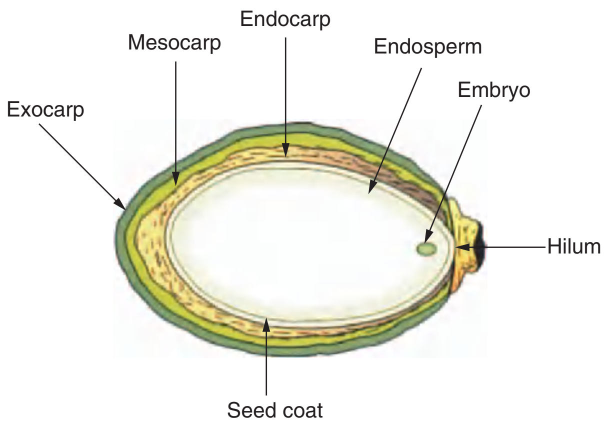

Figure 8 *Minquartia guianensis* drupe (longitudinal section). Reproduced with permission from Vozzo JA (ed.) (2002) *Tropical Tree Seed Manual*. Agricultural Handbook no. 721. Washington, DC: US Department of Agriculture Forest Service.

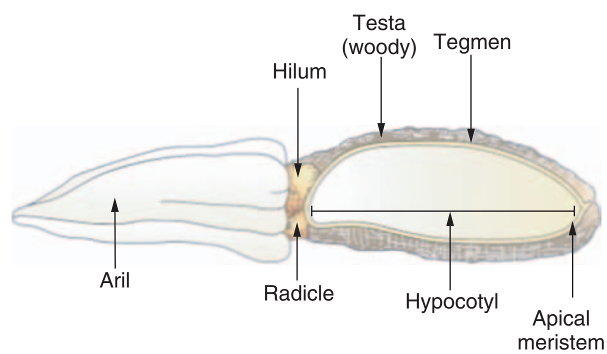

Figure 10 *Lecythis ampla* seed (longitudinal section).

Otoba novogranatensis is more sensitive to desiccation than *Minquartia guianensis,* due to endosperm rumination and tegmen vascularization. *Caryocar costaricense* has a curved, accumbent embryo and the plumule and radicle dehydrate immediately after endocarp dehydration. The dehydration of *Lecythis ampla* seeds first affects the seed coat and then the meristematic poles (radical and apical); they die instantly after seed coat dehydration.

The seeds enclosed in berries (*Calophyllum brasiliense*) or drupes (*Caryocar costaricense*, *M. guianensis*) are protected by the pericarp tissues, which help maintain seed moisture. In these cases, the functional unit is the fruit and dehydration is slower.

The moisture level below which a seed loses its viability varies from one seed to another. Variations are found among seeds collected from the same tree as well as from different trees, zones, seasons, or years. The recalcitrant behavior seems to be genetically determined and its genetic base is still not well understood. The variations found can be explained if the seed history from flower inception to seed dispersal and germination is analyzed carefully.

The difference found between temperate and tropical recalcitrant seeds must be added to the gradient found in recalcitrance manifestation. The first cannot be dried but can be stored for 3–5 years at near-freezing temperatures; the latter cannot be dried and will not survive temperatures below 10–15°C, depending on the species.

Data for tissue, cell, and biochemical alterations produced by dehydration in the recalcitrant seeds are limited, and no appropriate strategies and mechanisms to manage them under storage conditions have been found. The morphological diversity found in these seeds and the variations in the sequence and speed of seed dehydration further complicate the issue. The problem of cellular desiccation is complex; it seems to involve genetic components that lead to mechanisms of cellular protection. These mechanisms limit the cell damage produced by seed dehydration and promote cellular repair, reversing the changes induced by water loss. The accumulation of protecting substances in the tolerant tissues is

Table 1 Structural variation of recalcitrant seeds from five neotropical species during seed dispersal. Reproduced with permission from Vozzo JA (ed.) (2002) *Tropical Tree Seed Manual*. Agricultural Handbook no. 721. Washington, DC: US Department of Agriculture Forest Service

Structure	Calophyllum brasiliense	Otoba novogranatensis	Minquartia guianensis	Caryocar costaricense	Lecythis ampla
Fruit	Berry	Septicidal capsule	Drupe	Drupe	Pyxidium
Type of diaspores	Fruit	Seed	Fruit	Fruit	Seed
Endocarp surrounding the mature seed	Soft, thin, crushed	Absent	Drupe, hard endocarp	Drupe, hard endocarp	Absent
Seed coat	Hard	Hard	Soft	Papyraceous	Hard
Testa	Hard	Hard	Soft	Soft	Hard
Tegmen	Thin, soft	Thin, ruminate	Soft, fragmentary	Thin, soft	Remnants
Endosperm	Absent in the mature seed	Massive, nuclear–cellular	Massive, cellular	Absent in the mature seed	Absent in the mature seed
Embryo	Massive, complete	Minute, rudimentary	Minute, rudimentary	Massive, complete	Massive, undifferentiated
Cotyledons	Massive, fused	Differentiates and develops during germination	Differentiates and develops during germination	Small, scaly	Differentiates and develops during germination, small, scaly
Hypocotyl	Thick, massive	Differentiates and develops during germination	Differentiates and develops during germination	Thick, massive	Thick, massive
Epicotyl	Very small	Differentiates and develops during germination	Differentiates and develops during germination	Very small	Differentiates and develops during germination

Water storage	Whole embryo	Mainly endosperm	Mainly endosperm	Hypocotyl	Hypocotyl

quite possible. Disaccharides (saccharose) and oligosaccharides (raffinose and stachyose) may have an important role in the stabilization and maintenance of the membrane system and other sensitive systems.

The Gymnosperm Seed

Gymnosperm seeds are not enclosed within a gynoecium. They are exposed on scales or similar structures clustered in gynostrobiles (female strobiles). The zygote forms the embryo (2*n*), which remains immersed in the nutritious tissue (endosperm) of the megagametophyte (*n*). The integument gives rise to the seed coat (2*n*, part of the tissues of the maternal tree) (**Figure 11**).

The seed matures in two to three seasons. The content, behavior, and fluctuation of growth regulators are similar to those of the angiosperms. The lipid content in the seeds is high, although carbohydrates and proteins are also present.

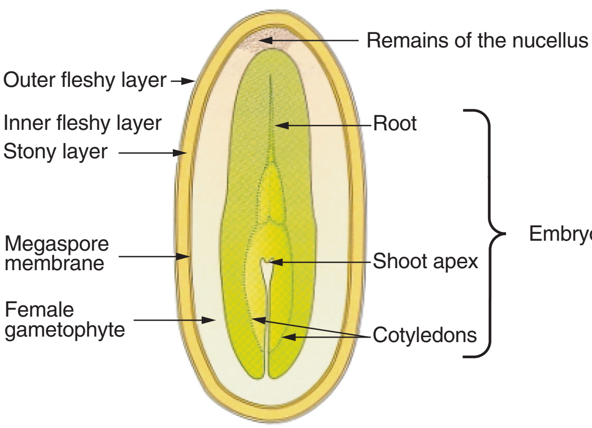

Figure 11 *Pinus* seed. From *Comparative Morphology of Vascular Plants*, 2edn. by Foster and Gifford © 1974, 1989 by WH Freeman and Company. Used with permission.

Fruit and Seed Dispersal

Seed dispersal is a critical stage in the life cycle of the species. It transports physiologically independent individuals to the habitat occupied by their parents or to new suitable territories, where the seeds may colonize if environmental conditions are favorable. The unit of dispersal (diaspore, propagule, or diseminule) is determined by the embryo, the seed, the fruit, or the fruit and associated parts of the modified perianth, the receptacle, or combinations.

Diaspores can be dispersed in space and time. Dispersal in space is the transport from one site to another, usually far from the parent tree. Dispersal in time is the quiescence or inactivity of diaspores for a variable period of time. Later, they can activate by environmental stimuli and resume the germination process.

The dispersal of diaspores can be biotic (zoochorous) or abiotic (azoochorous) and their morphology is related to the method of dispersal. In biotic dispersal the vectors are numerous: invertebrates (flies, dung insects, ants (myrmecochory), earthworms, and snails), herbivorous fish (ichthyochory), marine turtles, lizards and desert iguanas (saurochory), birds (ornithochory), and mammals including human beings (mammaliochory). Abiotic dispersal is by wind (anemochory), water (hydrochory) or the tree itself (autochory). The last is achieved by active ballistics (tension generated by the dehydration of hygroscopic tissues), passive ballistics (movements of the seeds enclosed in the fruit), creeping diaspores, and barochory (dispersal by weight).

Biotic dispersal could be epizoochorous if the transport of diaspores is passive, external, and occurs through diaspore adhesion to animal skin (hairs) or feathers. It is synzoochorous when animals, eating part of the seeds but not ingesting them, actively transport the diaspores, and it is endozoochorous if the diaspore containing the seed or the seed itself, is ingested and eventually regurgitated or defecated intact. Zoochorous dispersal requires nutritious tissues in the diaspore, chemical attractants, mimetism, or adhesive structures.

In tropical forests, most dispersal is achieved by vertebrates, which obtain food from the seeds and other edible parts of the fruit. Zoochorous dispersal ($\geq 80\%$) is dominant in the tropics. In primary forests, zoochory may increase to 87–90%. Most diaspores dispersed by water come from riparian species and are typical in marshes or mangrove vegetation, while those dispersed by wind grow at forest edges.

The specificity of disperser or dispersers is uncommon. Most fruits and seeds are used and dispersed by several or many vectors, which may include consumers, commensals, predators, commensals and dispersers, or predators and dispersers.

Germination

The process of germination involves the transition of cells from a dehydrating stage and low metabolic activity to a hydrated and metabolically active stage. Water is absorbed in a triphasic way: imbibition, germination *sensu stricto*, and embryo development. Imbibition is the rapid absorption of water leading to a regular increment in the respiratory activity. Germination *sensu stricto* is the process of embryo activation, not accompanied by any apparent morphological change. Embryo development is marked by radicle elongation and a significant change in the physiology of the embryo. This phase is crucial, because seedling development depends on it. In most cases, the seed germinates only if the respiration and production of ATP are adequate, creating an oxygen requirement.

Germination culminates with radicle protrusion into the adjacent tissues. In recalcitrant seeds with minute, rudimentary embryos or large embryos with a rudimentary radicle (reduced to a radical meristem), the development of the radicle implies cell division and elongation.

Environmental Influences

The external environmental factors regulating the activity of the maternal tree during seed maturation include temperature, light, photoperiod and thermoperiod, relative air moisture, and water potential in the soil. The internal parameters are the water potential of the maternal tree, its nutritional and hormonal state, and the position of the seed on the tree. The environmental factors involved directly in the process of germination are temperature, light, and gas.

Water

In orthodox seeds, water imbibition allows metabolic reactivation and restoration of membranes and organelles, activation of the enzymatic system, respiration, and synthesis of RNA and proteins. The water imbibing the seed is equivalent to two or three times the dry weight of the seed. The net diffusion occurs in a descendent gradient of water potential (or energetic state of the water); in other words, from pure water to water containing solutes). The potential of a cell inside a seed is determined by the osmotic potential (ψ_p), by the concentration of solutes (more solutes = less osmotic potential), the matric component (ψ_c), by the hydration of matrices (cell walls, starch, protein bodies), and the pressure potential (ψ_p), permitting water intake and putting pressure on the cell wall. In the water potential of the soil, only ψ_c has an important function. Water absorption has three phases:

1. A rapid initial imbibition that is strongly influenced by the matric forces.
2. A phase of slow water intake in which metabolic activity begins. The length of this phase is correlated with the intensity of the dormancy.
3. A rapid phase intensified by metabolism activation occurring only in nondormant seeds involved in active germination. In many cases, it coincides with seed coat breaking and radicle protrusion.

Reserve mobilization and enzymatic activation depend on hydration; the best germination occurs with a low moisture tension (0.005–0.500 bars). If the tension is zero, the water pellicle around the seed inhibits the absorption of oxygen.

Temperature

Under natural conditions, temperature determines the capacity and rate of germination, removing the primary and inducing secondary dormancy. For germination, the upper limit is about 45°C and the lower 3–5°C. Many species germinate at about 40°C, but the seedlings are abnormal; others can germinate near the lower temperature limit but they rarely produce normal seedlings. The regimes of alternating temperature (20°C at night and 30°C during the day) seem optimal for species from temperate zones, although similar results are obtained with constant temperatures of 25°C. In tropical species the best range is usually 25–30°C.

Light

Light stimulates germination, but it is not strictly necessary for most seeds; however, some pioneer tropical species (*Cecropia*, *Heliocarpus*) typical of areas in early succession, have photoblastic seeds. A pigment called phytochrome is involved in the photo control of the germination; it exists in two reversible forms (**Figure 12**).

Light sensitivity is influenced by pretreatment with temperature. With an increment of cold pretreatment, seed germination can be increased in darkness and the sensitivity to far-red light decreased. The requirement of light for germination varies with the amount of imbibed water.

Genetic Influence

The genome received by the diaspore controls germination (**Figure 13**) (**Table 2**) and a network of genes regulates ovule morphogenesis. Several parts of the diaspore differ in genotype; the tissues of the fruit, other tissues surrounding the seed, and the seed coat have the maternal genotype. The endosperm is one-third paternal and two-thirds maternal in the most common type of seed. The embryo is one-half paternal and one-half maternal. In general, the genotype of one or both parents affects the structure and composition of the various parts of the diaspore. For example, the genes expressed in the megagametophyte play a role in the induction of seed development, primarily in embryo and endosperm development. The expression of some maternal genes is required for normal endosperm development. The endogenous annual rhythm of the germinability of the seed and the internal mechanisms regulating it are not well known.

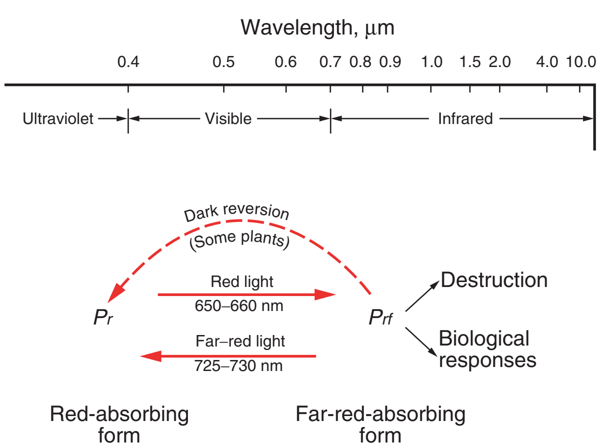

Figure 12 Diagram of reaction for spectral-driven phytochrome reversibility. Reproduced with permission from Vozzo JA (ed.) (2002) *Tropical Tree Seed Manual*. Agricultural Handbook no. 721. Washington, DC: US Department of Agriculture Forest Service.

Seed Respiration

Respiration permits the acquisition of energy. It requires oxygen and the removal of CO_2. High levels of CO_2 can inhibit germination, and a lack of oxygen has the same effect although some species can germinate in anaerobic conditions.

The inhibited seed has three active routes of respiration: glycolysis, pentose-phosphate, and the citric acid cycle (Krebs cycle). Glycolysis – catalyzed by cytoplasmic enzymes – and the Krebs cycle (inside the mitochondria) are essential for the production of ATP. The respiratory process in the orthodox seed involves three or four stages:

1. High oxygen (O_2) consumption and a linear increment in respiration during tissue hydration (hydration and activation of mitochondrial enzymes in the Krebs cycle and the electron chain).
2. Decrease in the respiration proportional to the stabilization of O_2 intake. The seed is hydrated and the enzymatic system is active. Between stages (2) and (3), the radicle protrudes (it coincides with phases (2) and (3) of the imbibition process). The seed coat (or seed coat + endocarp or pericarp) can be a physical barrier limiting O_2 intake.
3. Respiratory reactivation due to activation of the embryo axis and meristems and mobilization of stored reserves. The breaking of the seed coat may contribute to increasing the intake of O_2.
4. Respiration restricted to storage tissues whose reserves are being degraded and removed.

Longevity, Viability, and Dormancy

The period of time in which the seed remains viable in the ground is called longevity. Viability is the germinative capacity; its loss is the final stage of

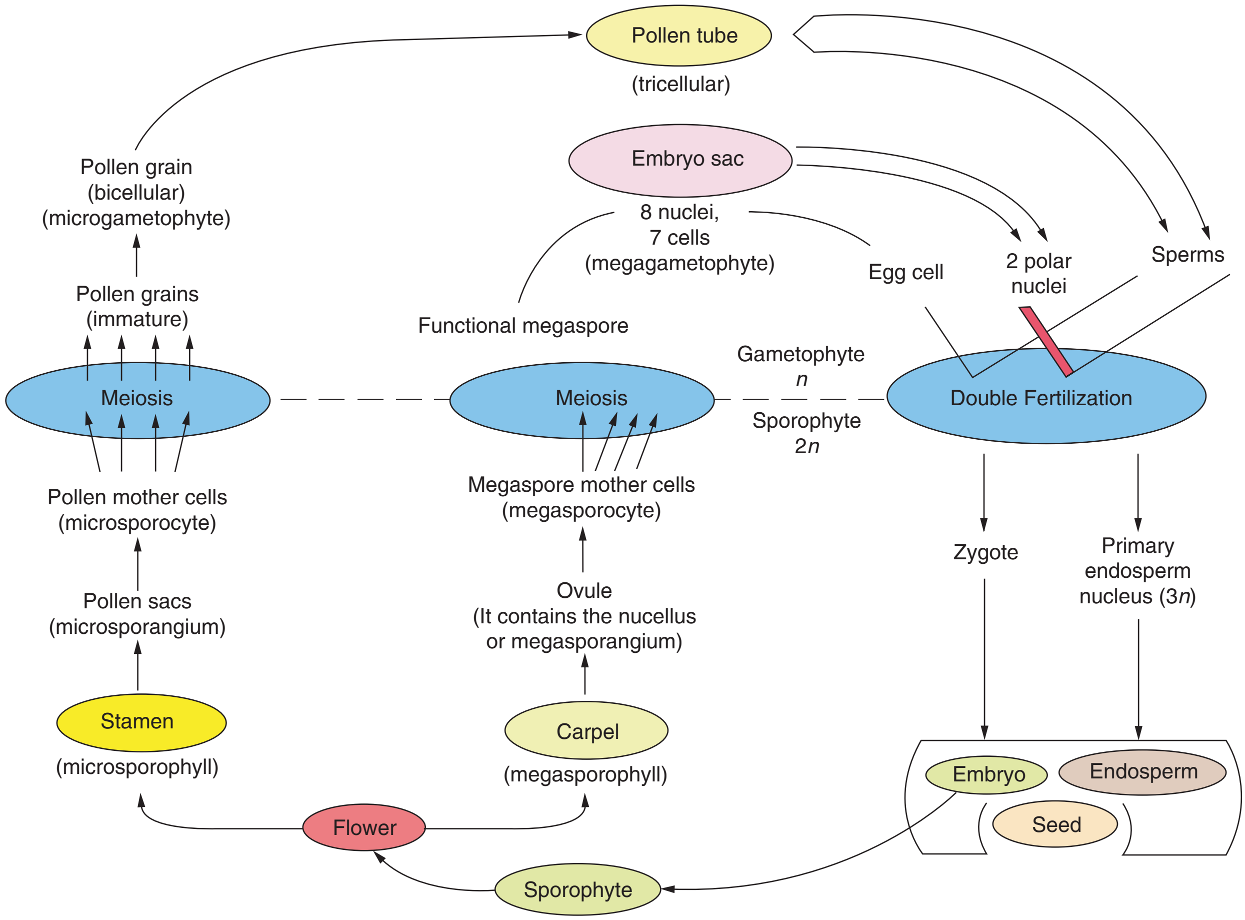

Figure 13 Angiosperm reproductive cycle. Reproduced with permission from Vozzo JA (ed.) (2002) *Tropical Tree Seed Manual*. Agricultural Handbook no. 721. Washington, DC: US Department of Agriculture Forest Service.

seed deterioration. Species from wet tropical forests tend to lose viability rapidly; perhaps 60% to 70% lose it in 3–6 months. Some species lose viability in days or weeks.

To survive in the ground, seeds must maintain viability during the time in which germination is inhibited by dormancy or quiescence. Dormancy is the suppression of germination under favorable environmental conditions. Approximately 10% of tropical species show dormancy. Several conditions cause dormancy: rudimentary or physiologically immature embryos, hard or impermeable seed coats, endogenous growth regulators inhibiting germination, or inadequate storage; some dormancies are the product of multifactorial interactions. Soaking in running water, hot water, hydrogen peroxide, and physical scarification are treatments used to break seed coat dormancy.

Dormancy can be innate or induced. Innate dormancy (primary) prevents the germination of seeds during their development and maturation in the maternal tree and usually some time after dispersal or collection. Dormancy is innate external (primary external) when the seed coat, the endocarp or the pericarp are hard or woody, impermeable to gases or water, or mechanically resistant (e.g., *Enterolobium*, *Samanea*). The environment can reinforce the quiescence. When the embryo contains inhibitory substances or it is physiologically immature, the dormancy is innate internal or primary internal (e.g., *Juniperus virginiana*).

The innate dormancy declines before or after dehiscence. This period is called postmaturation dormancy. The heritability of dormancy is complex because the distinct parts of the seed are genetically different.

Induced dormancy (secondary) develops after the dispersal or collection of nondormant seeds or seeds emerging with partial or total primary dormancy. Essentially, it reflects no sensitivity to germination inductors, internal or external.

Germination can be inhibited by exposing the seeds to long periods of white light, especially to densities of high radiant flows or far-red light. Dormancy can also be prevented, delayed, or reduced by intermittent light of low intensity. Innate dormancy is absent in the recalcitrant seeds of the tropics.

Table 2 Levels of genetic variation, events and facts

Levels of genetic variation		*Events and facts*
Gamete production	Microsporogenesis and microgametogenesis	• The microsporocyte or pollen mother cell (2*n*) has two chromosome sets (maternal and paternal). • Meiosis gives rise to four haploid microspores. They are not genetically equivalent. • Each microspore undergoes asymmetric division and finally produces a pollen grain with a vegetative cell and two sperm cells (frequently dimorphic).
	Megasporogenesis and Megagametogenesis	• The megasporocyte or megaspore mother cell (2*n*) has two chromosome sets (maternal and paternal). • Meiosis gives rise to four haploid megaspores. They are not genetically equivalent. • Three megaspores degenerate, one survives (chalazal) and is functional. • Megaspore divisions originate the embryo sac (megagametophyte). It contains the egg cell (*n*). • The megagametophyte is regulated by its genes and those of neighboring cells and tissues. • The megagametophyte regulates seed development after fertilization.
Gamete level		• The egg cell and the sperms have nuclear and cytoplasmic DNA (mitochondria and plastids). • Plastid DNA (plastome) interacts strongly with nuclear DNA. • In most species, plastids are inherited by maternal line (includes plastid DNA). • Plastids reproduce by binary fission. Some mutants are unable to reproduce; the mutation is lethal. • Mitochondrial DNA is usually inherited by maternal line (egg cell). • Sperm cells (two per pollen tube) are frequently dimorphic. One may have mitochondria; the other may have plastids. Probably different patterns of male cytoplasmic DNA transmission. • Is sperm behavior in double fertilization predetermined or at random?
Parent trees		• Self-sterility (homogamy) and separation of sexes in space or time to favor cross-pollination • Female parent tree: ○ The egg cell (embryo sac) in the ovule of each flower could be genetically different to that of the neighboring flowers. ○ In flowers with several ovules per gynoecium (ovary), the egg cell (embryo sac) of each ovule could be genetically different to that of the neighboring ovules. ○ Pollen received by egg cells (embryo sacs of different ovules) in an ovary with several fruits could be genetically different and provided by several sources. ○ Seeds are not genetically equivalent. • Male parent tree: ○ Pollen grains are not genetically equivalent. • Multiple parent trees: ○ Mixture of pollen grains genetically different
Incompatibility systems		• They maintain a high degree of genetic heterozygosis in the species population. • They operate at the stigma or style level. • Incompatibility could be sporophytic or gametophytic.
Gametophytic mutations		• They are lethal if the megagametophyte (embryo sac) is affected. • If the pollen is affected fertilization could fail or seed abortion takes place at different stages of development. • If both gametophytes are affected there is not fertilization, seed is empty (no embryo) or the embryo is not viable. • Endosperm: If endospermic DNA is aberrant seeds fail to develop.
Diaspore genome		• Several parts of the diaspore differ in genotype; the tissues of the fruit, other tissues surrounding the seed, and the seed coat have the maternal genotype. The endosperm is one-third paternal and two-thirds maternal in the most common type of seed. The embryo is one-half paternal and one-half maternal. In general, the genotype of one or both parents affects the structure and composition of the various parts of the diaspore.
Pollination and seed dispersal		• In cross-pollination species, the paternal genes move twice (pollination and seed dispersal) in each generation; the maternal genes move once (in autopollination or cross-pollination). Therefore, in cross-pollinated species the paternal genes move farther in each generation. • Pollination is at random. One or several donors provide pollen to the same flower or different flowers in the tree. • The pattern of dispersal contributes to structure population, to potential genetic drift, and to natural selection.

The emergence from dormancy is frequently regulated by a promoter–inhibitor system, where the principal promoter is gibberellic acid (GA_3) and the main inhibitor is abscisic acid (ABA). Low levels of inhibitor and high levels of promoter induce germination. According to some studies, it is not possible at present to determine the precise function of ABA in the induction of dormancy.

Shoot Growth and Canopy Development

S W Hallgren, Oklahoma State University, Stillwater, OK, USA

Introduction

As shoots grow and become numerous a canopy develops. The mass and surface area of the leaves in the canopy reach a maximum amount relatively early in the life of a stand. Subsequent growth of the trunk and branches serves to lift the canopy higher and higher above the ground. The form and arrangement of the branches and leaves in the canopy are an important reflection of the architectural type. Tree architecture is difficult to study and describe because trees are very large, very long-lived, and have a complex hierarchy of components. Much of tree architecture is inherited. Trees look different because they have evolved in different climates – tropical palms (e.g., *Corypha elata*) versus alpine firs (e.g., *Abies alba*), coastal mangroves (e.g., *Rhizophora mangle*) versus savanna baobabs (e.g., *Adansonia digitata*) and niches (overstory Douglas-firs (*Pseudotsuga menziesii*) versus understory Pacific yews (*Taxus brevifolia*), overstory oaks (e.g., *Quercus alba*) versus understory dogwoods (e.g., *Cornus florida*). In addition to variation in the inherited types, there is tremendous genetic variation in response to the local environmental variables of solar radiation, competition, and availability of nutrients and water. The phytochrome-mediated response to plant shade is strongly inherited. Trees appear to grow toward the light, but are really growing away from shade. The intensity of competition determines the tree size and shape. Some species can grow larger than others under extreme competition. The xylem is well suited to support the tree and conduct water, but the hydraulic limits of the xylem to transport large volumes of water from the soil to the distant transpiring leaves also sets limits to tree size and form.

Tree Growth

Plant growth is defined as the increase in size by cell production and enlargement. Apical meristems at the tips of stems are responsible for primary growth to increase stem length and for the production of initials for the lateral appendages to the stem. The lateral meristem or cambium at the periphery of the stem between the xylem and phloem provides secondary growth to maintain vascular connections and increase mechanical support through increased diameter. Stems carry the leaves responsible for photosynthesis and the flowers responsible for reproduction. Although plant growth may appear simple from this description, when the entire scope of species is considered, growth provides an enormous variety of patterns in time and space that produce a bewildering array of architectures. Extensive studies of tree architecture have shown the existence of predictable types that reflect adaptation to environmental factors and competition.

The tree phenotype is the manifestation of the genetic information in the genotype acting through developmental processes under the constraints of the environment to produce an adapted type. There is a huge genetic diversity of trees because they have become adapted to such a wide range of terrestrial environments from rain forests to arid deserts and from warm tropics to cold boreal regions. Because trees are long-lived sessile organisms and cannot move in space to escape environmental stresses that change through time, they have very high phenotypic plasticity that allows them to acclimatize to long- and short-term environmental changes. A site that provided plenty of light may become strongly shaded by competition. A site that was once adequately supplied with moisture may become too wet or too dry.

Almost all trees begin life near or at the soil surface. Because it is the primary site of energy exchange, plants at the bare soil surface experience the greatest extremes and the most rapid environmental changes. Small young trees experience a single soil and shoot environment. There are qualitative and quantitative changes in tree–environment interactions as the tree becomes larger.

Rapid early growth allows the tree to become established and escape the harsh conditions at the soil surface. The roots and shoots grow farther and farther away from the soil surface and the single plant begins to experience many different environments at the same time. The environmental extremes and rapid changes are not experienced by the large tree in the same way as the small tree, because most of the tree is far above or below the soil surface and the large tree shades the environment near its base. Consequently, there are quantitative and qualitative changes in shoot growth as a tree ages and becomes larger.

Tree Architecture

The growth and proliferation of individual shoots lead to development of the tree and canopy architecture. Trees can be viewed as an assemblage of components or modules that are repeated and follow a hierarchy of types. Each component type more or less serves the same purpose, responds the same way to the environment, and is autonomous at its own level. The above-ground components of a tree in order of increasing size are: (1) apical meristem; (2) leaf; (3) shoot unit or metamere (node with its lateral appendage, usually a leaf, and structure in the axil of the lateral appendage and the proximal internode); (4) extension unit for a growth period; and (5) crown. The greatest diversity of tree architecture is found in the tropics where there are stable equable climates, a great diversity of climates, large areas of forest, and relatively little environmental change over thousands of years.

There are over 20 distinct architectural models among the tropical trees. Major functional characteristics determining models are the life span of the apical meristem and how the vegetative apical meristems differentiate. The apical meristem is of central importance, as it produces elongation growth and is the origin of the secondary or lateral meristem. In addition, many types of trees such as palms, palm-like trees, and tree ferns do not have a secondary meristem.

Apical meristems produce either a sexual or vegetative axis in an irreversible developmental process. The production of a sexual axis ends the life span of the apical meristem while the life span of the vegetative axis may continue indefinitely. Apical meristems show continuous or rhythmic growth. Continuous growth produces an axis with essentially equivalent internodes, leaves, and lateral branches. In contrast, rhythmic growth with alternating periods of growth and rest produces an axis with alternating long and short internodes and leaves and lateral branches that differ with internode length. Whether a species shows continuous or rhythmic growth has a substantial influence on its response to the environment and its form. Continuous growth is associated with unchanging environment and even when there are changes the tree responds by increasing or decreasing growth, but it does not produce resting buds. Examples include members of the family Palmae, the mangrove *Rhizophora mangle*, and species in the genera *Juniperus*, *Thuja*, and *Chamaecyparis*. Rhythmic growth is associated with a climate with substantially different seasons of growth and rest and the production of a resting bud. The genus *Pinus* is widespread and shows a lot of variation in growth pattern. Northern species such as *P. resinosa* often have a very rigid pattern of rhythmic growth that produces one shoot flush each year in the spring and is under strong genetic control. It shows little capacity to take advantage of prolonged favorable weather by producing more than one shoot in a year. In contrast, southern species such as *P. taeda* may show rhythmic production of one to several flushes depending on the weather.

Apical meristems produce either orthotropic or plagiotropic shoots. Orthotropic axes are erect, show radial symmetry, may have a spiral leaf arrangement, and are produced most often by the leading shoot. They are associated with vigorous young growth and tend to decrease in very old and severely stressed plants. Plagiotropic axes are horizontal, show dorsiventral symmetry, have a distichous leaf arrangement, and are produced most often by lateral shoots. They are associated with slow weak growth and tend to increase in very old trees and severely stressed plants. These architectural characteristics are genetically controlled and constrain the ultimate tree form.

The majority of trees develop the form of a large central trunk with side branches while a relatively small number of trees, mainly those mentioned above with no secondary meristem, develop a single nonbranched axis. The excurrent or conical tree form is associated with conifers and cold climates with abundant snow and ice. The form obviously facilitates the shedding of ice and snow which could damage the crown if allowed to accumulate. The deliquescent tree form is associated with angiosperms and warm climates lacking snow and ice. This form may be an advantage where competition for light is extreme.

Shade Avoidance

The radiation environment is the most important factor determining shoot growth and canopy development. The leaves of trees are displayed to capture light energy, because plants need light energy for photosynthesis. Leaves and their stems have two options when subjected to shade: (1) adapt to functioning in the shade and (2) grow toward the unaltered light to increase photosynthesis. Shade leaves have greater photosynthetic efficiency in the low light because they develop greater surface area for light interception and they are thinner with less pubescence and less dense mesophyll cells for better light penetration and reduced reflection. In addition, shade leaves are oriented horizontally to intercept more light than the vertically oriented sun leaves. Shade plants increase the ratio of photosynthesizing machinery to respiring structural support material. Although plants can adapt to shade, those growing in the shade are usually not as vigorous as plants in full sun. Current research findings indicate that plants actually grow away from shade cast by competing plants. Competing plants change the quality of the light and this change is a signal that induces a growth increase response in internodes. The capacity to avoid plant shade was not important and probably did not evolve until plants became large enough to cast shade on their neighbors.

The shade signal is read by phytochrome in plants. Phytochrome has two interconvertible forms. One form (Pr) absorbs mainly red photons (maximum absorption 665 nm) and the other (Pfr) absorbs mainly far-red photons (maximum absorption 730 nm). The absorption by either form causes it to convert to the other form. Light in this range of the spectrum is little affected by clouds or rain but can be changed significantly by vegetation. Plants strongly absorb red (R) and reflect far-red (FR) light; consequently, the R:FR ratio (ratio of photon flux at 660 nm and 730 nm) tends to be reduced by canopy shade. The R:FR ratio varies significantly with degree of shade (0.05–1.15 in canopy shade to 1.05–1.25 in full sun) and elicits large changes in the proportion of phytochrome in the Pfr form (Pfr/P ranges from 0.65 in full sun to 0.20 in deep shade). A wide variety of plant processes are known to respond to the R:FR ratio, including meristem activity, tissue differentiation (e.g., flowering versus vegetative), senescence, abscission, assimilate distribution, and chloroplast development (**Table 1**). Logarithmic stem elongation has been shown to have a strong inverse linear relation to the Pfr/P value. It has been shown that the strength of the elongation response to Pfr/P is genetically controlled and is very low in shade-tolerant plants and very high in shade-intolerant plants (**Figure 1**). It would be very interesting to learn whether the other plant responses to the R:FR ratio are similarly related to genetic variation in shade tolerance.

It appears that much of the plant response to shade is mediated by phytochrome. The very plastic response of trees to the radiation environment provides the capability to fine-tune tree architecture to achieve the greatest fitness. Even the germination of seeds is regulated by the light environment in some species. This capacity is under genetic control and plants adapt to a wide range of shade environments. The trees producing a canopy that creates the greatest change in the radiation environment (greatest change in R:FR ratio) generally show the smallest

Table 1 Shade avoidance responses

Plant physiological process	*Shade avoidance response*
Extension growth	Accelerated
Internode extension	Rapidly increased
Petiole extension	Rapidly increased
Leaf development	Retarded
Leaf area growth	Slightly reduced
Leaf thickness	Reduced
Apical dominance	Strengthened
Branching	Inhibited
Flowering	Accelerated
Rate of flowering	Greatly increased
Seed set	Severely reduced
Fruit development	Truncated
Senescence	Accelerated
Leaf senescence	Advanced
Leaf abscission	Advanced
Assimilate distribution	Marked change
Deposition in storage organ	Severe reduction

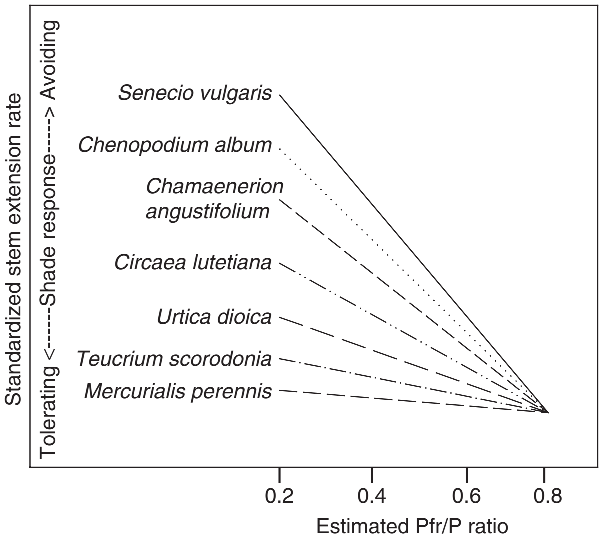

Figure 1 The elongation response to change in the Pfr/P ratio is much greater in plants that avoid shade than in those that tolerate shade. Reproduced with permission from Smith H (2000) Plant architecture and light signals. In: Marshall B and Roberts JA (eds) *Leaf Development and Canopy Growth*, pp. 118–144. Oxford, UK: Blackwell.

response to changes in shade. In contrast, trees producing a canopy that creates the smallest change in the radiation environment generally show the greatest response to shade.

Recent advances in phytochrome research have provided significant knowledge of plant response to shade. It has been common knowledge for a long time that tree stem and leaf growth are affected by light and for the most part there was a sense that intensity of light was the main signal. It has become clear that light quality as it is altered by vegetation is a major signal in photomorphogenesis. Shoot growth and canopy development are guided by the radiation environment. Genes encoding for several phytochromes responsible for very different processes, including seed germination, flowering, elongation, and tuberization, have been found in *Arabidopsis*.

Current research activity seeks to determine how to manipulate the shade avoidance response mediated by phytochrome through genetic means. There are many mutants that have provided new information. A transgenic crop has been produced that appears to have reduced shade avoidance. It has reduced stem elongation which presumably allows greater energy investment in the part of the plant to be harvested, the fruit. In the case of trees, it may be more productive to search for ways to increase the shade avoidance response to produce more stemwood. The large number of phytochromes and their interactions will make the genetic engineering of shade avoidance a long and meticulous process. But it will certainly proceed faster than traditional breeding for the same trait.

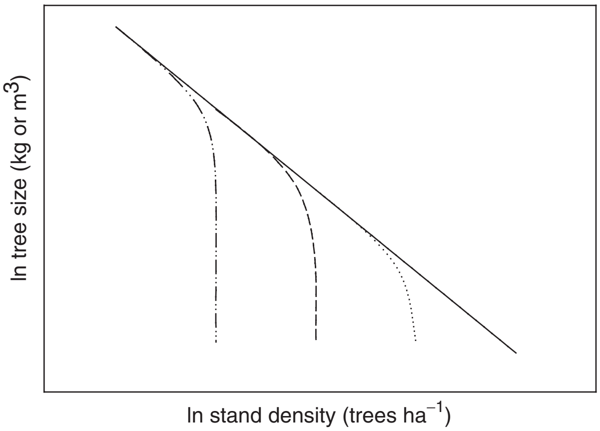

Figure 2 The maximum size–density relation for even-aged single species stands has a slope close to $-3/2$ when ln (tree size) is plotted against ln (density). Trees in low-density stands increase in size until they reach the maximum attainable for the given density. Further increase in size will only occur when density decreases through mortality.

The Maximum Size–Density Relation

The maximum size–density relation depends on the assumptions that trees of a certain species all have the same allometric growth and that trees on a fully occupied site will experience self-thinning. Trees growing in even-aged single-species stands will grow to a certain size that depends on density and they can not grow larger unless density is reduced by mortality (**Figure 2**). This appears to be consistent with the concept of a maximum biological productivity. Furthermore, the size–density relation is independent of site quality and stand age. The relationship between average plant size and stand density is bounded asymptotically by the $-3/2$ power rule:

$$s = a\rho^{-3/2}$$

where s = plant weight or volume, a = a constant, and ρ = stand density. This can also be written as:

$$\ln s = \ln a - 3/2 \ln \rho$$

The relation is common to all species studied to date and, although the slope varies somewhat, it is usually close to $-3/2$. The height of the line does vary considerably by species. At a stand density of 2470 trees ha^{-1} *Abies magnifica* and *Sequoia sempervirens* will attain a maximum average stand diameter of 25.4 cm; density must be reduced to 2050 for *A. concolor* and *Pinus ponderosa*, 1470 for *Pseudotsuga menziesii*, 1110 for *Pinus taeda* and 990 for *P. palustris* to achieve the same diameter. Apparently, the efficiency with which each species occupies space varies considerably among species. The maximum size–density relation is a powerful tool for determining tree size and shape.

Hydraulic Architecture

The leaves displayed by branches in the canopy to capture light energy and fix carbon also transpire large amounts of water. Transpiration is a consequence of opening stomata to exchange CO_2. In addition, it serves at least three other purposes: (1) it moderates leaf temperature variation by evaporative cooling; (2) it transports mineral ions from the soil to leaves and ends of branches; and (3) it transports information about the environment from the roots to the leaves and branches. The necessity to transport large amounts of water from the soil to the leaves requires a special architecture of stems and leaves dictated by the properties of water, the physical environment, and the plant.

As soon as the stomata open, water evaporates from the inside of the leaf, causing a drop in water potential. Water moves into the roots from the soil and up the xylem from the roots to replace the transpired water. It moves along xylem conduits down a water potential gradient. The water is under tension and resists cavitation due to cohesive forces. The xylem provides a rigid conducting system of tubes where the secondary cell walls are the tubes and the lumens are the conducting voids filled with water. Gymnosperm xylem is composed mainly of very small closed tracheids, and in angiosperms the conducting elements are mainly vessels, thousands of times larger than tracheids, composed of stacked vessel elements with perforated end-walls. Water moves between conducting elements through pits along the sides and ends.

Flow through the xylem is proportional to its conductance and the driving force. Conductance depends on diameter of the lumens, conduit number, roughness of the interior walls, and restrictions of the pits. The driving force is a pressure difference in water potential set up by transpiration from the leaves. To maintain water flow the xylem must be constructed to have a conductance sufficient to transport water under a driving force that can be created and sustained in the conduits. The average driving force across the entire plant is essentially the water potential difference between the root tip and the leaf tip per unit of length ($MPa\,m^{-1}$). The driving force may not be of the same magnitude throughout the plant. If the water potential gradient is too small anywhere along the xylem the water will not move.

Water flow occurs when the water potential difference is adequate to create a flow. The greatest potential differences and greatest water flows occur when soil water is plentiful and the water potential is high. As soil water declines the water potential in the plant also declines to maintain water flow. Eventually, water potential in the plant will decline to a level that increases the risk for cavitation, a break in the water column filled with air or water vapor. Water flow in a conduit ends when a cavitation occurs and does not resume until it is refilled. If cavitations become numerous and transpiration continues, water potential must drop further to maintain flow in the remaining flow channels. The decreasing water potential may provoke runaway cavitation, a vicious cycle of increasing cavitation and decreasing water potential that can continue and eventually result in total failure of the xylem to conduct water. There is a lot of evidence that trees often approach low water potentials close to the threshold for catastrophic cavitation at midday on sunny days. Stomata close just in time to prevent disaster. In fact, some persons wonder if that is not the main purpose for stomata.

There is a potential for xylem characteristics that promote high conductivity and those that protect against cavitations to have conflicting effects. Conductivity can be increased by producing larger-diameter conducting elements with few flow constrictions between them; however, there is some evidence these qualities may increase the vulnerability to cavitation. Although it seems that high conductivity and low vulnerability to cavitation would be beneficial traits, the research results concerning a possible trade-off between these two traits are not conclusive. On the other hand, high vulnerability of certain plant parts could turn them into expendable parts that cavitate to protect the rest of the plant from excessively low water potentials.

Canopy architecture must meet the requirement that the xylem conduct sufficient water to meet transpiration demands. The capacity to absorb and transport water to the transpiring leaves depends on conductivity and vulnerability to cavitation of the xylem and rhizosphere. For a given root area/leaf area ratio this capacity is determined by hydraulic properties of the xylem and soil (**Figure 3**).

Stem length and leaf area will be determined by the hydraulic properties of the xylem in addition to root absorbing capacity and the capacity of the soil to provide water.

Recent research findings have pointed to the possibility that plants can fine-tune water use through signaling soil water availability and controlling xylem conductivity. Roots may be sending a

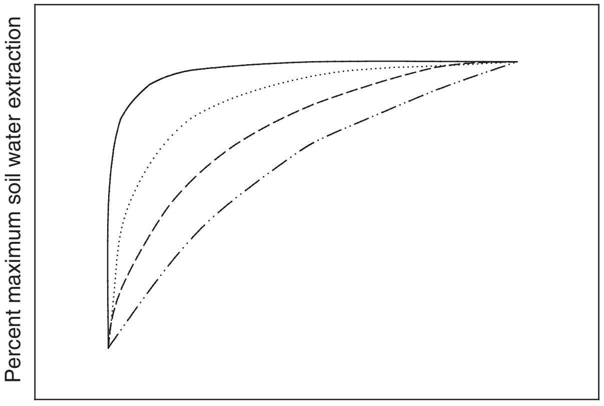

Figure 3 The maximum soil water extraction potential before cavitation causes failure to conduct somewhere in the soil–plant system occurs at the highest attainable root area/leaf area ratio. Decreasing soil water extraction potential occurs with declining root area/leaf area ratio due to loss of conductivity first in the xylem and later in the rhizosphere. Each curve represents the relation between extraction potential and root area/leaf area ratio for a different soil and xylem type. The upper curve could be a loam soil and drought-resistant species highly resistant to cavitation and the lower curves a sandy soil and drought-susceptible species not resistant to cavitation. Modified with permission from Hacke UG, Sperry JS, Ewers BE, *et al.* (2000) Influence of soil porosity on water use in *Pinus taeda. Oecologia* 124: 494–505.

signal in the water flow to the leaves to regulate stomatal opening depending on soil water status. Research has indicated that the ion content in the xylem sap influences hydrogels and xylem conductivity. Hydrogels in the pit membranes between xylem elements may open and close pit pores to increase and decrease conductivity to different parts of the canopy. The question is whether the phloem or some other mechanism adjusts xylem conductivity depending on canopy demands. Both mechanisms of fine-tuning water use would mean the tree would be less subject to low water potentials and water stress. Tree architecture could be more closely tuned to environmental demands without heavy overbuilding to produce xylem with excess conductivity or excess protection against cavitation.

Conclusions

Tree growth is started by linear primary growth of the apical meristem which is followed by volume growth of the secondary lateral meristem. Although this constrains the plant form, trees have evolved a startling variety of architectural types. The shoot is elaborated and multiplied to produce a canopy which serves the purpose of capturing light energy and facilitating the reproduction of adapted types through flowering. Inherited architectural types have been identified and described. They range from the steeply conical forms that shed snow and ice in cold climates to the deliquescent crowns that dominate the forest and capture a good share of the solar radiation in dense tropical forests. The greatest variety of inherited architectural types is found in tropical forests.

The main environmental factor shaping canopy development is the radiation environment. Phytochrome is the substance in plants that interprets the radiation environment and elicits a light response in almost all growth activities. Although plants appear to grow to the light, the elongation response to light is a mechanism to avoid shade. Increased understanding of the shade response improves the interpretation of canopy development and produces better management of stand density. Despite genetic engineering being tedious and complicated because of interactions among the different phytochromes and a potential for negative effects of genetic transformations, it appears to show a lot of promise for increasing harvest yield in trees. It is easy to imagine there may be economic value for an increased shade avoidance response that produces trees that grow faster in height, straighter, and with fewer branches. The size and shape of trees in dense stands follow a trajectory defined by the maximum size–density relation. An interesting question is whether phytochrome plays a role in the effects of competition described by this relation.

Trees must transport large amounts of water to transpiring leaves. Recent research suggests that the conducting system from the roots, through the xylem to the leaves is far more than just passive tubes responding to physical laws. Xylem morphology and anatomy balance conductivity with protection against cavitation. Cavitation in some plant parts may protect others against low water potential. Signaling within the plant and variable xylem conductivity may permit fine-tuning of water use by the tree. These mechanisms may allow tree architecture that is not excessively expensive and overbuilt to protect against water stress.

Root System Physiology

M A Topa, Boyce Thompson Institute for Plant Research, Ithaca, NY, USA

Introduction

The biotic and abiotic interactions that occur between tree roots and the soil rhizosphere environment are easily the most complex and least understood interactions in plants. Questions concerning the 'missing' carbon sink in terrestrial ecosystems under various global climate change scenarios have increased our interest in elucidating the role below-ground systems play in carbon sequestration and carbon/nutrient cycling. Fine root systems (roots ≤ 2 mm diameter + associated rhizosphere biota), in particular, play a critical role in forest ecosystem function, with more than 50% of annual net primary productivity allocated below ground in many forests. Similar to their aboveground ephemeral counterparts (leaves), fine roots are relatively short-lived, but are the principal tissues for below ground resource acquisition. Yet fine root system demography (i.e., annual production, lifespan, and timing of root initiation and mortality) and function remain one of the most difficult and least understood areas of study because of its complex biodiversity and dynamic nature. The opacity of the soil and complex nature of the root/rhizosphere biotic system pose unique challenges to tree biologists studying root system function and belowground biodiversity.

Because of these challenges, our understanding of root system structure and function in trees is based largely on highly controlled seedling and mesocosm studies. However, to scale from seedlings to mature trees, root system biologists must consider how root function (much of it driven by carbon and nutrient source–sink relationships) and root ontogeny change as seedlings mature (**Table 1**), and how the biodiversity of rhizosphere microorganisms in the field alters root system function. As trees age, whole-plant source–sink relationships change, and nutrient demands are buffered by stored reserves and internal recycling of N and P. Storage carbon plays a critical role in buffering day-to-day or seasonal fluctuations in the carbohydrate supply to roots. Balanced partitioning of recently fixed carbon between immediate use and storage is essential for plant growth and for survival during stress. If an environmental stress decreases the photosynthetic capacity of a tree, then the demand on carbon reserves increases. Because of their low buffering capacity, seedlings are more dependent upon recently acquired nutrients and recently fixed carbon than mature trees, exhibiting a more immediate response and greater susceptibility to environmental stresses than observed in older trees. Consequently, the biggest challenge facing root system biologists is finding new technologies that will allow us to examine *in situ* root system function and demography on trees of variable age or size, with an increased emphasis on mature trees.

As seedlings mature into saplings and trees, their perennial roots will modify the physical, chemical,

Table 1 Comparison of some structural and functional characteristics of seedlings and mature trees that will alter shoot/root relationships and root function

Structure/function	*Seedling*	*Mature tree*
Carbohydrate storage	Low	High
Carbon allocation	None to reproduction, higher to foliage than roots	Higher proportion to reproduction, roots, storage
Drought resistance	Low	High
Leaf conductance	High	Low
Dependence upon recently acquired nutrients	High	Low; buffered by stores
Nutrient retranslocation	Insignificant	High
Proportion of fine roots in secondary:primary growth	Low	High
Proportion of fine roots to total root biomass	High	Low
Proportion of photosynthetic tissues to total biomass	High	Low
Rate of net photosynthesis	High	Low
Root system growth and metabolism	Greater dependence on recently assimilated carbon	More buffered by storage carbon

Modified from Vogt KA, Publicover DA, Bloomfield J, *et al.* (1993) Belowground responses as indicators of environmental change. *Enviromental and Experimental Botany* 1: 189–205.

and microbiological characteristics of their soil environment. Rhizosphere microorganisms such as mycorrhizae, *Rhizobium*, rhizobacteria, and mycorrhizal helper bacteria can stimulate tree growth through enhanced mineralization and nutrient acquisition, biological control of pathogens, and production of plant growth regulators. Tree roots in the field are generally colonized by a high diversity of mycorrhizal species, with the degree and rate of colonization by individual fungal species changing temporally, spatially, with tree or stand age, and with soil and climatic environments. Functioning of the mycorrhizal root and its overall effect on tree growth are mediated by a hierarchy of biotic and abiotic factors at the rhizosphere (soil chemistry, texture, moisture, temperature, and biota), community (plant competitors, animal associates, and tree pathogens) and ecosystem (precipitation patterns, temperature dynamics, and atmospheric chemistry) levels. Since over 90% of the world's land plants belong to families that are commonly mycorrhizal, root function of most trees cannot be examined without considering how mycorrhizas modify the soil environment and host growth. Mycorrhizal associations are discussed in greater detail elsewhere (*see* **Tree Physiology**: Mycorrhizae), but a limited discussion on how they alter tree root function is presented here. Although an entire book could be written on the subject of tree root physiology, I focus on the following aspects of tree root structure and function: root architecture and development, fine root system turnover, and fine root system function. For a more in-depth discussion of these and additional topics, I refer the reader to the list of further reading at the end of this article.

Root Architecture and Development

Root systems of higher plants show considerable architectural variation between species, within a species, and within an individual root system. This variability suggests that any genetic predisposition in root architecture is modified by the external soil environment. In long-lived perennial species, the degree of root plasticity is probably an adaptive response to spatially and temporally heterogeneous soil environments, enhancing a tree's ability to compete for limiting soil resources. Root systems of trees are often described as one of two types: those with taproots that grow rapidly downward, with taproot and lateral roots penetrating lower soil horizons, and those with more shallow, slower-growing primary roots and extensive, rapidly growing lateral roots. However, intraspecific variation in root growth is so great because of soil environmental modifications that interspecific comparisons can be difficult, and generalizations about species rooting depth and spatial deployment are misleading for many species. Certain species are more plastic than others with regard to environmental control of root architecture and spatial deployment in soils. For example, red maple (*Acer rubrum*) develops shallow, lateral roots in swamps and deep taproots in drier, upland soils, whereas some *Eucalyptus* species in dry areas develop a long taproot, but form a shallow root system on better sites.

In general, tree roots will grow in that portion of the soil where moisture, aeration, mechanical properties, and fertility are most favorable. A deep taproot system with a substantial number of lateral roots penetrating the lower soil horizons is typical of easily penetrable, often droughty soils. In contrast, shallow, platelike rooting is a response to edaphic limitations that restrict root growth to upper soil horizons, such as mechanical impedance of lower soil horizons or high water tables found in flooded soil environments. In more easily penetrable soils, the highest density of fine roots is often found in upper 0–10 cm soil horizons because these horizons are generally more aerated, have a higher organic matter content (with higher pools of organic N and P), are more fertile than deeper soils, and are well watered by summer precipitation. This is especially true in tropical and many temperate zone forests. In coniferous forests, rooting density in upper soil horizons tends to increase with stand age, presumably because canopy closure reduces understory competition and the litter layer becomes deeper and well established.

One of the common complaints among tree root biologists is the lack of standardization of root classification systems, making interstudy comparisons difficult and confusing. The problem is not a recent one, reflecting the complex and highly plastic nature of tree root systems growing in a dynamic environment. Studies dating from the early twentieth century used various classification systems that were intertwined with very elaborate, descriptive elements of form, often personalized by the various researchers. Lateral roots were described as: growth roots; long, main, and pioneer roots; surface roots, pioneers, seekers, and searchers; leaders; runners and pioneers; extension roots; primary laterals; or simply laterals or long laterals. More recent ecological, physiological, and silvicultural studies often select a classification system (**Table 2**) based on the ease of use with their particular system (e.g., seedling versus mature tree, greenhouse versus field-grown plants) or experimental design (soil cores, ingrowth cores, minirhizotron observations, etc.). Unfortunately, most of these classification systems do not emphasize differences in morphology or root function, often lumping together roots that may have very different lifespans and function. This is particularly true for smaller-diameter roots ≤ 1.0 mm. Consequently, many researchers use a combination of classification systems to describe their roots. In those species such as *Pinus* that are strongly mycorrhizal, more emphasis needs to be placed on discriminating between mycorrhizal and nonmycorrhizal roots because of differences in lifespan, morphology, and function.

The heterorhizic root system is perhaps one of the most function-oriented classification systems that has withstood the test of time, in part because of its distinction between mycorrhizal and nonmycorrhizal roots. A heterorhizic root system is composed of long lateral and short roots, and is best typified in *Betula*, *Fagus*, and *Pinus*. Long laterals are first- and second-order roots (using developmental terminology) that generally originate in the root collar region, are considered permanent, and increase in diameter by undergoing secondary growth via a cambial layer. Individual long roots exhibit cyclic growth activity independent of each other, with pauses in growth often marked by metacutization. Metacutization is a process of lignification and suberization, resulting in

Table 2 Tree root classification systems

Developmental	Based on the order in which roots arise from primary root or taproot. First-order root arises from primary root or taproot; second-order root arises from first-order root; third-order root arises from second-order root. Often used in seedling studies when entire root is harvested since order of development is easily discernible
Architectural	Based on relationship to smallest root. The ordering system is the complete opposite of the developmental system, with smallest roots labeled first-order. Used in seedling or field studies
Heterorhizy	Long- and short-root habit exemplified by Betulaceae, Fagaceae, and Pinaceae. Long lateral roots are long-lived (many as old as the tree), are subdivided into various types depending upon diameter and point of origin, exhibit cyclic growth with pauses marked by metacutization, and are the framework of the root system. Classes of long roots, based on decreasing diameter, include: pioneer $>$ mother $>$ subordinate mother. Short roots are short-lived, typically ≤ 5 mm in length, do not undergo secondary growth, and are commonly mycorrhizal. Applicable to field studies
Woody/nonwoody roots	Used for some angiosperms not readily classified by long and short roots (e.g., red maple). Framework of permanent woody roots bearing many fans of relatively short-lived nonwoody roots. Nonwoody root fans consist of second- and higher-order nonwoody roots emerging from a first-order nonwoody root (developmental classification terminology)
Coarse/fine roots	Nonstandardized classification system based on root diameter only. The various root diameter classes vary with different studies, but fine roots are often defined as ≤ 2 mm. However, upper-diameter size limits for fine roots vary from 0.5 to 10 mm. Most often used in field ecosystem studies

a resting root that is protected against significant fluctuations in soil environmental conditions such as drought. Short roots are more ephemeral and arise from root primordia similar to those giving rise to long lateral roots, but are characterized by rounded tips with no true root cap, slow rates of cell division, short length, and no secondary growth. Short roots are considered important sites of water and nutrient uptake, and are commonly mycorrhizal, particularly in *Pinus*.

When considering the functional implications of root architecture in trees, it is important to recognize that tree root systems contain various classes of roots that differ functionally and morphologically. Large woody roots are long-lived and are functionally important for carbohydrate and nutrient storage, for structural stability and anchorage, and as transport conduits between fine roots and stems. Since nonmycorrhizal and mycorrhizal fine roots function primarily in water and nutrient acquisition and are often short-lived, enhanced plasticity of the fine root system response versus larger woody roots may be more critical for capturing a heterogeneous supply of soil resources. Accumulating evidence from minirhizotron and other studies suggests that plasticity in fine root initiation, proliferation, and lifespan responses to changes in soil moisture, temperature, and fertilization are important for water and nutrient acquisition in heterogeneous soil environments. Fine root initiation from long-lived deep or other favorably located lateral roots is a competitive advantage for trees when competing with herbaceous understory species for limiting soil resources.

From a carbon standpoint, it may be more cost-effective to shed roots in an unfavorable soil location or during unfavorable times during the year and to construct new roots in potentially more favorable microsites, rather than maintaining existing roots that are less capable of acquiring water and nutrients. However, if the nutrient supply in the new location is short-lived, or a competitor occupies the site more effectively, then root proliferation would not be cost-effective; consequently, there is a certain amount of risk involved in this strategy. In forested ecosystems experiencing a seasonal drought typical of Mediterranean climates, upper soil horizons dry out during the long drought periods. Fine root systems often proliferate in these upper horizons during the wet periods (most likely because of the higher organic matter and nutrient content of soil in this layer), but experience high mortality during the drought. Trees become more dependent upon deep, more stable sources of water during these dry periods, and it is not unusual for fine roots to proliferate from preexisting woody roots in deeper soil horizons. It has been suggested that functional specialization may occur in trees that have two distinct layers of fine root growth in the soil, with the upper layer of roots primarily responsible for nutrient uptake and the lower layer meeting the bulk of the tree's water demands.

Because of the technical difficulty in monitoring root growth *in situ*, most available experimental data on the functional implications of tree root growth and architecture are from destructive harvests or a continuous monitoring via minirhizotron technology of only a portion of the root system. Magnetic resonance imaging (MRI) is an innovative, nondestructive technique in which functional roots can be visualized as a three-dimensional image set within a potting container or intact soil core, and changes in root growth and architecture can be monitored *in situ* over time. The application of this technique to study roots in soil was initially explored over a decade ago. The technique is especially powerful because it provides not only spatial information describing the geometry of root extension through the soil, but it has the ability to distinguish functional from nonfunctional roots *in situ*, as well as the development of water depletion zones in the rhizosphere. The ability of MRI to distinguish functional roots within an undisturbed soil volume provides a unique and powerful tool for examining *in situ* functional implications of root growth and architecture in seedlings over time. New technologies used in combination, such as ground-penetrating radar and stable isotope technology, may provide a better understanding of functional implications of lateral root architecture and distribution of trees in the field.

Fine Root System Turnover: Carbon Costs

The larger woody supportive roots extending from the base of a tree are long-lived (often as old as the tree) and comprise most of the lateral root biomass. However, woody supportive roots account for little of the tree's total root length and metabolic carbon demand. In contrast, fine roots comprise only 5–10% of total root biomass, yet can account for up to 90% of the tree's total root length. In many forests, the annual carbon cost for fine root system production and maintenance may account for 30–75% of net primary productivity, indicating that fine root system carbon demands may represent one of the largest carbon sinks in forested ecosystems. However, estimates for both annual production and lifespan are biased by the methodology and calculations used, making cross-study comparisons difficult. Consequently, we have a poor understanding not only of what controls root lifespan, but how much annual carbon is used to support fine root system (roots + mycorrhizal tips + extramatrical hyphae) growth, respiration, maintenance, nutrient uptake, carbon exudation, and storage reserves. Of these, root system respiration is probably the biggest carbon sink, accounting for up to half of the carbon that is allocated below ground. The high percentage of net primary productivity (NPP) allocated to tree root systems suggests that, although roots may be the most distant carbon sinks from source leaves, they are not the 'poor relations,' having more control over the amount of fixed carbon that is allocated to them than previously thought.

Recent studies using minirhizotron (**Figure 1**) and soil core methodologies suggest that fine root system lifespan is a function of stand characteristics, climate or latitude, tree or stand age, species and ecotype, soil environmental variables such as fertility, water availability, temperature, and soil depth at both stand and microsite levels, carbon status of the tree, timing of root birth, root diameter, root class or type, root order, mycorrhizal colonization, root pathogens, and herbivory. The high variability in fine root system demography (timing of birth and death, and overall lifespan) at the soil microsite level suggests that soil environmental characteristics, in particular, modify stand, seasonal, and genetic controls, and that plasticity is an opportunistic response to a variable resource environment. The lifespan of fine roots in conifers is generally longer than in deciduous trees, ranging from less than 1 to over 20 years, depending upon root order and diameter, with lifespan generally increasing with root diameter.

In contrast to their aboveground ephemeral counterparts (leaves), fine roots of most trees do not appear to have any active separation from the parent in the form of abscission layer. Although lateral branch 'scars' have been observed on parent

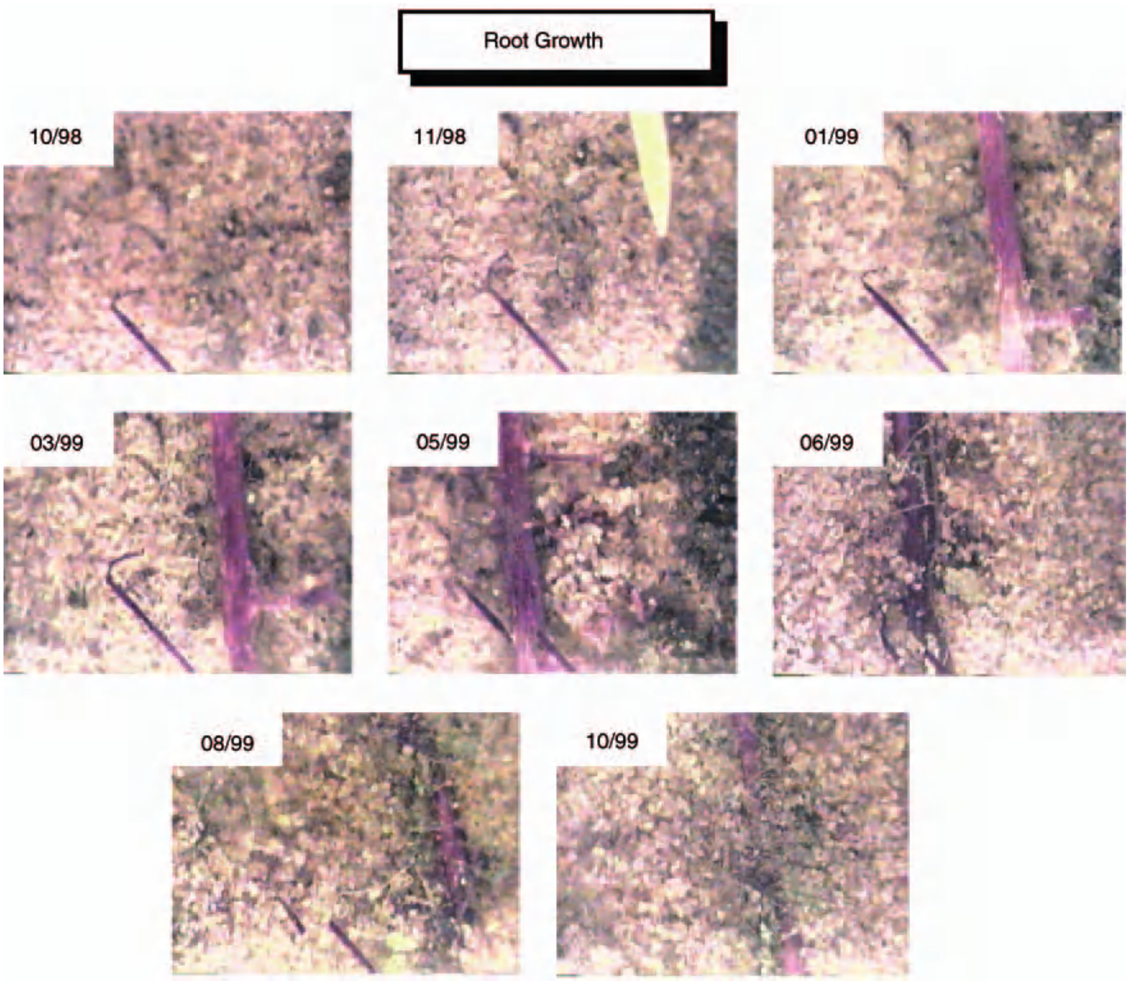

Figure 1 Example of how *in situ* root growth is followed over time using minirhizotron technology. A clear plastic tube is inserted in the ground at a 45° angle, and a camera is inserted into the tube at weekly or monthly intervals, recording images of the same root cohorts growing next to the tube. In the example, a new white root tip appears in 11/98, undergoes browning and secondary growth with bark development, and starts to degrade and disappear by 10/99.

roots in the field, the mechanism causing the mortality of branches is unknown. The development and morphology of the 'scars' have not been examined – the phellogen (bark cambium) of the parent root may simply seal the tissue off once the lateral root branch has started to senesce, as in a wounding response. In trees, suspension of root growth does not necessarily imply that the root is dying. The factors leading to growth suspension (a process called metacutization) may or may not be the same as those that result in root shedding. The mechanism by which roots are shed is poorly understood. It was once thought that roots have a predetermined lifespan and died when their finite supply of carbon was exhausted. However, experimental evidence indicates that root carbohydrate stores are dynamic, varying with season, on a diurnal basis, with age, environmental stress, and tree physiology, and can be replenished throughout the lifespan of the root. Experimental manipulation of the carbon supply has shown that root longevity is strongly influenced by the carbon status of the plant. The internal mechanism is probably one that ultimately restricts carbohydrate transport to the roots and, once root storage reserves have become exhausted, the affected roots will die.

Fine roots appear to have an indeterminate lifespan and die when environmental conditions become unfavorable (e.g., during a long drought), and/or the carbon cost of maintaining roots becomes too great relative to other carbon sinks in the tree. The high root mortality associated with heavy fruiting in *Prunus* and *Citrus*, or with stresses (e.g., defoliation) that can result in carbon shortages in trees may be necessary to maintain whole-tree carbon balance. Atmospheric pollutants such as ozone can affect root growth in trees by reducing the supply of photosynthate available for transport to roots due to inhibitory effects on photosynthesis and leaf growth, and increased leaf carbohydrate demands resulting from accelerated leaf turnover, membrane repair processes, and synthesis of antioxidants. Since most tree–fungal interactions are mediated through a carbon/nutrient exchange within the association, the extent of mycorrhizal formation is particularly sensitive to the availability of carbohydrate from the shoot, and thus, any environmental stress that alters this availability.

Because most forest soils are N- and/or P-deficient, many tree species have coevolved a high dependence on mycorrhizal associations. Mycorrhizae account for 5–80% of total fine root system biomass in conifers, and up to an additional 5–20% of net primary productivity. Hyphae of mycorrhizal fungi have a smaller diameter than roots and cost roughly 10% more to construct, but vastly increase the exploitation potential of tree roots because of their high surface area. In ectomycorrhizae, short roots are covered with a mantle of hyphae from which extramatrical hyphae extend into the soil (**Figure 2**). Over 200 individual hyphae have been observed emerging from a single mycorrhizal tip. An individual hypha may extend more than 2 m and form more than 100 lateral branches. Mycorrhizal associations come at a considerable carbon cost to the tree, but they offer protective benefits against root pathogens, increase the exploitation potential of a root system for immobile nutrients such as phosphate, ammonium, copper, and zinc, protect trees from heavy metals, and help maintain the tree's water status during dry periods.

Although construction costs of mycorrhizal root tips are higher than nonmycorrhizal roots, there is some evidence suggesting that mycorrhizal roots live longer than uncolonized roots on the same tree. This may be due in part to their protective effect against root pathogens, or to the mycorrhizal root's efficient ability to exploit limiting resources from the soil, ultimately increasing carbon flow into mycorrhizal roots. Endomycorrhizal and ectomycorrhizal fungi protect roots from pathogenic organisms possibly by: (1) producing antibiotics and antifungal chemicals (such as phenolic compounds); (2) encouraging the growth of beneficial microorganisms in the rhizosphere; and/or (3) physically protecting the root tips. Unlike woody and fine lateral roots, mycorrhizal roots do not undergo secondary growth, and are more susceptible to pathogenic invasion. Consequently, protecting the root from pathogens is in the mycorrhizal fungi's best interest. Roots of trees brown as they age and undergo secondary growth. In the region immediately proximal to an uncolonized white tip, browning occurs as epidermal and cortical

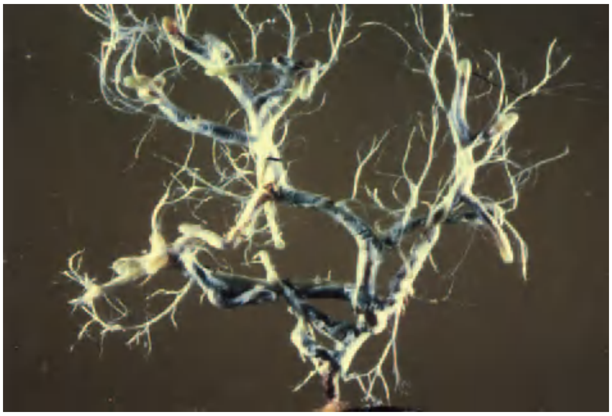

Figure 2 Ectomycorrhizal root of *Pinus* spp. Note extramatrical hyphae emanating from bifurcated root tip. Courtesy of Dr. Larry Peterson.

tissues break down and fill with condensed tannins. The tannin and suberin deposits are believed to serve a protective function against both pathogenic and mutualist fungi in this tannin zone and in tissue that has undergone secondary growth with a well-developed periderm.

Fine Root System Function: Nutrient Uptake

Supplying trees with nutrients is one of the major functions of their root systems. Perennial root systems of trees can modify rhizosphere soil over time, often enhancing the soil chemical environment by increasing its organic matter content and nutrient and water retention capacities, and making it a more hospitable place for beneficial rhizosphere microbes. Although the soil solution is the immediate source of nutrients for plants, it is in equilibrium with nutrients in the solid soil phase. When depleted by roots, the soil solution can be replenished by desorption and ion-exchange reactions. Whether energy is expended in uptake (traditionally referred to as active uptake) and if uptake is under metabolic control are in part determined by whether uptake is with or against the electrochemical gradient and if the ion is transported across the plasma membrane from the root apoplast into the symplasm.

The radial pathways for ion and water movement are extracellular (apoplastic) and intracellular (symplastic). The apoplastic pathway is a system of pores and wall surfaces outside the plasma membranes of epidermal, cortical, and stelar parenchyma cells, with the Casparian band in the endodermis blocking apoplastic passage of ions into the stele. In the symplastic pathway, plasmodesmata provide continuity or passage between the cytoplasm of living cells, offering a pathway of low resistance. In trees, nutrient uptake along the root axis varies with the nutrient. Uptake of some nutrients, such as calcium and iron, appear to be restricted to apical zones, while uptake of others (such as phosphate and nitrate) occur in older tissues of roots, even those undergoing secondary growth. How nutrients are transported across the periderm of fine roots is unknown, but field and greenhouse studies suggest that it does occur.

The ability of tree roots to acquire nutrients from a given volume of soil may vary with species, genotype, degree of mycorrhizal colonization, and rhizosphere microbial populations. Many plant nutritionists prefer to use the term 'acquisition' when referring to nutrient uptake by roots because it emphasizes that more is involved in getting inorganic nutrients into plants than ion transport across cell walls. Nutrient acquisition is the dynamic interaction between plant, soil, and rhizosphere microbial properties, and is a function of root growth and development, overall plant growth, nutritional status of the plant, uptake (kinetic) properties of the root transporter, concentration of nutrient at the root surface, transport properties from the soil to root (including mass flow and diffusion), mobilization of ions by roots (including desorption, dissolution, and hydrolysis of organic compounds), and mobilization by associated rhizosphere microorganisms (including mycorrhizal and bacterial associates). In mobilization, root exudates (H^+, HCO_3^-, reducing agents, chelating agents, and organic anions) are released into the rhizosphere to alter rhizosphere pH, to balance the electrochemical gradient resulting from anion and cation uptake, and to make some ions more available for plant uptake while excluding others (e.g., heavy metals). In addition, enzymes such as phosphatase are released by rhizosphere microorganisms and roots of some tree species, mobilizing organic sources of P that would otherwise be unavailable for uptake.

The nutritional characteristics of seedlings and mature trees, in particular, the nutrient transport systems, and what regulates these systems, are poorly understood. Although genotypic variation in nutrient uptake has been observed in many species, whether the differences are a result of genetically controlled differences in the transport system (e.g., maximum rate of uptake capacity ($V_{\max}$) or affinity of the transporter for the ion (K_m)), or are simply a consequence of differences in growth, is less clear. Studies addressing how growth controls nutrient uptake at the root plasma membrane are scarce. Many studies with herbaceous and woody species (the latter, seedling studies only) have found a positive correlation between nutrient uptake rates and relative growth, suggesting that plant 'demand' is an important determinant of nutrient uptake rate. However, in trees, nutrient storage may be as strong a nutrient sink as growth. Thus, any relationship between growth and nutrient uptake will be confounded by a tree's inherent capacity for storage and nutrient retranslocation from other plant tissues.

The stimulation of physiological uptake capacity and root growth in nutrient-rich zones and their suppression in nutrient-poor zones are well-documented responses to a spatially heterogeneous supply of nutrients in herbaceous species, and more recently, in some woody species. These compensatory responses may enable trees to grow in naturally heterogeneous soil environments by allocating limiting resources in ways that maximize nutrient absorption. Although the stimulation of uptake capacity in nutrient-rich patches is a well-documented response, the mechanism regulating uptake is not fully understood. Split-root experiments with herbaceous species have suggested that, when roots encounter a P-rich zone, uptake capacity not only increases but is maintained, despite high internal P concentrations in those roots. Accumulating evidence with herbaceous plants suggests that shoot 'demand' regulates N and P uptake and loading into the xylem, possibly via cycling of that nutrient in the phloem. Regulation of nutrient uptake in trees is complicated by their perennial long-lived habits, high storage capacities, and seasonal remobilization of certain nutrients, in particular, N and P. Recent studies suggest that organic forms of N and P in trees are more important storage forms of those nutrients than inorganic forms. In roots, immediate assimilation of N and P into an organic form would keep cytoplasmic concentrations of the inorganic form low, maintaining or stimulating continued uptake of that nutrient.

For nutrients that are highly mobile in the soil (e.g., NO_3^-), a high uptake capacity (a physiological response) is an important component of root competition where depletion zones of adjacent roots overlap. However, for immobile ions such as inorganic phosphate (P_i), stimulation of root growth in a nutrient-rich zone might be more critical than an increase in physiological uptake capacity. Phosphate concentrations of most soils are seldom higher than $10\,\mu mol^{-1}$ P. Diffusion of P to the root may limit P_i uptake more than any kinetic parameter controlling influx, i.e., V_{max} and even K_m. In soil-grown plants, higher uptake rates by roots growing in a P-rich zone will soon become limited by low P_i concentrations in the rhizosphere. Highly branched root systems are believed to be more efficient at exploiting soil for immobile ions such as NH_4^+ and phosphate. Consequently, for immobile nutrients, nutrient acquisition is probably most enhanced by increasing the surface area available for absorption via root proliferation, an alteration of root architecture, root hair initiation, or mycorrhizal colonization. In general, the finer the root, the greater the return per unit investment of carbon.

Spatial and temporal nutrient heterogeneity occurs in soils from both natural and managed ecosystems at scales relevant to individual plants; consequently, a plastic response in root physiology and/or in growth would be an important competitive trait. Temporal pulses of nutrients become available to plants during spring snow melt, during autumnal leaf fall, with seasonal rains, etc. Spatial patchiness of supply is common in most soils and greatest for immobile nutrients such as P_i. Soil tillage may increase the size of the patch, but not eliminate it. Fine root proliferation in a nutrient-rich patch is not necessarily cost-effective if the ion is highly mobile, the patch is short-lived, or a competitor occupies the patch more effectively. The degree of root proliferation is influenced by soil concentration and whole-plant demand for that nutrient, and may be species-specific. Root system response to patches may differ among species from different successional stages or nutrient status. For example, fast-growing species from nutrient-rich habitats may exhibit higher plasticity in physiological rates of uptake and root morphology, while slow-growing species from nutrient-poor habitats may conserve carbon by depending upon long-lived root systems, and respond to soil heterogeneity primarily by increasing uptake rates. However, this latter strategy would be less effective for acquiring immobile ions such as P_i and ammonium.

Because of their extensive hyphal network, mycorrhizal associations increase the exploitation potential of a root system for immobile nutrients such as phosphate, ammonium, copper, and zinc. Nutritional benefits of mycorrhizae are most significant in N- and P-deficient soils. Except in the most productive forests, N and/or often P concentrations in the soil generally limit growth of most trees, especially during periods when nutrient demands are high. Consequently, it is not surprising that many tree species, particularly coniferous species, have coevolved a mutualistic dependence on mycorrhizal associations, with development most pronounced in infertile than fertile soils, or where nutrients become available in seasonal flushes. It has been estimated that, when root growth is restricted, external hyphae of endomycorrhizae can deliver up to 80% and 25% of the plant's P and N requirements, respectively, with greater nutritional benefits possible in ectomycorrhizal associations.

Ectomycorrhizae improve host N and P nutrition in deficient soils by accessing organic pools that would otherwise be inaccessible to roots – this is particularly critical in forest ecosystems, where the largest pools of N (and P) are the organic pools. Proteins and other organic N compounds are bound in recalcitrant forms of organic matter or are chemically fixed in clays, which protect them from rapid microbial breakdown. Thus, even though soil N greatly exceeds plant N, many forested ecosystems are N-limited because only a small fraction of total N is available in an inorganic form to plants. However, mycorrhizae allow woody plants to compete with soil microorganisms for organic forms of both N and P. The ability of ericoid and ectomycorrhizae to use protein as a growth substrate is correlated with the production of extracellular acid proteinases in external hyphae, whereas extracellular acid phosphatases and phytase catalyze the release of P_i from organic complexes in the soil. Some tree species, particularly those that are adapted to highly organic, nutrient-deficient soils, appear to have proteinase, phosphatase, and phytase activity in nonmycorrhizal roots. However, because nonmycorrhizal roots are at a spatial disadvantage in competition with microorganisms, activity levels in nonmycorrhizal roots in the field are probably low compared with mycorrhizal roots. It is important to note that, although mycorrhizae increase the supply of N and P available to the host root apoplast, further uptake and transport of these nutrients across the root plasmamembrane into the symplast and ultimately xylem are dependent upon characteristics of the tree's transport system.

In the process of cation and anion uptake, roots of plants excrete protons, bicarbonate ions, and organic acids to their rhizospheres to maintain an electrical charge balance. However, in doing so, rhizosphere pH can be altered. Since the solubility of many nutrients in the soil is pH-dependent, plant roots can enhance solubility of a limiting nutrient (such as P) or decrease the solubility of potentially toxic elements (e.g., Al) simply by altering their rhizosphere pH. Other forms of root exudates associated with nutrient uptake include sugars, amino acids, acid proteinases, phosphatases, and phytases. The efflux of organic substrates from roots such as exudates, mucilages, lysates, and water-insoluble components associated with growth (sloughing of root cap cells and cell wall debris) are a significant source of carbon for microbial and mycorrhizal associates because they are easily assimilated. Colonization by mycorrhizal fungi is generally higher in roots with high (sugar) exudation rates. Microbial use of rhizodeposited carbon substrates has a major influence of nutrient availability in the rhizosphere, with the overall benefits to the tree (and forest) most likely justifying the carbon cost. Unfortunately, our understanding of root exudation, both benefits and costs, is limited by the technological difficulty in measuring this process *in situ*, particularly since any disturbance to the root will alter exudation and respiratory losses.

Fine Root System Function: Water Uptake

Plant water deficit has been implicated more than any other environmental stress as the most important soil parameter limiting carbon fixation, growth, and net primary production on a global scale. Up to 80–90% of the variation in diameter growth in trees can be attributed to variations in rainfall and plant water stress. Excellent reviews on the importance of water on tree growth, the absorption of water and the ascent of sap are provided in the further reading section. This section will focus instead on how tree roots respond to water stress. In dry soils, trees with large canopies and/or poor stomatal control are particularly susceptible to water stress. If water loss via leaf transpiration exceeds water absorption by roots, a tree must regulate its water use, find additional water sources, or find other means of conserving water while meeting metabolic and growth requirements to avoid hydraulic failure. Some hydraulic models have suggested that in the soil → root → leaf → atmosphere hydraulic pathway, xylem of fine roots may be the weak link and act as hydraulic 'fuses' analogous to the protective function of electrical fuses. By localizing any break or cavitation in the hydraulic pathway to the more vulnerable but ephemeral fine roots, trees can minimize root replacement and xylem-refilling costs. The tree can get rid of fine roots that no longer have access to a reliable water supply and allocate more carbon to root growth in soil microsites or horizons with a more abundant and stable supply of water.

Trees are capable of growing in a wide range of soils that differ greatly in their hydraulic characteristics, presenting different challenges to roots trying to extract water from them. For example, coarse soils lose more moisture and conductivity at higher water potentials than fine soils because of weaker capillary forces retaining water in the larger pore spaces. Consequently, plants growing in sandy soils may become water-stressed at relatively high soil water potentials compared to plants in fine soils. Trees can differ considerably in their potential for water extraction, depending upon root-to-leaf ratio, rooting depth and density, degree of mycorrhizal colonization, and their resistance to cavitation. Since water is absorbed via roots and lost via transpiration in leaves, the ratio of fine root area to leaf area must be high enough to avoid hydraulic failure in the rhizosphere (i.e., loss of hydraulic contact between the root and soil), while approaching maximum extraction potential. Not unexpectedly, both nutrient and water deficits in the soil generally lead to similar shifts in whole-tree carbon allocation, i.e., more carbon is generally allocated to root growth to enhance the exploitation potential of fine root systems. However, in coarse soils with high soil porosity, a tree's response to fertilization amendments could compromise its drought tolerance because fertilization generally decreases the fine root-to-leaf area ratio.

In arid environments and in forests that are subjected to seasonal drought, deep taproots and lateral roots growing in lower soil horizons (with a more stable water supply) may support much of the tree's water demands during times of water stress. Upper soil horizons are more subject to large fluctuations in water content than deeper soil horizons because of evaporation and plant water uptake, whereas deeper soil horizons are likely to be buffered by ground water recharge. In arid and semiarid environments, it is not uncommon for taproots to extend 10–20 m into the soil to tap into a more stable water source. Using stable hydrogen isotopic analysis of source water, several researchers have found that even riparian trees in arid and semiarid regions utilize ground water instead of less reliable surface water sources (i.e., stream water and precipitation). This utilization strategy may in part be due to the large fluctuations in stream discharge rates that generally occur during the lifetime of most trees in riparian habitats, helping the trees to survive periods of low discharge during extreme droughts.

Although deep roots provide access to a stable water source, trees are generally more dependent upon fine root growth in the more nutrient-rich upper soil horizons to meet the bulk of their nutrient requirements. Consequently, trees in forests experiencing seasonal drought often experience fine root proliferation in upper soil horizons during the wetter periods to maximize nutrient exploitation of these horizons, but high mortality during the seasonal drought. In less arid environments, this ability to switch among different water sources could increase a plant's ability to compete for limiting water resources when upper soil horizons dry out. Whether nutrient uptake by surface roots in the drier upper horizons continues to occur during this switch to deeper water sources is most likely a function of plant nutrient demands, soil moisture in these upper horizons, soil porosity, the degree of fine root system production, and whether hydraulic lift may be rewetting these drier horizons. In hydraulic lift, water absorbed by deep roots of trees or shrubs passes through roots in the drier, upper soil horizons, and rewets rhizosphere soil during periods when transpiration ceases (generally at night). The process is believed to be primarily passive, driven by root and soil water potential gradients. The 'lifted' rhizosphere water in these upper soil horizons is then reabsorbed the next day and transpired. Hydraulic lift has been demonstrated in tree species occurring in arid, semiarid, and even in some mesic forest environments. The persistence of hydraulic lift over long periods in otherwise dry upper horizon soils could prolong the lifespan and activities of fine root systems in upper soil horizons, improve ion mobility in rhizosphere soil, and maintain nutrient uptake in the more nutrient-rich upper horizon soils.

The root–soil interface, or rhizosphere, is a dynamic environment between the tree root, rhizosphere biota (both microbes and mycorrhizas), and soil environment. With the exception of nitrogen-fixing organisms and mycorrhizae, we know very little about how rhizosphere microbes (including those microbes associated with mycorrhizae) may alter root function and tree growth. It is impossible to study tree root physiology and forest (belowground) ecosystem function without considering rhizosphere biota. With increasing demands for shorter rotations and faster-growing trees in plantations, existing fertility of forest soils must be improved. A greater consideration of how forest management practices alter soil biology and root function could ultimately lead to more efficient tree root systems.

Nutritional Physiology of Trees

P Smethurst, CSIRO Forestry and Forest Products and Cooperative Research Centre for Sustainable Production, Hobart, Tasmania, Australia

Published by Elsevier Ltd., 2004

Introduction

Healthy trees require balanced nutrition to support metabolism and growth. Nutritional physiology is the field of knowledge pertaining to the uptake, utilization, storage, and internal transport and recycling of mineral nutrients. Here, nutritional physiology is described where possible with particular reference to trees and forests. First, a brief historical perspective of major developments in this field is followed by a description of essential nutrients. Finally, some aspects that pertain more to trees than other plant forms are outlined, i.e., nutrient pools and cycling. Trees have somewhat unique nutritional aspects related to their longevity, size and, in common with some other plant forms, the generally heterogeneous and low-nutrient-availability conditions to which some trees are adapted.

History and Key Contributors

The early history of tree physiology is that of plant physiology in general (**Table 1**). As long ago as 2500 BC, writings mentioned the fertility of the land, e.g., in Mesopotamia. Since those times, and up until about the end of the sixteenth century, interest developed in the effect of soil amendments on plant growth. By the end of this period, it was recognized that each soil type provided a different sort of nourishment and that it was affected by amendments and related to the ash content of plants. The next century and a half was characterized by the search for this nourishment, which was referred to as the 'principle vegetation.' This period was accompanied by advances in chemistry that enabled analysis of plant and animal materials. It was not until 1775 that Francis Home's analyses and experiments indicated that there was more than one 'principle.' Field plot experimentation commenced in the nineteenth century around the period when Liebig and Sprengel arrived at the law of minimum, i.e., yield was in direct relation to the single most limiting nutrient and unrelated to the level of others. With further advances in chemical analysis and experimental techniques, the importance of nutrients present in ever lower concentrations became evident from about the midnineteenth century. During the twentieth century, much work was done on the precise role played by each nutrient using ever more sophisticated techniques, e.g., histology, microscopy, chemical purifications and analysis, and isotopic tracers.

Trees were included in some of these earlier studies, e.g., van Helmont studied the growth of a small willow, but specific studies of trees as distinct from other plant forms were not initiated until much later. During the twentieth century, some unique aspects of trees were elucidated, i.e., physiology of woody tissues, nutrient retranslocation, hydraulic properties, and nutrient budgets.

In recent decades, notable developments have occurred in understanding: (1) the processes delivering nutrients to roots; (2) the transport processes across plant membranes (e.g., during uptake by cells in roots and leaves); (3) the detailed biochemistry of nutrients; (4) the genetic and hormonal controls of a plant's response to its nutritional environment; and (5) nutritional effects on photosynthesis and assimilate partitioning.

Nutritional physiology has now reached the stage where individual or small numbers of genes have been identified that control specific nutritional process, e.g., nutrient transport across membranes. There is a remarkable degree of similarity in genetic make-up across the plant kingdom. Hence, processes studied in plants in general are also likely to be applicable to trees, but it appears that subtle differences in the control of genetic expression lead to the main differences in nutritional physiology between trees and other forms of plants.

Nutrients and Their Functional Roles

Carbon, hydrogen, and oxygen are essential for plant growth and are taken up as either CO_2 or water. Other elements essential or beneficial to growth are called mineral nutrients. Each mineral nutrient has one or more specific functions (**Table 2**). Essential nutrients are generally divided into groups based on concentration; macronutrients have concentrations greater than about $10\,\mu mol\,g^{-1}$ dry weight, and micronutrients less than this concentration. Other nutrients considered essential or beneficial for some higher plants are sodium (Na), silicon (Si), and cobalt (Co). There is also interest in selenium (Se), aluminum (Al), iodine (I), and vanadium (V), but further research is needed to clarify their status.

The concentration of ions in cytoplasm is maintained within limits imposed by the conditions required to maintain the integrity of organelles and cellular processes. An abundance of any particular ion will cause more of that ion to be stored at high concentrations in vacuoles or in other relatively nonreactive forms or locations. The distribution of

Table 1 Significant events in the development of tree nutritional physiology

Date or period	*Author(s)*[a]	*Significance*
2500 BC	Various	Fertility of land recognized
900–0 BC	Various	Amendments promoted fertility
1563	Palissy	Ash content of plants represented material removed from soil
1561–1624	Bacon	Unique nourishment in soil
1577–1644	von Helmont	Water was the only nourishment
1627–1691	Boyle	Chemical analysis indicated that plants contained salts, spirits, earth, and oil, which were all formed from water
1604–1668	Glauber	Saltpeter (KNO_3), not water, was the main component of vegetation
1643–1679	Mayow	Seasonal niter variations in soil implied uptake by plants
1700	Woodward	Growth dependent on impurities in water
1741–1820	Young	Pot experiments showed that substances added to soil could promote or retard growth
1775	Home	More than one principle in vegetation
	de Saussaure	O_2 uptake and CO_2 released by plants, but the opposite occurred under light and CO_2 was essential for growth; soil supplied ash and N; roots were selectively permeable to water and salts; plant composition varied with soil and age
1802–1882	Boussingault	Field plot experimentation
1787–1873	Sprengel and von Liebig	C came from the atmosphere, and H from water; alkaline metals needed to neutralize acids formed by plants as a result of metabolic activities; P necessary for seed production; toxicities related to excessive uptake and inadequate excretion; plant analysis led to fertilizer recommendations; law of the minimum
1843–*c.* 1890	Laws and Gilbert	N needed to be added to nonlegumes; soil fertility could be maintained by chemical fertilizers
1860–present	Various	Identification of essential and beneficial nutrients required in very low concentrations
1920	Hoagland	Composition of soil solution related to plant growth
1970–1991	Asher, Ingestad	Concepts and methods linking relative rates of growth, nutrient supply, and uptake
1977, 1984	Nye and Tinker, Barber	Mass-flow and diffusion theory in relation to nutrient supply and uptake
1950–1980	Passiourra	Soil–plant water relations
1970–1990	Jarvis	Forest water relations
1970–1992	Marschner, Mengel and Kirkby	Plant mineral nutrition
1960–1990	Various	Nutrient budgets of forest ecosystems; descriptions of tree root systems
1970–1993	Epstein, Clarkson	Kinetics of nutrient uptake
1991	Nambiar and Fife	Nutrient retranslocation in trees
1990s	Various	Genetic control of nutrition in several simple or agriculturally important plants

[a] Since 1900, it has been increasingly difficult to attribute significant advances to individuals, but some key examples are indicated; significant advances tend now to be marked more by key syntheses of an accumulation of many incremental advances than by major new discoveries.

nutrients within a cell is therefore not uniform but localized into zones of either storage or use. Forms, utilization, and storage of the essential nutrients are summarized as follows.

Nitrogen

Because of the importance of N in plant metabolism, leaf area development, greenness (chlorophyll amount and function), and overall plant growth and yield are strongly dependent on an adequate N supply. Most forest tree species grow well with either NH_4^+ or NO_3^- as their main N source, but a few have a preference for one or the other form. Nitrate is usually reduced to ammonia in the roots, but, with high levels of supply, reduction can be delayed until it reaches the leaves. Ammonia, which damages cellular processes, is rapidly incorporated into amino acids and its equilibrium with NH_4^+ is highly pH-dependent. In leaves, a complex and incompletely understood set of interactions between vacuolar, cytoplasmic, and apoplastic NH_3 and NH_4^+ concentrations occurs such that acceptable concentrations of NH_3 are maintained in the cytoplasm and these processes are mediated by ion-transporters in the membranes between these compartments.

Potassium

Potassium does not bond with C and is present in plant tissues (organic matter) as inorganic K^+. The main role of K is in water relations (turgor control) and in the neutralization of weak acids in the cytosol and chloroplast; enzyme activation is another

Table 2 Mineral nutrients essential for healthy growth of higher plants, including trees

Nutrient	*Adequate foliar concentration for many species (μmol g^{-1} DW)*	*Function*
Nitrogen (N)	1000	Amino acids, proteins, nucleotides, nucleic acids, chlorophyll, and coenzymes
Potassium (K)	250	Osmosis and ionic balance; stomata control; activates many enzymes; phloem loading; plant movement
Calcium (Ca)	125	Cell walls; enzyme cofactor; membrane permeability; regulates membrane and enzyme activities; secondary messenger
Magnesium (Mg)	80	Chlorophyll; activates many enzymes
Phosphorus (P)	60	Energy transport; nucleic acids, several coenzymes, phospholipids
Sulfur (S)	30	Some amino acids and proteins; coenzyme A
Chlorine (Cl)	3	Osmosis and ionic balance; probably photosynthesis reactions producing O
Iron (Fe)	2	Chlorophyll synthesis; cytochromes and nitrogenase
Boron (B)	2	Ca utilization; nucleic acid synthesis; membrane integrity
Manganese (Mn)	1	Some enzymes; chloroplast membrane integrity; O release during photosynthesis
Zinc (Zn)	0.3	Many enzymes
Copper (Cu)	0.1	Enzymatic oxidation and reduction
Nickel (Ni)	0.001	Enzyme function in N metabolism
Molybdenum (Mo)	0.001	N fixation and N reduction

important role. To some extent K can be substituted by other cations (Na, Mg, and Ca) or organic solutes.

Calcium

Calcium in plants is mostly in vacuoles and in cell walls; there is very little in cytoplasm. In vacuoles, Ca is commonly precipitated as insoluble crystals of oxalates, and in some species as insoluble carbonate, phosphate, or sulfate. Apart from storage, and by interaction with cytosolic Ca across vacuolar membranes, vacuolar Ca serves in osmoregulation and as a secondary messenger. In cell walls, Ca is bound to pectate polysaccharides. Very low concentrations of free Ca^{2+} (*c.* 100 nmol L^{-1}) are maintained in cytoplasm, apparently to avoid precipitation with organic phosphates such as adenosine triphosphate (ATP), and to avoid inhibition of many enzyme systems. The role of Ca in enzyme activation seems to be regulated through reversible binding to small proteins such as calmodulin. Ca is also very important to membrane stability, thereby regulating the leakage of cytoplasmic solutes and maintaining compartmentation of cells.

Magnesium

Magnesium is an essential part of chlorophyll, and up to half of total Mg may be in this form. It also combines with ATP to allow it to function in many reactions, and it activates many enzymes needed in photosynthesis, respiration, and nucleic acid synthesis. A substantial proportion of Mg is also involved in the regulation of cellular pH and the cation–anion balance. The concentration of Mg in the cytoplasm is strictly controlled so as not to inhibit photosynthesis and storage is mainly in vacuoles.

Phosphorus

Phosphorus is taken up largely as inorganic phosphate (P_i). The form of P_i, in both the plant and soil, is highly pH-dependent such that the degree of protonation ranges from none (PO_4^{3-}) in alkaline solutions to three (H_3PO_4) in strongly acid solutions. Inorganic P is rapidly incorporated into organic compounds, e.g., sugar phosphates, phospholipids, nucleic acids, and phosphate esters. As P supply increases beyond sufficiency, P_i accumulates in vacuoles and as polyphosphate and phytate.

Sulfur

Sulfur is taken up by roots as SO_4^{2-}, which either accumulates or is reduced to $-S_2$ or –SH forms. Sulfur is an essential component of many metabolic compounds, e.g., some amino acids, enzymes, coenzymes, and cofactors, and the S–S bond is responsible for maintaining many of the folds in proteins. Sulfur is particularly important for photosynthesis and oil production.

Chlorine

Chlorine seems to be important in charge-balance and osmotic functions, and it is concentrated in chloroplasts but does not occur as a metabolite.

Iron

Iron acts as a structural component and cofactor for enzymatic reactions, and it is absorbed and utilized in the Fe^{2+} form.

Boron

Boron uptake is mainly passive as boric acid (H_3BO_3). Boron is involved in development and growth of meristems, but it is poorly retranslocated from older shoots to more actively growing shoots. Boron has a strong affinity for OH^- groups and is thereby mainly involved in cell walls, sugar translocation, membrane transport, carbohydrate metabolism, RNA metabolism, and photohormonal activity. Boron can accumulate in the ends of needles of conifers to very high concentrations, which reflects unidirectional transport during transpiration.

Other Micronutrients

Further details of Mn, Zn, Cu, Ni, and Mo are given in the further reading list; although these nutrients occur at very low concentrations, they are essential for plant growth.

Nutrient Supply

Nutrient uptake by roots accounts for nearly all nutrient uptake under natural and cultivated conditions, but foliar uptake is important under some circumstances, e.g., in densely populated areas where NH_3 gas and other nutrients in dust are significant, in nurseries where nutrients are applied as foliar sprays, and in forest plantations where foliar sprays are used to correct some micronutrient deficiencies.

Nutrients are taken up by roots mainly as inorganic ions from soil solution. The rate of uptake depends primarily on the concentration in the soil solution immediately adjacent to the root. The rate of nutrient uptake is independent of the rate of water uptake, but the concentrations of nutrients at root surfaces depend strongly on soil water content. Soil water content is important because it affects root growth and nutrient transport to the root surface in both the water flux created by transpiration (called mass flow), and the diffusive flux towards or away from the root. The forms of ions taken up by roots differ somewhat with plant species and growing conditions, and they are regulated by a combination of soil processes, the importance of which depends on the nutrient in question. These processes include organic matter mineralization/immobilization, mineral dissolution/precipitation, solid/liquid equilibria, oxidation/reduction reactions, and solid, liquid, and gaseous inputs and outputs (*see* **Soil Development and Properties**: Nutrient Cycling).

Uptake and Translocation

Nutrients move passively between, but external to, cells in the root cortex (apoplastic transport). Uptake, i.e., nutrient movement across the plasmalemma of root cells, can be a passive process, but it is more often an active process requiring energy, because the ion movement is usually against a gradient in electrochemical potential. A variety of mechanisms specific and nonspecific to individual ions are involved in uptake, some of which are well understood, but most of which are only postulated or poorly defined. Some of these mechanisms are restricted to certain groups of related plants but most occur widely across the plant kingdom, including trees.

Some nutrients are transformed soon after uptake, e.g., NO_3^- is often reduced to NH_4^+ and incorporated into amino acids in roots prior to transport to the shoot. Nutrients generally diffuse radially inwards in roots from one cell to the next by crossing plasmodesmata (**Figure 1**). Water can also pass from cell to cell via a transcellular path, but this is unlikely to be an important path for nutrients. Via plasmodesmata, nutrients pass the casparian strip, which largely blocks apoplastic transport at the endodermis, and they continue on to the cytoplasm of the xylem parenchyma cells. A mainly active process then releases nutrients into xylem vessels for passive transport towards the shoot. Transport in xylem sap involves exchange with cell walls and surrounding living cells. Coniferous trees lack continuous vessels but instead have tracheids which somewhat impede the flow upwards. However, they allow intensive transfer of solutes between xylem and phloem. Xylem-to-phloem transfer is important because water transport is directed mainly towards zones of high transpiration; these are not the zones of high nutrient demand because their main growth phase has passed. Phloem-to-xylem transfer occurs but its importance is largely unknown. The proportions of xylem and phloem transport depend on the ion of interest and other conditions.

Nutrients diffuse from the xylem into the apoplasm of the target tissue, which is usually a leaf. Transfer into the cytoplasm is analogous to uptake in roots and hence it is usually active. The uptake of foliar-applied nutrients is by the same mechanism if the nutrient has been able to pass the cuticle which is waxy and poorly pervious in some species.

Nutrient Pools and Internal and External Cycling

One key difference between trees and most other plant forms is their lifespan. The oldest trees are

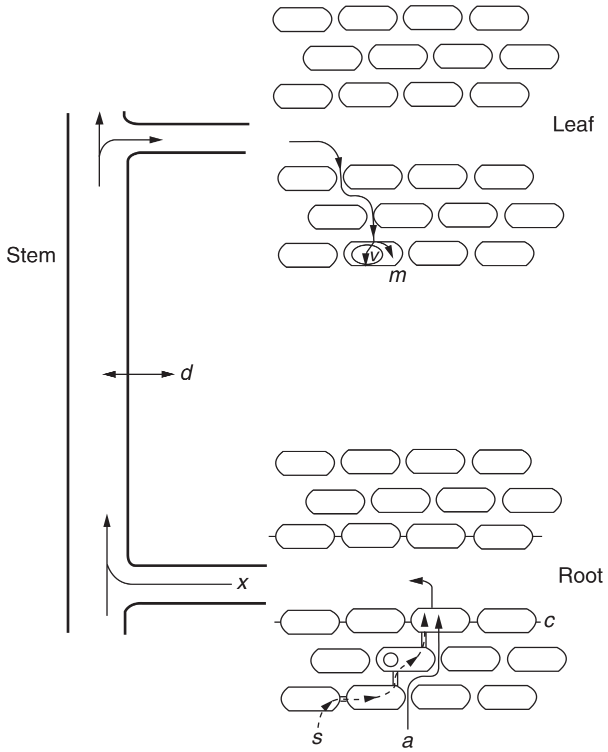

Figure 1 Simplified diagram of the path of nutrients from soil solution to utilization and storage in leaves. Nutrients move through roots external to the plasmalemma of cells, i.e., apoplastic (*a*) pathway, or are taken up across these membranes and transfer to adjacent cells via plasmodesmata, i.e., symplastic (*s*) pathway. Symplastic transport may include transformation and intermediate storage, e.g., in vacuoles (*v*). Apoplastic passage to the xylem is largely blocked by an impermeable casparian band (*c*) and suberized cell walls. Once released to the xylem stream (*x*), nutrients are transported towards the shoot, but during transport they may diffuse (*d*) reversibly into adjacent tissues, e.g., phloem and sapwood. In leaves, nutrients continue to be carried in veins and into cell walls via diffusion and mass flow of the transpiration stream. Uptake into leaf cells then occurs across the plasmalemma, followed by metabolic use (*m*) or storage, e.g., in vacuoles (*v*). Some nutrients are involved in symplastic–apoplastic exchange during the life of a leaf, and withdrawn to other tissues before or during senescence.

several thousand years old, and even most production forests are one or more decades old when harvested. In contrast, most of our knowledge about nutritional physiology has been developed from studies of species that live for only a year or two. Because of the longevity of trees, some aspects of nutrition develop that are not as obvious in ecosystems based on shorter-lived species. Of particular note are the low concentrations of nutrients in wood compared to other tissues, the large pools of nutrients potentially held in trees, the large proportion of annual nutrient supply that can be satisfied by internal nutrient recycling, and the importance of external nutrient cycling in older forests. Some of these points are illustrated by an examination of the budgets of various nutrients for a typical 50-year-old, high-productivity eucalypt forest (**Table 3**) and a typical 16-year-old loblolly pine (*Pinus elliottii*) plantation (**Table 4**), and for K in 10- and 40-year-old black pine (*P. nigra*) plantations (**Figure 2**).

In recent decades, substantial knowledge has accrued on nutrient budgets for a variety of forest ecosystems and the processes controlling the rates of transfer of nutrients between pools has been greatly clarified. For example, it used to be thought that nutrient retranslocation from nonsenescing foliage was a response to low nutrient availability, i.e., under nutrient-stressed conditions the proportion of nutrients retranslocated would be increased, even if the total amount was less when compared to less nutrient-limited conditions. However, in many species, it seems retranslocation is driven by the rate of growth, such that the total amounts and proportions of nutrients (on a whole-tree basis) required for new growth that are met by nutrient retranslocation increases with growth rate, which in turn is often positively correlated with external nutrient supply. Relatively fertile conditions can stimulate growth to such an extent that external nutrient supply cannot meet the demand of an expanding canopy. Nutrients are then withdrawn from leaves or needles lower in the canopy that remain alive and retranslocated to zones of higher demand. Hence, retranslocation is demand-driven. A separate mechanism drives nutrient withdrawal from senescing leaves such that the proportion of nutrients in individual leaves (or needles) withdrawn prior to senescence will depend on genotype, nutrient status, and other environmental factors. This process is most pronounced in deciduous trees, but it is also significant in evergreens. Leaf senescence is triggered by seasonal and microclimatic effects related to reduced light availability or temperature, and in some cases is under hormonal control (e.g., auxins and cytokinins). Leaf senescence and nutrient withdrawal to various degrees can also be triggered by water or nutrient limitations or toxicities (e.g., of salt or Al) or shading.

In contrast to non-woody species, sapwood provides trees with a transient store of some nutrients under some conditions. For example, N can move into sapwood during periods when uptake greatly exceeds the requirement for new growth, and later be withdrawn when nutrient supply–demand conditions are reversed.

Conclusions

Interest in soil fertility and plant nutrition can be traced back several millennia, and several centuries

Table 3 Mass of organic matter and amounts of nutrients in pools and transfers in a typical eucalypt forest of high productivity aged 50 years

for trees *per se*, but the rate of improvement in our scientific understanding of nutritional physiology has increased markedly in recent decades. The growth, maintenance, and reproduction of plants requires 14 nutrients supplied mainly from the soil through a variety of uptake mechanisms in roots. Transport from the roots, via xylem to leaves, involves a variety of passive and active mechanisms to move nutrients between zones of different concentration. Ultimately, nutrients are utilized in specific metabolic roles, or, if in excess, are generally reversibly stored in particular zones of the cell or less

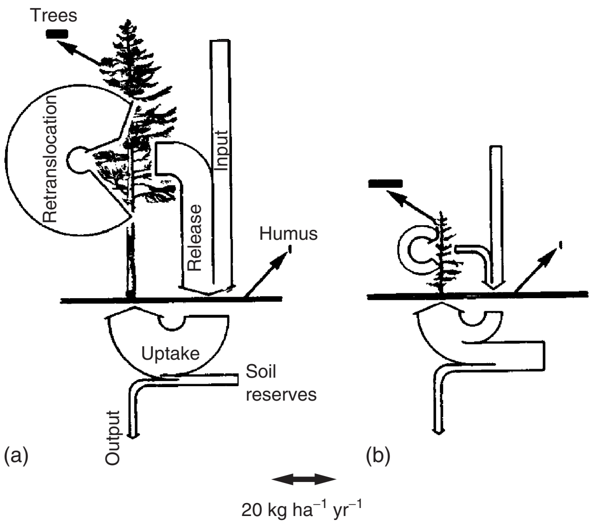

Figure 2 Patterns of *K* cycling in (a) 40-year-old and (b) 10-year-old *Pinus nigra* plantations. This diagram illustrates the change in sources and sinks of nutrients as a tree grows. The older trees here had about half the annual requirement for K as the younger trees. Most of this requirement was met by retranslocation and cycling through the litter layer, in contrast to a younger tree that relied heavily on soil reserves. London: Academic Press.

reactive forms. Nutrient retranslocation occurs to meet the demands of an expanding canopy and some nutrients are conserved by withdrawal from leaves during senescence; these processes are quite pronounced in trees. Numerous physiological mechanisms are under some degree of genetic control, the elucidation of which will be a major focus of investigation for the next few decades. In contrast to non-woody plants, trees can to some extent store nutrients in sapwood under very high nutrient supply regimes and later withdraw these nutrients during periods of insufficient supply from soil.

Canopy Processes

R O Teskey, University of Georgia, Athens, GA, USA

Introduction

A forest canopy is the aggregate of the leaves of trees that typically forms a layer overhead. It may also include the leaves of vines, epiphytes, and parasitic plants when they are present. A canopy can have large gaps, allowing plentiful light to reach the forest floor, or be closed and dense, with almost no light penetrating below it. The primary purpose of the forest canopy is to capture solar energy needed for photosynthesis. A number of factors can reduce the potential carbon gain of forests by preventing the achievement of a high leaf surface area in the canopy or by reducing the rate of net photosynthesis of leaves. A forest canopy also releases a large amount of water into the atmosphere in the process of transpiration. The amount of water transpired from a forest is closely associated with the leaf surface area of the canopy.

Canopy Photosynthesis

Within-Canopy Environmental Characteristics

Attributes of the canopy are the sum of the functions of all the leaves that make up the canopy. Through the process of photosynthesis each leaf creates carbohydrates from atmospheric carbon dioxide (CO_2). Leaves within a canopy photosynthesize at different rates, depending on available resources and microclimate at specific canopy positions. The most important rate-controlling factors are solar radiation, temperature, CO_2 concentration, vapor pressure deficit (an index of the dryness of the air calculated from relative humidity and temperature), available soil moisture and acquired nutrients. During the daytime, microclimatic conditions, temperature, humidity and CO_2, can vary within the canopy, with higher temperatures, lower humidity and near-atmospheric CO_2 concentrations occurring near the top of the canopy, and lower temperatures, higher humidity and lower CO_2 concentrations occurring near the bottom of the canopy. These trends tend to reverse at night. If the canopy is open, allowing wind to penetrate throughout, there is little appreciable difference in temperature, humidity, or CO_2 concentration among canopy positions.

Of the environmental factors affecting photosynthesis, the one that varies to the largest extent within the canopy is solar radiation. Only a portion of the solar spectrum is used in photosynthesis, between wavelengths of 400 and 700 nm. This portion of the spectrum is called photosynthetically active radiation (PAR). Most of the radiant energy found in longer wavelengths, i.e., heat, is reflected or transmitted through the leaves, while most of the PAR is absorbed by the leaves. This creates variations in light quality above, within and below the canopy. Often 80–95% of the incoming PAR is absorbed in a well-developed forest canopy, allowing little solar energy to pass through to the plants in the understory. Plants below the canopy respond to this light stress by developing thin leaves that efficiently photosynthesize in low light conditions (high quantum yield) and have growth patterns that are characterized by long internode lengths that minimize mutual shading and shading from competing plants.

The amount of PAR received at different depths within the canopy can be approximated using Beer's law:

$$I_z = I_0 \exp(-kL_z) \tag{1}$$

where I_z is the average solar radiation at height z within the canopy, I_0 is solar radiation above the canopy, k is the light extinction coefficient, and L_z is the leaf area index for that portion of the canopy above height z. The light extinction coefficient varies with species and forest type. Typical values of k for coniferous forest canopies range between 0.4 and 0.65, and between 0.5 and 0.8 for broadleaf deciduous forest canopies. In most cases, in coniferous and deciduous forests the value of k falls between 0.5 and 0.6. The pattern of solar radiation through hypothetical forests with different values of k (**Figure 1**) illustrates the effectiveness of light absorption by the canopy and the reduction in available light with depth within the canopy. It should be noted that the application of Beer's law assumes that the canopy consists of leaves that are randomly distributed throughout the canopy. This is never the case in actual forests because the foliage is always arrayed on branches and often clumped near the end of the branch. Clumping is particularly evident in conifers and this results in more light transmission through the canopy than would be predicted by Beer's law. In coniferous forests, discrepancies of 30% or more in calculated light transmission through the canopy can be attributed to nonrandom spatial variation in the foliage. This error is often lower in deciduous species.

Within-Canopy Foliar Characteristics

Leaf morphology changes dramatically in most tree species as a consequence of changing light conditions from the top to the bottom of the canopy. The most limiting factor to photosynthesis at the bottom of the canopy is solar radiation, and leaves at that level show an acclimation to this limitation by developing a high specific leaf area (SLA, defined as the surface area-to-mass ratio of a leaf) meaning they are very thin, often with only two or three cell layers capable of photosynthesis. This improves their ability to efficiently fix carbon at low light levels, and the photosynthetic light compensation point is lowered, although the maximum light saturated rate of photosynthesis is also reduced. Leaves near the top of the canopy are not light limited, but are often water- and heat-stressed. In this portion of the canopy the leaves have multiple photosynthetic cell layers in the mesophyll, and therefore a lower SLA, are smaller, reducing the boundary layer, and can

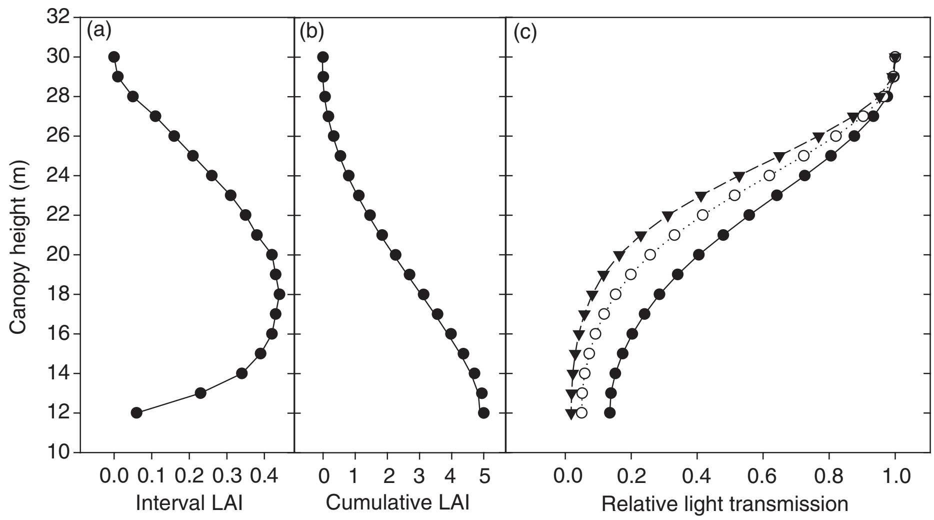

Figure 1 (a) Projected leaf surface area profile by 1-m intervals within a typical (hypothetical) forest canopy with a leaf area index (LAI) of 5 ($m^2 m^{-2}$). (b) Cumulative LAI with canopy depth. (c) Relative light transmission through the canopy calculated from Beer's law (eqn [1]) assuming light extinction coefficients of 0.4 (triangles), 0.6 (open circles), and 0.8 (filled circles).

have lower stomatal density, all attributes that make them more able to conserve water and/or dissipate heat. In broadleaf species, leaf orientation also tends to shift from canopy top to bottom, with leaves in their most horizontal position at the canopy bottom and in their most vertical position at the top. This improves light absorption at the bottom of the canopy and reduces the heat load on the leaves at the top of the canopy.

Between the top and bottom of the canopy a continuous gradient of changing SLA usually can be found as the microenvironment changes. Values of SLA can double from the top to the bottom of a forest canopy. The SLA of a leaf is inversely related to the daily sunlight under which the leaf developed within the canopy. The light saturated rate of net photosynthesis of the leaf is also inversely correlated to its SLA. On the other hand, there is a direct positive relationship between SLA, the nitrogen content of the leaf, and physiological activity. Higher levels of nutrients, in particular nitrogen, are found in regions of the canopy that receive the highest amounts of solar radiation, and also have the highest SLA, i.e., the leaves found at the tops of trees and the upper third of the canopy. Most, if not all, quantifiable aspects of leaf metabolism decrease from top to bottom of the canopy, including maximum rates of photosynthesis and respiration, number of mitochondria and chloroplasts, and chlorophyll, starch, and sugar contents.

Leaf Area Index

A forest canopy consists of thousands of individual leaves arrayed in complex patterns. Leaf shapes, sizes, and longevities as well as branching patterns vary tremendously among tree species. However, there are effective ways of making useful comparisons between forest types at the scale of the canopy by reducing variation in measurements of these attributes. One of the most widely used bases for comparison of canopies is the measurement of leaf area index (LAI). To calculate LAI, the surface area of the leaves is summed and divided by the ground surface area that they occupy. Both areas are measured in the same units, e.g., $m^2 m^{-2}$, so LAI is dimensionless. The 'projected' leaf area of the leaves in the canopy is often used to determine LAI. Projected leaf area is the surface area of a leaf that intercepts a direct beam of light. In the case of a flat leaf of a deciduous broadleaf species, it is simply the area of one side of the leaf. For more complex leaf shapes, such as conifer needles, it is the area of the leaf that intercepts a direct beam of light projected onto a flat surface. Projected leaf area provides a measure of the surface area of leaves that can absorb direct beam solar radiation. The use of projected leaf area as the basis for comparison among species minimizes variation by reducing the myriad complex leaf shapes into the effective absorbing surface area. Occasionally when comparisons of LAI are made, total surface area of leaves (all-sided leaf area) is used instead of projected leaf area. The reader is cautioned that these values of LAI will be two to four times greater than those based on projected leaf area. The difficulty in accurately measuring leaf area in conifers has sometimes led to the substitution of leaf biomass for leaf area. This is suitable for comparisons made within a species, but can introduce unwanted variation when comparisons are made across species with a wide range of SLA.

When maximum LAI values (projected leaf area basis) of forests growing in fertile and moist conditions are compared, they are typically between 5 and 7. Assuming that 95% of the incoming solar radiation is the practical maximum that can be absorbed by a canopy, then with a light extinction coefficient (*k*) of 0.5, using Beer's law (eqn [1]) full interception would occur at LAI = 6. If the value of *k* was 0.4 or 0.8, then the LAI value for full interception would be 7.5 and 3.8, respectively. Although unusual, occasionally LAI values for forests have been reported to be substantially higher, in the range of 10 to 20. One possible explanation is that in these cases the foliage was highly clumped. Clumping has the effect of reducing the effectiveness of interception of solar radiation by individual leaves. In turn, to maximize intercepted radiation the trees would have to produce substantially more leaves than in a less clumped forest canopy.

As a young forest approaches canopy closure, its maximum leaf area will exceed the stable LAI value. In favorable conditions this transient LAI could temporarily exceed 7. This reflects the high degree of competition between trees that occurs at this point of stand development. However, such a high LAI cannot be sustained and the highest long-term average LAI is usually around 5. Lower maximum LAIs are very common, and reflect site resource limitations to tree growth. The LAI of a forest is not constant, and will tend to fluctuate yearly due to differences in seasonal weather patterns, drought, or perturbations that the forest may experience such as fire, insect infestation or disease. If the stress is severe, the LAI will be reduced within the year. Drought and insect defoliation, for example, can have this effect. However, more commonly, a stress or decrease in resource availability will result in a lower leaf area in the subsequent year. Similarly, an increase in resources will increase the LAI in the current year in a forest that contains tree species with recurrent or continuous flushing patterns, and will cause an increase in LAI in the following year in all species. The increase in LAI in the subsequent year is due to the development of more leaf initials within the dormant period bud and the acquisition and storage of resources, particularly carbohydrates and nutrients, to support the additional leaves.

Intercepted Solar Radiation

For a given species, LAI and leaf biomass have strong positive correlations with most measures of stand growth or productivity across sites or treatments. These same relationships, while generally remaining positively correlated, are more variable when comparisons are made among species because LAI does not adequately account for how effectively solar radiation is absorbed by the canopy. Absorption is a function of the total amount of leaves in the canopy and how those leaves are displayed. The latter is determined by canopy and branch architecture, and leaf distribution and orientation. The depth of the canopy, branch pattern and orientation, leaf size, shape and arrangement on the branches, and overlap among leaves and branches within the canopy all affect how much solar radiation a canopy can absorb.

The quantity of solar energy absorbed by the canopy determines to a large extent how much carbon is gained through photosynthesis, and this in turn, defines the productivity of the forest. A generalized relationship between absorbed radiation and forest growth can be seen in **Figure 2**. This diagram illustrates that the general relationship between stand growth and the amount of intercepted solar radiation is usually linear. Over short time periods, for example days or weeks within a single growing season, there could be substantial nonlinear variation in this relationship, but over longer time

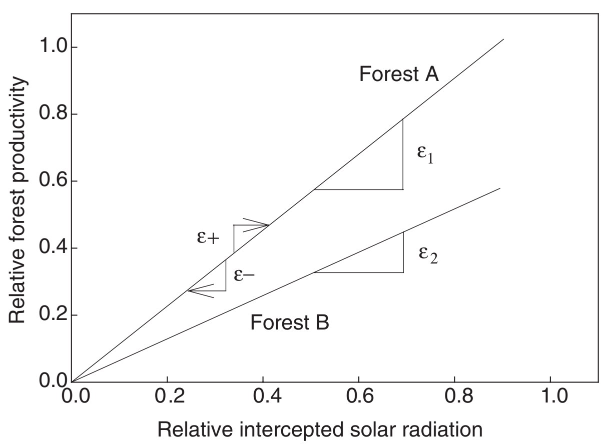

Figure 2 Idealized relationships between intercepted radiation and forest productivity. The two lines represent forest types with a high dry matter : radiation quotient (ε_1, Forest A) and a low dry matter : radiation quotient (ε_2, Forest B). When comparing between forest types, a higher canopy photosynthesis (ε_1 versus ε_2) results in greater carbon gain per unit of intercepted radiation. However, within the same forest type short-term changes in ε caused by increased resource availability ($\varepsilon+$) or environmental stress ($\varepsilon-$) produce adjustments in canopy leaf area, so that over time forest productivity for a given forest type tends to remain linearly related to intercepted radiation. Adapted and modified with permission from Jarvis PG and Leverenz JW (1983) Productivity of temperate, deciduous and evergreen forests. In: Lange OL, Nobel PS, Osmond CB, and Ziegler H (eds) *Physiological Plant Ecology, vol. 4, Encyclopedia of Plant Physiology New Series 12D*, pp. 233–280. Heidelberg, Germany: Springer-Verlag.

periods, such as growing seasons and years, variation is greatly reduced and a linear relationship becomes evident. The linear nature of this relationship holds within and across species, which is an indication that it is a more robust measure of canopy carbon gain than LAI. Different types of forests and species will produce relationships with different slopes due to inherent differences in physiological processes, including photosynthetic capacity of the leaves.

The slope of the relationship, ε, has been termed the dry matter : radiation quotient and is determined by a wide range of factors. It is important to remember that the term ε is an amalgamation of many important physiological attributes that contribute to growth, including photosynthesis, respiration, carbon allocation and plant responses to environmental stresses. The maximum potential value of ε can be estimated based on the following information: (1) a tree requires 20 mole quanta of solar energy to assimilate a mole of CO_2, (2) there are 2.3 mole quanta per MJ of absorbed solar radiation (or 4.6 mole quanta per MJ of PAR), (3) the mass of a mole of CO_2 is 44 g, and (4) an estimated conversion factor from mass of CO_2 to mass of dry matter is 0.5. The maximum potential conversion of solar radiation to dry matter in a plant is $(2.3/20)(44 \times 0.5) = 2.5\,\mathrm{g\,MJ^{-1}}$ (total solar) or $5.0\,\mathrm{g\,MJ^{-1}}$ (PAR). Typical values of ε for crops range from 1.1 to $1.7\,\mathrm{g\,MJ^{-1}}$ (total solar) while for forests values have been reported from 0.2 to $1.4\,\mathrm{g\,MJ^{-1}}$. This range in reported values indicates that the dry matter : radiation quotient of forest canopies of different species or species mixtures can vary greatly. However, the ε for a single species or a group of species, on a single site or on similar sites, will be nearly constant, because, in large part, the pattern of carbon allocation among leaves, roots, and stem is controlled principally by soil resources, especially nitrogen and water availability, and the genetic characteristics of the species. Likewise, the inherent photosynthetic and respiratory capacities of the foliage and woody tissues are fixed.

On a single site, in any given year, conditions that affect photosynthesis of the leaves will vary. When conditions are less favorable, the trees allocate more carbon to roots, and, because there is less carbon remaining for leaves, fewer, or smaller, leaves are produced. When conditions are more favorable for photosynthesis, more, or larger, leaves, are produced, and less carbon is allocated to the root system. In the short term, this produces temporary shifts to higher or lower values of ε. However, over longer time periods, such as a growing season or year, the changes in carbon availability and proportions allocated for root and leaf growth result in a strongly linear relationship between intercepted radiation and aboveground stand growth.

Since we know that many factors affect the rate of photosynthesis of leaves, why is intercepted solar radiation so strongly correlated with forest productivity? While there is still more research needed to fully understand these phenomena, the current explanation is that tree species in general utilize a similar strategy for growth and survival, which is to grow more leaves when more resources are available, rather than increase the photosynthetic capacity of a fixed amount of leaves. For example, on droughty or low-fertility sites, the carbohydrate and nutrient supply is limited, allocation favors roots, and fewer leaves are produced; thus, the amount of solar radiation intercepted is low. On resource-rich sites, available carbohydrates and nutrients are used to create more leaves, which in turn intercept more radiation and produce higher levels of carbohydrates for export to the rest of the tree. An individual species that is naturally occurring or planted across a wide variety of sites can often be defined by a single line (**Figure 2**) that represents its long-term productivity as a function of intercepted radiation. In other words, ε remains relatively constant for a species. On resource-rich sites, more leaves are produced in the canopy and more radiation is absorbed by them, while on the resource-poor sites, fewer leaves can be produced, and growth is proportionately reduced.

Measurement Approaches

Canopy carbon gain has been estimated in a number of ways. It has been inferred from changes in biomass, modeled by integrating the rates of physiological processes over time, and measured by micrometeorological techniques. The recent development of relatively reliable and robust instrumentation for eddy covariance measurements (a micrometeorological technique that measures the CO_2 concentration in eddies of air allowing the calculation of the flux of CO_2 into and out of an ecosystem) has made this an important method for estimating total net CO_2 uptake or release by a forest ecosystem. Usually eddy covariance measurements are only made above the canopy, so this technique cannot discern where within the ecosystem (soil, plants, animals) the CO_2 is being absorbed or released. As a result, unless it is combined with more measurements, it only provides an estimate of net fluxes of all photosynthetic and respiratory activity. However, this is a very useful approach for characterizing whole ecosystem carbon dynamics, and provides insight into canopy processes. One result of these measurements has been to establish that the rate of CO_2 uptake of canopies in response to PAR is very similar to the light response curves of individual leaves.

Transpiration

All plants lose water through their stomata as they absorb CO_2 from the atmosphere. When the stomata are open during the day, a tremendous amount of water can be lost from the forest canopy. Water loss through stomata is linearly related to stomatal aperture, which is estimated by measuring stomatal conductance. The average stomatal conductance of all the leaves in the canopy is called canopy conductance. Light in visible wavelengths is required for the stomata to open. As a result, transpiration occurs mostly during daylight hours. Only about 5–10% of water loss occurs at night. This loss results from stomata that do not always close fully, particularly as leaves age, and a small amount of diffusion through the leaf cuticle.

Canopy water loss depends on soil water availability, canopy leaf area and environmental conditions, especially PAR and vapor pressure deficit. Vapor pressure deficit (VPD) describes the dryness of the air, and more specifically, the potential gradient for water movement from the leaf to the atmosphere. A high VPD indicates that there is a large water vapor gradient from the leaf to the atmosphere that will cause rapid diffusion of water from the leaf when the stomata are open. The rate of transpiration is closely correlated with VPD, especially under conditions of plentiful soil moisture. Mitigating factors that cause the stomata to close, such as leaf water stress, modify the rate of transpiration and its relationship with VPD.

Estimating Evapotranspiration

Evapotranspiration (E_t), i.e., the combined total of transpiration and evaporation, from a forest has been estimated in many ways. Micrometeorological methods such as the Bowen ratio (the ratio of sensible heat flux to latent heat flux computed from vertical gradients of air temperature and water vapor) and eddy covariance, can be used to estimate evapotranspiration from a forest. Physiologically based methods, including sap flux, porometry, and lysimeters, as well as stream flow from catchments and soil water depletion have been used as well. One of the most proven and widely used approaches is the Penman–Monteith equation:

$$E_t = sA + (c_p \rho_a D g_a)/\{\lambda[s + \gamma(1 + g_a/g_c)]\} \qquad (2)$$

where s is the rate of change of saturation vapor pressure with respect to air temperature, c_p is the specific heat of dry air of density ρ_a, D is vapor pressure deficit of the air, g_a is boundary layer conductance for water vapor, λ is the latent heat of vaporization of water, γ is the psychrometric constant, and g_c is canopy conductance.

In the case of aerodynamically rough canopies, such as in coniferous forests and other forests made up of small leaves, g_a is usually large in relation to g_c. The small leaf size and large boundary layer conductance results in close coupling between leaf and air temperatures, allowing the equation to be simplified to:

$$E_t = (c_p \rho_a / \lambda\gamma) D g_c \qquad (3)$$

Particularly in the simplified form, the dependence of E_t on VPD and canopy conductance is clear. For conifer and other narrow-leaf tree canopies, stomata play an important role in controlling the rate of transpiration. In contrast, in broadleaf canopies, transpiration is much more closely related to the input of solar radiation, and less dependent on canopy conductance. However, there is no notable distinction between daily or hourly maximum rates of E_t in canopies of coniferous, deciduous, or mixed species stands.

Daily Evapotranspiration

Estimates of E_t of forests range from less than 1 to as much as 7 mm day^{-1}, although maximum values are usually reported in the range of 5–6 mm day^{-1}. The low values will occur during drought, or conditions of high atmospheric humidity or low solar radiation, or in forests with very low LAI. The high values indicate that forests can be very effective at absorbing solar radiation, and very well coupled to the atmosphere, because these represent values that are at the theoretical maximum for evaporation. In full sunlight a maximum of 380 calories day^{-1} of energy are available at the earth's surface. As 570 calories are required to evaporate 1 cubic centimeter of water, this is equivalent to a maximum of 6.6 mm day^{-1} of evaporation. Although LAI values indicate that leaf surface area is many times larger than the unit ground surface, water loss cannot exceed that of an equal surface area of water receiving the same amount of energy. Values of E_t that exceed the maximum rate are uncommon, but can occur if an additional source of energy is available, for example from advection.

In summary, when considered from a physiological perspective, a forest canopy is a system for harvesting solar energy. Leaves are displayed throughout the canopy for this purpose as efficiently as possible, within the constraints of the morphology and branch architecture of the tree species that contribute to the canopy. If unconstrained by a lack of site resources for growth, the canopy captures a very large proportion of the sun's available energy. Due to the close coupling between resource acquisition and canopy development, LAI and intercepted radiation are excellent indices of forest productivity. This is because improvements in resource acquisition that increase canopy photosynthesis in the short term lead quickly to increased leaf growth. Likewise, when fewer resources are available, decreased canopy carbon gain causes a subsequent reduction in leaf growth. Forest canopies can also lose appreciable amounts of water through the process of transpiration. Canopy transpiration is positively correlated with LAI, canopy conductance, and available energy. At high values of LAI, the rate of transpiration of forest canopies is comparable to that of open water, providing another example of the effectiveness of forest canopies in absorbing solar energy.

Stress

R H Waring, Oregon State University, Corvallis, OR, USA

Introduction

Throughout their lives trees are exposed to a range of stressful conditions. If they are to survive, they must adapt by modifying their metabolism (physiology), cellular structure (anatomy), and form (morphology). Adaptation to a wide range of stresses, however, limits growth and the ability to compete in more favorable environments. The trade-offs are important to recognize in selecting trees that might grow best in a particular environment and in modifying the environment to reduce stressful conditions.

The nomenclature for defining physiological stress is derived from physics with the idea that a force upon a body causes a strain in the opposite direction. The strain is elastic if completely reversible following removal of the stress, or plastic if only partly reversible. How long it takes a plant to recover following exposure to a particular stress or whether the stress is fatal are questions that can be answered by careful observation. Survival following exposure to one stress, however, often increases a plant's susceptibility to another. On the other hand, repeated exposure to one kind of stress can lead to adaptations that increase a tree's ability to tolerate or to avoid the stress.

A brief analysis is presented below of the kinds of tolerance and avoidance mechanisms that trees have evolved to withstand specific stresses. To demonstrate how seasonal variation in climatic conditions imposes stresses on common processes, such as photosynthesis, a simulation model is introduced, and the performance of pine and eucalyptus is compared in an environment where neither species is native. Then, some general biochemical and structural indices of tree stress are introduced. These stress indices change not only in response to variation in climate and soil conditions but also in response to competition among trees. The stress indices are useful in assessing tree susceptibility to attack from insects and disease. In the last section, procedures for separating climatically induced stress from other types are discussed that apply at the landscape level.

Tree Adaptations to Specific Stresses

Trees may alter their biochemistry to tolerate a particular stress that occurs infrequently but the metabolic cost is high for such temporary adjustments. Frequent exposure to a particular stress leads to avoidance mechanisms that may permanently change a tree's physiology, anatomy, and morphology. Tolerance and avoidance mechanisms differ depending on the kind of stress but both types of adaptations may reduce the amount of resources available for above-ground growth under more favorable conditions. If an environment is sufficiently harsh, however, trees that can adapt encounter little competition. Examples of tolerance and avoidance mechanisms are presented in this section in relation to radiation, drought, flooding, temperature extremes, mechanical forces, toxic compounds, and nutrient deficiencies.

Radiation

Solar radiation includes a wide spectral range in wavelengths. The sun's ultraviolet (UV) radiation (200–400 nm) can destroy chemical bonds, whereas its visible light (400–700 nm) is essential for photosynthesis, and its infrared radiation (700–2500 nm) heats plant and soil surfaces. Trees produce a series of phenolic compounds that absorb particular parts of the UV spectrum or they may adapt by producing waxes and whitish hairs on leaf and stem surfaces that reflect a large amount of radiation.

Trees growing in shaded environments can increase photosynthetic pigments that absorb light, such as chlorophyll. Leaves in the upper canopy, however, are exposed to varying light intensities, sometimes greater than their photosynthetic capacity. Under such conditions, many species have evolved the ability to generate special pigments that cycle from absorbing to reflecting modes throughout the day. The shapes of leaves exposed to high radiation are generally smaller, more dissected, and less directly oriented to absorb sunlight than leaves adapted to more shaded conditions. Leaf thickness also generally decreases from the top to the bottom of a forest canopy in response to available light.

Drought and Flooding

Drought and flooding represent extremes in water availability. To avoid drought, vascular plants have evolved the ability to grow roots that can extract water from >10 m depth in the soil and transport it through a series of connected, dead, woody (lignified) cells to leaves situated more than 50 m above the ground. Gymnosperms, represented by pines (*Pinus*), spruces (*Picea*), firs (*Abies*), *Araucaria*, and *Ginkgo*, transport water through specialized (bordered) pits on the connected side walls of tracheids, whereas angiosperms, represented by evergreen and deciduous hardwoods such as *Magnolia*, beech (*Fagus*), maple (*Acer*), and ash (*Fraxinus*), have vessels with perforated plates at each end. The bordered pits and perforated plates reduce the possibility of air being introduced into the conduits when under tension and, if air is introduced, they are designed to remove it.

As tension on water columns increases due to high evaporative demand or drought, stomata are induced to close before irreversible damage to the vascular system results. Trees adapted to periods of seasonal water stress also have the ability to increase solute concentrations in living cells, to reduce the size of vessels and tracheids, and the amount of leaf area supported by a unit of vascular tissue, while at the same time increasing their root systems.

To adapt to periodic flooding, water tupelo (*Nyssa aquatica*), black ash (*Fraxinus nigra*), and other swamp hardwood species have developed metabolic systems that permit root growth and photosynthesis to continue under anaerobic conditions. In addition, baldcypress (*Taxodium distichum*) and other species exposed to chronic flooding have adapted anatomically to allow diffusion of air through specialized tissue to their roots.

Temperature Extremes

Plants adapted to high or low temperatures differ in the biochemical composition of their cellular membranes. These differences influence the ease that chemical elements, organic compounds, and water can be absorbed and transferred from roots to shoots. Tropical trees are adapted to high temperatures but withstand little frost, whereas temperate trees can adjust their cellular structure, when in a dormant state, to prevent ice crystal formation down to $-45°C$, and boreal trees can, when fully preconditioned, withstand temperatures approaching absolute zero.

Plants adapted to subfreezing temperatures reduce their photosynthetic activity before conditions become unfavorable in response to shorter day length. If climatic conditions become warmer, low-temperature adaptations are a disadvantage. At the other extreme, some broad-leafed tree species, when exposed to high radiation when their stomata are closed, initiate the production of volatile isoprene compounds, which protect the photosynthetic machinery within the leaf, and create haze that reduces solar radiation.

Mechanical Forces

Snow, ice, and wind exert mechanical stress on leaves, branches, and stems. Trees species have adapted by folding leaves, by developing flexible stems and branches, by increasing the density of their wood, by shortening and altering the orientation of branches, by increasing the taper of stems, and the proportion of growth allocated to large-diameter roots. In unstable soils, the shape of stems and extension of surface roots may be quite asymmetrical, serving to buttress trees against the forces of gravity.

Mechanical stresses are also induced by feeding and other activities of animals that remove leaves, branches, and bark. Adaptations to herbivory vary from the development of thorns, and prickly leaves to biochemical defenses.

Toxic Compounds

Toxic compounds are widely dispersed in the environment in the form of gases, such as ozone, and as heavy metals such as lead, chrome, nickel, and selenium. Ozone diffuses through stomata into the chloroplast and injures the photosynthetic machinery as well as a tree's ability to transport photosynthate from leaves. Species that are conservative in their use of water maintain less open stomata and therefore take up less ozone over a given period. On the other hand, species that shed their foliage annually suffer less damage per leaf than more drought-adapted species that have long-lived evergreen foliage. To repair ozone-damaged cells requires expenditure of photosynthate and other resources that might otherwise go toward growth or defense.

Heavy metals interfere with the enzyme reactions essential for plant growth and development. Some tropical trees can store toxic compounds in vacuoles that do not disturb cell metabolism; others adapt by producing metal-binding peptides that keep heavy metals out of solution. The synthesis of these compounds is metabolically expensive, and again, like other specific adaptations to stress, reduce a species' ability to compete in environments lacking heavy metals.

Nutrient Deficiencies

Nutrient limitations can reduce growth and increase a tree's susceptibility to other stresses. Trees differ in their demands for specific nutrients, but exhibit a similar optimal balance. At slow growth rates, the overall demand for nutrients is low, and optimal balance can be achieved through selective uptake of scarce nutrients by roots and symbiotic (mycorrhizal) fungi. Some trees species also have symbiotic associations of bacteria that can fix atmospheric nitrogen gas (N_2) into ammonium (NH_4^+), a form available to the host tree as well as to other species. The fixation of nitrogen and acquisition of other nutrients via symbiotic bacteria and fungi, or through production of exudates that stimulate free-living microbial activity to release nutrients from decomposing litter, require a high expenditure of metabolic energy, reducing resources that could go into growth and defense. In many areas once limited by nitrogen, atmospheric depositions have increased from <2 to $>50\,\mathrm{kg\,ha^{-1}\,year^{-1}}$. This increased availability of nitrogen favors above-ground growth, even when other nutrients are in less than optimal supply. As a result of imbalanced nutrition, plants expend energy and create tissues less tolerant to a variety of other stresses.

Process Modeling to Integrate Stress Effects

Trees are exposed throughout their lives to a wide range of different stresses. The question arises, which species might grow best? To assess species performance under a wide range of environmental conditions, physiologically based process models have been developed that have a common structure (**Figure 1**). The maximum rate of photosynthesis is determined by the nutritional status of leaves and the amount of light they absorb. Additional environmental constraints are imposed by frost, drought, high evaporative demand, suboptimum temperatures, and nutrition (and by additional stresses if important, e.g., wind stress, insect defoliation, and ozone). The models take account of interactions among stresses as they affect photosynthesis, respiration, and growth.

If *Pinus ponderosa* and *Eucalyptus globulus* were selected for planting in a cold, drought-prone region of Argentina, *P. ponderosa* would be predicted to photosynthesize and grow nearly four times as well as *E. globulus*, largely because of differences in performance at temperatures between 0°C and 10°C (**Figure 2**). Both species have similar responses to humidity deficits but because the pine grows more foliage it extracts more water from the soil and experiences somewhat more drought stress during the late summer than eucalyptus.

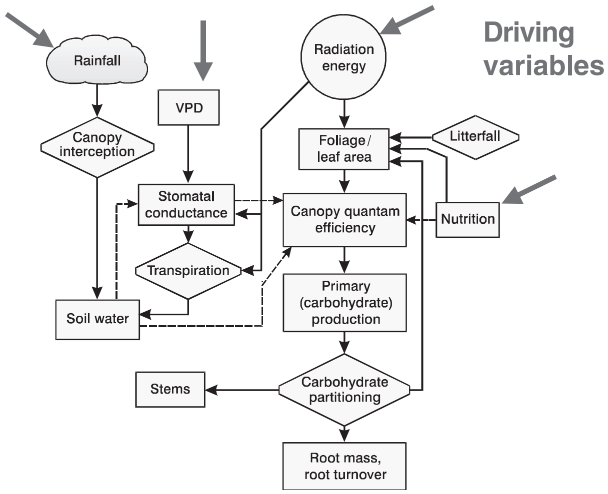

Figure 1 Structure of a physiologically based tree growth model where photosynthesis is constrained by environmental factors that also affect respiration and allocation of resources to growth. VPD, vapor pressure (humidity) deficit. Reproduced with kind permission of Natural Resource Modeling, published by the Rocky Mountain Mathematics Consortium.

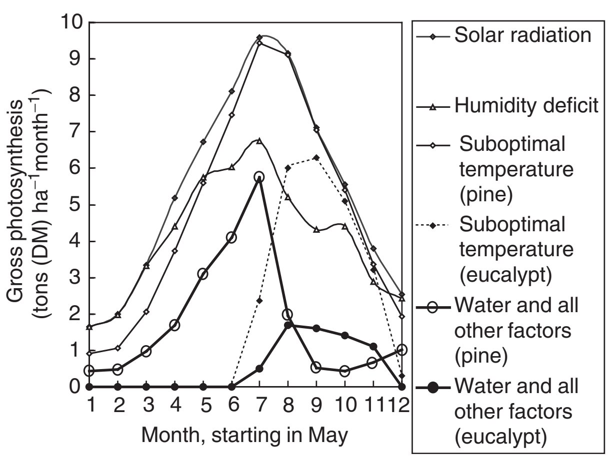

Figure 2 *Eucalyptus globulus* is predicted to grow at less than one-third the rate of *Pinus ponderosa* because it is more poorly adapted to temperatures between 0°C and 10°C that occur frequently at 750 m elevation near Bariloche, Argentina (41° S latitude). Drought and high evaporative demand (humidity deficits) reduce photosynthesis and growth for both species well below limits set by absorbed radiation. DM, dry matter.

The photosynthetic component of process models is well developed and capable of analyzing the impact of rising atmospheric carbon dioxide. Some process models keep track of seasonal changes in storage reserves and predict timing of budbreak, shoot and root elongation, and dormancy. A major challenge remains: to predict competitive relationships in forests composed of many species, some of which fix nitrogen, have roots that access ground water, are tolerant to toxic compounds, or to attack from herbivores and pathogens.

General Indices of Stress

Biochemical Indices

Both biochemical and structural features of trees have been used to assess tree vigor and susceptibility to attack by insects and pathogens. In many cases, specific biochemical compounds have been identified that attract or repel attack. These secondary plant metabolites include alkaloids, nonprotein amino acids, ligans, lipids, phenolic acids, phytoalexins, quinones, terpenes, and steroids.

In a search for general biochemical indicators of stress, physiologists have focused on the storage of starch, an energy source, and amino acids, the building blocks of protein. The seasonal variation in both of these resources can be large so comparisons are generally made during the dormant season. When starch reserves drop below normal, trees become more susceptible to disease. Also, when amino acid concentrations increase with tissue N content, that too is an indication of increased susceptibility. The energy required to store excess amino acids reduces that available for production of defensive compounds. Thus, in Scots pine (*Pinus silvestris*), the concentration of defensive compounds (procyanidins) decreased by 45% while the fraction of arginine in the amino acid pool increased by nearly 400% as foliar N concentrations changed from 1.4% to 2.1%. Expressed as a ratio, a threshold of susceptibility can be identified when leaf N% is in excess of 1.5%. Biochemical ratios of defensive compounds to sugars have also been used to define threshold susceptibility to injury from pathogens (**Figure 3**).

Structural Indices

Wood growth is greatly reduced under stressful conditions but differs with tree size. Physiologists take into account differences in size by calculating partitioning coefficients that express the relative allocation of resources to roots, stems, branches, and foliage. With the knowledge that sapwood cross-sectional area at breast height is correlated with a tree's leaf area, and that stem growth can be related to annual increment in diameter, a general index of tree vigor (growth efficiency) can be defined. Following establishment of a plantation of trees, growth efficiency drops rapidly as the canopy develops and natural mortality (self-thinning) begins. In regions where extensive forests of a particular species exist, outbreaks of insects are

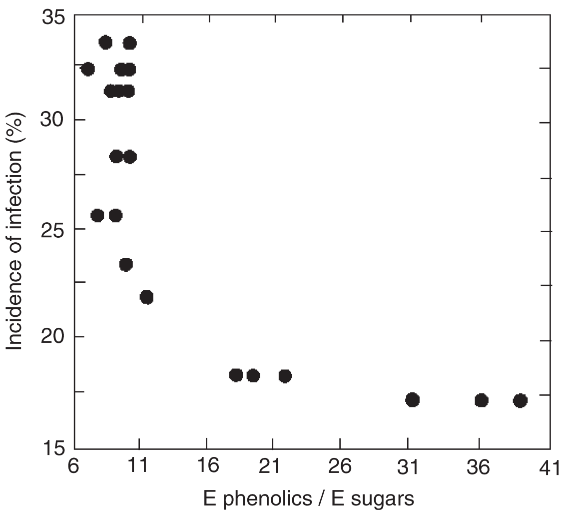

Figure 3 Incidence of infection by a root pathogen, *Armillaria*, on Douglas-fir increased when the ratio of energy (E) required to metabolize defensive compounds (phenolics) in reference to the energy available in sugars drops too low. Figure 4 A spruce budworm outbreak in a balsam fir (*Abies balsamea*) stand in Quebec, Canada indicates that tree mortality (dashed line) recorded between 1972 and 1990 restored average tree growth efficiency (circles) to values recorded before the outbreak. Reproduced with permission from Waring RH and Running SW (1998) *Forest Ecosystems: Analysis at Multiple Scales*, p. 192. Copyright (1998) Academic Press, San Diego, CA.

associated with periods when stand growth efficiency drops below normal. The resulting mortality improves the growth efficiency of surviving trees (**Figure 4**). The growth efficiency index, combined with knowledge of the density of bark beetle attack, provides a basis for predicting survival or death of individual trees. Although unusual weather conditions can cause stress, it is often possible to improve tree vigor and biochemical defenses through thinning and application of fertilizer.

Separating Climatic from Other Stresses

Process models, provided with climatic data as well as information on stand structure, can provide monthly and annual estimates of photosynthesis, growth, and growth efficiency. With weather satellites in orbit around the earth, it is possible to obtain estimates of cloud cover and thereby to estimate incoming solar radiation. On clear days, it is also possible to estimate ambient air temperatures, humidity deficits, and periods of drought. With some simplifying assumptions, global variation in terrestrial primary production has been predicted exclusively from weather satellite-derived data. New satellite systems provide 8-day estimates of photosynthesis, and more accurate estimates of changes in canopy leaf area and annual above-ground production. In the future, remote sensing systems already tested from aircraft are being designed to provide improved estimates of changes in forest structure (leaf area and biomass) and canopy biochemistry (lignin and nitrogen concentrations).

With frequent monitoring of the forest condition via remote sensing, it is possible to distinguish disturbances caused by fire, insect outbreaks, logging, and wind storms from those associated with gradual changes in climate and pollutant loads. If conditions shift permanently, trees adapted to the previous environment should experience more stress and eventually be replaced by others better adapted to the new environment.

Mycorrhizae

D L Godbold, University of Wales, Bangor, UK

Introduction

The term 'mycorrhiza' describes the symbiosis between a plant root and fungal partner. In most cases mycorrhizae are mutualistic symbioses in which both partners benefit from the association. In general, the fungal partner benefits from a supply of photosynthetically fixed carbon from the host plant, whereas plants benefit mainly from greater acquisition of mineral nutrients via fungal structures. Plants may also enjoy several other benefits such as protection against root pathogens and improved water uptake. This article describes the importance of mycorrhizae in forests, the structure of different mycorrhizal types, fungi forming these types, and their global occurrence.

Mycorrhizae can be divided into seven structural types (**Table 1**). With the exceptions of monotropoid and orchid mycorrhizae, all other types can be found on woody plants and trees. Within a single mycorrhizal type there is considerable diversity in structure, development, and function. The identity of the symbionts can have a considerable influence on the structure of mycorrhizae formed. For example, the fungus *Hebeloma crustulinforme* forms ectomycorrhizae with many species of *Picea* and *Pinus*, but arbutoid mycorrhizae with *Arbutus menziesii*. Similarly, fungi forming vesicular-arbuscular mycorrhizae may form mycorrhizae with extensive intracellular coils and few arbuscules in one plant species, and intercellular hyphae and many arbuscules in another plant species.

Ectomycorrhizae

Structure

Ectomycorrhizal roots are characterized by three structural components (**Table 1**, and **Figure 1**): (1) a

(1992) *Mycorrhizal Functioning*. New York: Chapman & Hall.

hyphal sheath or mantle which encloses the root; (2) an inward growth of hyphae between the epidermal or cortical cells forming the Hartig net; and (3) an outward-growing mycelium of hyphae or rhizomorphs forming the extramatrical mycelium. The hyphal mantel constitutes between 20 and 40% of the root dry weight. The cellular structure of the hyphal mantel varies between fungal species and is used to identify species of ectomycorrhizae. The Hartig net forms the contact zone between the cells of the fungal symbiont and host plant. The Hartig net is formed by penetration of hyphae from the inner hyphal mantel. The depth of penetration differs in angiosperms and gymnosperms. In most species of angiosperms penetration is restricted to the outer cortical layer, forming a so-called epidermal Hartig net. Within the epidermal types two forms are found. In the paraepidermal type, the epidermal cells are only partially enclosed by hyphae. In the periepidermal type the epidermal cells are completely encircled by the fungal hyphae. Most species of gymnosperm form a cortical Hartig net, in which several layers of cortical cells extending to the endodermis are enclosed by hyphal layers. Penetration between the root cells is believed to involve fungal enzymes that disrupt the middle lamella, leading to complete fusion of plant and fungal cell walls to form the intercellular matrix or involving layer. Intercellular penetration induces prolific branching of fungal hyphae, producing a fanlike structure that moves across the radial plant cell walls. The prolific branching of hyphae and fusion of the plant and fungal cell walls produce a structure with a high surface area for exchange of mineral elements and metabolites.

The hyphae of the extramatrical mycelium extending from the surface of the hyphal mantel greatly increase the area of contact with the soil. In forest soils, ectomycorrhizal hyphae in the soils have been estimated to have a length of $2000\,\mathrm{km\,m^{-2}}$, several orders of magnitude greater than the length of fine roots. The extramatrical mycelium provides the area of nutrient uptake in the soil and the transport pathway between the soil and the hyphal mantel. Extramatrical hyphae extend from the mantle both as single hyphae and as aggregates forming rhizomorphs. The degree of aggregation and the complexity of the rhizomorph structure vary greatly between fungal species. Six categories of rhizomorph are recognized, the simplest being loose aggregates of hyphae of similar diameter, the most complex having enlarged central hyphae in a highly organized structure. It is assumed that the structural differences in the rhizomorphs are associated with functional differences.

Occurrence

Only about 3% of plant species form ectomycorrhizae but the species that form ectomycorrhizae dominate many ecosystems that occupy a large proportion of the land surface. The majority of economically important timber tree species in temperate regions form ectomycorrhizae. The Pinaceae, from which most species are ectomycorrhizal, dominate the boreal forests of the northern hemisphere. The dominants of the northern temperate forests, Fagaceae, and the southern temperate and subtropical forests, Myrtaceae, are both families of mainly ectomycorrhizal species. Ectomycorrhizal species are also found in the tropics; the Dipterocarpaceae, the most important family in moist and monsoon forests of Southeast Asia, is composed of mainly ectomycorrhiza-forming species.

A number of leguminous tree genera from both the moist tropics and dry miombo woodlands, including *Afzelia*, *Eperua*, and *Intsia*, and *Brachystegia* with *Julbernaldia* respectively, are also known to form ectomycorrhizal associations. However, many of the tree species forming ectomycorrhizae also form vesicular–arbuscular (VA) mycorrhizae. The formation of ectomycorrhizae is linked to accumulation of an organic litter layer in soils.

Fungi forming ectomycorrhizae

A large number of fungi form ectomycorrhizae, the majority being basidiomycetes. Ectomycorrhizae are also formed by a number of ascomycetes and a few species of zygomycetes. It is estimated that between 5000 and 6000 species of fungi form ectomycorrhizae. About 75% of ectomycorrhizae are epigeous, and *c.* 25% hypogeous, including a large number of ascomycetes. Ectomycorrhizal fungi differ in the degree of host specificity. The majority of species have a broad host range colonizing a large number of tree species. However, a number of species have a more restricted range and there are an estimated 250 species that are genus-specific. The root system of an individual tree will normally be colonized by a range of ectomycorrhizal fungal species. The number of fungal species colonizing roots of a tree depends upon both tree species and environmental conditions.

Vesicular–Arbuscular Mycorrhizae

In forestry, VA mycorrhizae are poorly neglected in favor of ectomycorrhizae, yet VA mycorrhizae are found on a large number of temperate tree species and the majority of tropical species.

Structure

The fungal structure of VA mycorrhizae is an internal mycelium growing within the root, intracellular vesicles and arbuscules, and an extraradical mycelium extending into the soil. Whereas all VA mycorrhizae form arbuscules, *Gigaspora* and *Scutellospora* do not form vesicles.

Roots become colonized from hyphae originating from the hyphal mycelium in the soil, spores or old colonized root fragments. The hyphae of the internal mycelium spread from an entry point to form two recognized types of the internal mycelium colonization, the Arum and Paris types. In the Arum type, hyphae proliferate in the cortex by growing longitudinally between host cells. Hyphae grow through longitudinal intercellular air spaces. This type is regarded as the typical VA mycorrhizal type. In the Paris type, hyphae develop intracellular coils and the hyphae spread directly from cell to cell. Arbuscules are formed by repeated dichotomous branching. The width of hyphae decreases from an initial trunk hypha 5–10 μm in diameter to fine branch hyphae less than 1 μm in diameter. In the Arum type arbuscules form from dichotomously branched hyphae that penetrate the cortex cells, whereas in the Paris type arbuscules grow from the intracellular coils. The fungus is always located outside the cytoplasm in an apoplastic compartment. The periarbuscular membrane surrounding the arbuscule is modified functionally. Together with the fungal membrane of the arbuscule, the periarbuscular membrane forms an interfacial zone, important for the transfer of nutrients between the symbionts. Arbuscules are considered the major site of exchange between the fungus and host. Arbuscules start to form approximately 2 days after root penetration, and in fast-growing species arbuscular turnover is about 7 days. However, in slow-growing woodland plants arbuscules are longer-lived and more robustly branched. Compared with the arbuscules the hyphae of the internal mycelium are long-lived and can remain in roots for months.

Vesicles develop to accumulate storage products in many VA mycorrhizal associations. Vesicles are thick-walled hyphal swellings in the root cortex that contain lipids and numerous nuclei. Vesicles vary in shape from ovoid, irregular-lobed to box-like, depending on the fungal species. They are likely to act both as storage organs and as propagules. However little is known about the biology of these structures.

Similar to the extramatrical mycelium of ectomycorrhizal roots, the extraradical mycelium of VA mycorrhizae increases the area of contact with the soil and transport pathway between the soil and the root. The hyphae of the extraradical mycelium are highly branched with species-specific branching patterns.

Occurrence

Most herbaceous plants are colonized by VA mycorrhizae. However, VA mycorrhizae are not restricted to herbaceous plants and are found on a large number of temperate tree species and most tropical trees. The only family of tropical trees that are not typically VA mycorrhizal is the Dipterocarpaceae. Trees of savanna grasslands and semiarid bushlands are also dominated by VA mycorrhiza-forming species. Although, in temperate regions, VA mycorrhiza-forming species are less important in geographical area than ectomycorrhiza-forming species, the majority of temperate tree species form VA mycorrhizae. Whereas the Pinaceae (*Abies*, *Larix*, *Picea*, *Pinus*, and *Pseudotsuga*) are ectomycorrhizal, most other gymnosperms form VA mycorrhizae. This includes the Cupressaceae, Taxaceae, and Taxodiaceae. A number of families of angiosperms also commonly contain VA mycorrhizal-forming species, including the Rosaceae (*Malus* and *Prunus*), Leguminosae, Oleaceae, and Tiliaceae. VA mycorrhizae are reported to be the ecologically most important type in New Zealand forests. However, a large number of species also form both VA mycorrhizae and ectomycorrhizae. The formation of both VA mycorrhizae and ectomycorrhizae is particularly well described on *Eucalyptus*, *Populus*, and *Salix*. In most cases, VA mycorrhizae develop at earlier successional stages than ectomycorrhizae. VA mycorrhizae are more frequent on plants growing on mineral soils.

Fungi Forming Vesicular Arbuscular Mycorrhizae

The fungi of the order Glomales, which form VA mycorrhizae, have been classified into three families containing five genera, *Acaulospora*, *Entrophospora*, *Gigaspora*, *Glomus*, and *Scutellospora*. About 150 species have been described. Due to the difficulties involved to identify species colonizing roots, the number of species associated with roots of a single plant in the field is uncertain.

Ectendomycorrhizae

Ectendomycorrhizae are a distinct form of mycorrhiza formed on *Picea* and *Pinus*, mainly on juvenile trees and often in disturbed soils or nurseries.

Structure

Ectendomycorrhizae have some of the structural characteristics of both ectomycorrhizae, and endomycorrhizae. The development of ectendomycorrhizae is similar to that of ectomycorrhizae, resulting in a thin or hyaline hyphal mantel that does not cover the root tip, and a Hartig net that can extend to the inner cortex. However, unlike ectomycorrhizae, ectendomycorrhizae also have intracellular penetrations of hyphae which branch repeatedly once inside the cell.

Occurrence

Ectendomycorrhizae occur primarily on *Picea* and *Pinus*, and are commonly found in pot cultures or nursery trees of several years of age. They occur on a wide range of soil types, but are common on disturbed soils or soils of agricultural origin.

Fungi forming ectendomycorrhizae

Ectendomycorrhizae are formed by a number of fungi but most can be referred to as *Wilcoxina* and assigned to two taxa, *W. mikolae* and *W. rehmii*. *Wilcoxina mikolae* produces chlamydospores and occurs in disturbed mineral soils; *W. rehmii* does not produce chlamydospores and occurs on peaty soils.

Mycorrhizae in the Ericales

Two types of mycorrhizae are formed with woody plants in the Ericales that are important in forest, namely arbutoid and ericoid mycorrhizae.

Arbutoid mycorrhizae are formed on woody plants in the genera *Arbutus* and *Arctostaphylos*, and in genera of the Pyrolaceae including *Chimaphila*, *Moneses*, *Pyrola*, and *Orthilia*. Arbutoid mycorrhizae are characterized by a hyphal mantel and Hartig net similar to that of ectomycorrhizae, but also an intercellular proliferation of mycelia to form dense hyphal complexes. These hyphal complexes can only be revealed by anatomical investigation. The fungi-forming arbutoid mycorrhizae are mainly basidiomycetes that commonly form ectomycorrhizae in other tree species. These include genera of basidiomycetes such as *Laccaria*, *Piloderma*, and *Rhizopogon*, and ascomycetes such as *Cenococcum*.

Ericoid mycorrhizae are formed by most of the genera of plants in the Ericales; these include genera forming important midstory and understory plants such as *Rhododendron* and *Vaccinium*, as well as tree species within the genus *Erica*. The ericoid mycorrhizal root is a delicate structure of only two cortical layers, an outer hypodermis and an inner endodermis, surrounding a stele consisting of only one or two tracheids, a sieve element and a companion cell. Mycorrhizal colonization of the root is restricted to expanded epidermal cells, in which fungal hyphae penetrate the cell walls and form a dense hyphal profusion, fully filling the colonized cell. Examples of fungi-forming ericoid mycorrhizae have been identified as members of the genera *Hymenoscyphus* and *Oidiodendron*. Soils that support ericaceous vegetation are characteristically nutrient-poor.

Species Assemblages Colonizing Trees

Individual trees may be colonized by a large number of species of mycorrhizal fungi. Ectomycorrhizal fungi are divided into broad, intermediate, and narrow-range fungi, reflecting the number of potential host tree species that they colonize. Ectomycorrhizal species are also categorized into early and late successional species, reflecting the appearance of fruiting bodies of the species in developing tree stands. However, species categorized as early successional are also found in mature trees stands, and late successional species often colonize young or juvenile trees growing in mature stands. Little is known about species assemblages in VA colonization of tree species; however, most VA species are believed to be broad-range species. Current knowledge of species assemblages of VA is restricted by problems of *in planta* identification. Species assemblages of trees are influenced by environmental conditions, including, among others, soil fertility, especially nitrogen and soil acidity, elevated atmospheric carbon dioxide, and toxic levels of ozone. The influence of elevated atmospheric carbon dioxide and ozone is thought to be mediated by changes in rates of photosynthesis and hence carbon flow to the mycorrhizae.

Identification of Mycorrhizae

The population structure of arbuscular and ectomycorrhizae can be estimated using fruiting bodies (mushrooms) for ectomycorrhizae or soil spores for arbuscular mycorrhizae. For ectomycorrhizae, fruiting bodies within an area can be collected, identified, and their abundance estimated. However, this depends upon the ectomycorrhizal fungus-forming epigeous fruiting bodies. Fruiting body production often correlates poorly with the below-ground abundance. The spores of arbuscular mycorrhizae must be isolated from the soil and can be identified to genus or species using morphological characteristics.

Ectomycorrhizal fungi colonizing roots can be identified using morphological and molecular biological methods. Morphological identification uses both structural features of the mycorrhizal root tip such as color and ramification, and the cellular patterns of the hyphal mantel. This permits identification to genus or species level. Morphological methods can also be used to identify some arbuscular mycorrhizae. Morphological features that are important include variations in the size, shape, wall thickness, position, and abundance of vesicles, branching patterns, the diameter and structure of hyphae, and the staining intensity of hyphae. However, this method is of limited potential as a single mycorrhizal species may have a different morphology between plant host species. Both ectomycorrhizae and VA mycorrhizae can be identified *in planta* using molecular biological techniques. Ectomycorrhizae are commonly identified by using polymerase chain reaction (PCR) amplification of DNA followed by restriction fragment length polymorphism (RFLP). Target DNA for amplification is often the internal transcribed spacer (ITS) region rDNA. VA mycorrhizae are commonly identified using short arbitrary primers in random amplified polymorphic DNA (RAPD-PCR) techniques. Target regions are often the small subunit (18S) or large subunit (25S) ribosomal gene. These techniques are often used with subsequent RFLP analysis. Family-specific primers allow identification of the major families of VA mycorrhizae.

Tree Benefits of Mycorrhization

Mineral Nutrient Acquisition

The improved mineral nutrition of mycorrhizal plants is well documented, in particular, a role in the uptake of P by ectomycorrhizae or arbuscular mycorrhizae, and N uptake by ectomycorrhizae and to a lesser extent arbuscular mycorrhizae. In *Eucalyptus grandis* and *E. maculata*, inoculation with the ectomycorrhizal fungus *Pisolithus* spp. enabled the seedlings to utilize amino acids as organic N sources, which could not be utilized by nonmycorrhizal seedlings. Ectomycorrhizal colonization facilitates utilization of many organic sources of N, including amino acids, proteins, and leaf litter. *Pinus sylvestris* seedlings colonized with *Suillus bovinus* were able to utilize N from the litter fermentation layer of a forest soil. In addition to the elements P and N, mycorrhizae have been shown to facilitate plant acquisition of Mg, Cu, Zn, and Mn.

Much of the benefit of mycorrhizae in mineral nutrient acquisition is a consequence of the extramatrical or extraradical mycelium. Both ectomycorrhizae and arbuscular mycorrhizae can greatly increase the volume of soil exploited due to the extent and high surface area of the extramatrical mycelium. It has been shown in a number of investigations that the external hyphae of mycorrhizae can absorb P from outside the root depletion zone and transport P to the host plant. In an investigation with Norway spruce (*Picea abies*) and the ectomycorrhizal fungus *Paxillus involutus*, translocation of P by the extramatrical mycelium over a distance of 5 cm was demonstrated. In *Pinus sylvestris* mycorrhizal with *Suillus bovinus*, P was translocated over 30 cm, mainly in rhizomorphs.

The high effectivity of the hyphae of both ectomycorrhizae and arbuscular mycorrhizae in P uptake may also be due to the accumulation of polyphosphates in vacuoles, where they act as both a storage form of P and function in an alternative form of energy storage. In addition to the increase in surface area provided by the extramatrical mycelium, ectomycorrhizae have also been shown to exude organic acids and mobilize sparingly soluble P mineral sources. The ectomycorrhizal fungus *Paxillus involutus* has been shown to exude high amounts of malate and oxalate. *Pinus rigida* ectomycorrhizal with *Pisolithus tinctorius* was able to extract P from insoluble aluminum phosphate. The exudation of organic acids may be a primary factor in the weathering of minerals.

Both ectomycorrhizae and arbuscular mycorrhizae have high levels of phosphatase activity, which are important in the utilization of organic P sources. In forest soils the majority of P in the rooting layer is in the form of organic P. The levels of phosphatase in mycorrhizae are often similar to those of tree fine roots. As an example, in Norway spruce ectomycorrhizal with a number of fungi, similar levels of acid phosphatase were found in mycorrhizal and nonmycorrhizal roots. However, there are differences in the levels of phosphatase activity between different ectomycorrhizal species. In Norway spruce mycorrhizal with *Thelephora terrestris*, a higher phosphomonoesterase activity was found in mycorrhizal roots and rhizomorphs than nonmycorrhizal roots. However, independent of the levels of acid phosphatase activity between mycorrhizae and nonmycorrhizal roots, the large surface area of the extramatrical mycelium will greatly increase the potential to mobilize organic P.

Estimates of the contribution of inorganic P uptake to the total uptake by trees suggest that the contribution may be significant. In Norway spruce ectomycorrhizal with *Paxillus involutus*, 52% of the total P uptake was shown to be via the extramatrical hyphae. It is possible that experimental systems may overestimate the mycorrhizal contribution to P acquisition. However, as the mycorrhizal contribution is so high, it is very likely that under field conditions mycorrhizae play a significant role in P acquisition.

Water relations

Both ectomycorrhizae and arbuscular mycorrhizae can improve the water relations of plants. For example, in two species of *Acacia*, mycorrhizal plants had a higher number of open stomates under drought conditions. However, the mechanisms involved are still controversial. A number of mechanisms of increased host drought tolerance have been suggested, such as increased root hydraulic conductivity, alteration of stomatal regulation due to hormone signals, osmotic adjustment, hyphal water transport, and improved P nutrition. Improved water status has often been associated with improved host P nutrition. That mycorrhization nearly always results in an improved P nutrition of the host plant and/or larger plants often makes interpretation of the mechanisms involved in improved water relationships difficult. However, the rhizomorphs of ectomycorrhizae provide possible conduits for the transport of water. In *Pinus pinaster* inoculated with a number of strains of *Pisolithus tinctorius*, a significant correlation between plant water potential and the extension growth and rhizomorph diameters of the different strains could be shown.

Plant–Pathogen Interactions

Apart from beneficial effects on the nutrition and water supply of host trees, mycorrhizae have been proven to increase the resistance of trees to infection by pathogens of the fine roots. Different species of mycorrhizal fungi vary in their efficiency at preventing root infections, although the mechanisms involved in this process are rather poorly understood. Possible modes of action include the production of antibiotics by the mycorrhizal fungi, stimulation of host defense mechanisms, and the physical barrier presented by the Hartig net in ectomycorrhizae. In casuarina (*Casuarina equisetifolia*) arbuscular mycorrhizal fungi increased the resistance to the root pathogen *Fusarium vesicubesum*. Both ectomycorrhizal and arbuscular mycorrhizal fungi have been shown to produce antibiotics. In addition, ectomycorrhizal fungi produce phenolic substances and oxalic acid that suppress root pathogens.

Amelioration of Metal Toxicity

Ectomycorrhizal fungi have been demonstrated to alleviate growth depressions of tree seedlings due to toxic effects of Al, Ni, Zn, and Cd. For other important heavy metals, for example Hg and Pb, direct evidence of amelioration by ectomycorrhizal fungi is still lacking. Metal tolerance of higher plants may be due to a range of potential processes. These may include: (1) a reduction of metal exposure by excretion of chelating substances; (2) extracellular sequestration (e.g., by mucilage, pH gradients in the rhizosphere); (3) modified uptake systems at the plasmalemma; or (4) intracellular detoxification. Mycorrhizal fungi may also alter metal sensitivity of their hosts by any of the mechanisms outlined. A number of possible mechanisms have been suggested, including: (1) filtering of toxic metals in the hyphal sheath or Hartig net; (2) reduced transfer of metal to the shoot; (3) metal sorption on the extramatrical mycelium; and (4) chelation by organic acids and other substances released by mycorrhizal fungi.

The Costs of Mycorrhization

Production and maintenance of mycorrhizae impose a carbon cost on the host plant in excess of 30% of total photosynthesis. In seedlings growing at adequate nutritional levels, the carbon requirements of the mycorrhizal fungi may result in reduced growth rates of the host plants.

Mycorrhizae in Ecosystems

Boreal and Temperate Forests

In boreal and temperate forests there is good evidence to suggest that ectomycorrhizae play an important role in N recycling and acquisition. Ectomycorrhizal fungi release enzymes such as peroxidase and phenol oxidase that allow them to contribute to decomposer activity. In Ca-deficient forests, ectomycorrhizae have been shown to be involved in the uptake of Ca from mineral weathering. This may be due to the release of organic acids. High release of organic acids, especially oxalate, has also been shown in ectomycorrhizal fungi forming hyphal mats, resulting in bleaching of soil horizons.

The formation of a common hyphal mycelium between different tree species colonized by the same ectomycorrhizal fungus is thought to be involved in the transfer of carbon between species. This has been shown experimentally in a carbon transfer between *Betula papyrifera* and *Pseudotsuga menziesii* sufficient to improve growth. It is believed such carbon transfer may be important for tree seedlings growing in deep shade.

Subtropical and Tropical Forests

In an investigation of the distribution of arbuscular and ectomycorrhizal tree species in savannas, it was shown that ectomycorrhizal trees dominate soils with low levels of N and P, whereas arbuscular mycorrhizal species dominate soil low in P but relatively rich in N. This suggests that ectomycorrhizal trees may have a greater advantage for N acquisition than VA mycorrhizal species. However, in the humid tropics of French Guyana, ectomycorrhizal tree species were found not to dominate the poorest soils. In the moist tropics most tree species are VA mycorrhizal. Many of the soils are acidic and highly leached, with a consequence that the soils have low available P levels due to Al fixation of P. Under these conditions VA mycorrhizae may be important in the rapid cycling and uptake of inorganic P.

Ectomycorrhizal Fungal Fruiting Bodies as Nontimber Forest Products

Fruiting bodies of ectomycorrhizae are commonly collected and sold. In some forest areas the value of the mycorrhizal fungal fruiting body harvest exceeds the value of wood production. Harvesting is mainly restricted to a small number of valuable species such as *Boletus edulis*, *Cantharellus cibarius* (chanterelles), *Tuber magnatum* (white truffles), and *T. melanosporum* (black truffles).

Physiology of Sexual Reproduction in Trees

J Webber (Retired), Ministry of Forests, Research Branch, Victoria, BC, Canada

Introduction

The physiology of sexual reproduction in forest trees has progressed substantially over the past 20 years. Three previous symposia of the International Union of Forestry Research Organizations (IUFRO) not only summarized current knowledge but also laid out the ground work for future studies. Many of these questions are still valid today but substantial progress has been made in early maturation, flower induction, and pollination biology. Many questions still exist (mechanism of flowering) and new questions are being asked (environmental effects on progeny performance).

New technology, principally molecular techniques, is now available and offers exciting new possibilities for future flowering, pollination, and seed production studies. However, there has been a substantial shift in flowering research. Considerably fewer studies are being published on the mechanism of flowering in conifers but, equally so, the volume of work dealing with hardwoods, especially tropical hardwoods, is growing.

The perspective of this contribution in forest tree seed production has a definite commercial bias. Procuring seed as a mechanism for delivery of tree improvement programs as well as plantation forestry has been the incentive for pursuing both fundamental research and program development. Much of the emphasis has been with seed orchard development simply because it is the most cost-effective tool for delivery of genetic gain.

Developmental biologists may object to my use of the word 'flowering' when referring to conifers. Certainly the use of 'sporangiate strobili' would be more precise but also more awkward. Here 'flowering' is restricted to the general process of sexual reproduction in conifers. The terms 'seed' and 'pollen cones' refer to the mega- and microsporangiate cones, respectively.

Plantation Forestry

According to statistics provided by the Food and Agriculture Organization, global forest plantations have grown from about 18 million hectares in 1980 to 187 million hectares in 2000 (both hardwoods and conifers). This represents about 5% of the total global forest cover. Asia accounts for about 62% of the current plantation area, followed by Europe (17%), North and Central America (9%), South America (6%), Africa (4%), and Oceania (2%). Globally, broadleaved trees make up 40% of the total, of which *Eucalyptus* is the principal genus and conifers make up 31%, of which *Pinus* is the principal genus. Over the past decade, the percentage of these plantations destined for industrial use has increased from 36% to 48%. Tree improvement, as part of plantation forestry, has been a principal driver of flowering research, especially for temperate conifers.

Critical to the success of these programs is a sustainable supply of not only the species but also adapted families/provenances for the designated target areas. Propagules from asexual techniques (rooted cuttings and somatic embryogenesis) will likely increase but for the foreseeable future seed production will supply the bulk of our needs. The single most important source of seed will continue to be natural stands but in many countries, tree improvement and seed orchard programs are beginning to make substantial contributions of seed. In Canada, an estimated 3.9 billion seeds were sown in 1999, of which 0.63 billion (16%) came from seed orchards. The proportion of seed from seed orchards in Canada is expected to rise to about 80% in the next decade.

Seed orchards offer substantial advantages over natural stand production. With the correct choice of sites, flowering is more regular and inducible. Seed yields are higher because pollen supply is not limiting and crop protection measures (insect control) are more readily applied. When seed orchards are based on selected material from genetic improvement programs, the opportunity to take advantage of family-specific traits is available. This will become very important in the near future if forests cannot adapt to global warming. Tropical species will be less affected but north temperate species may not realize predicted gains and, at worst, plantations may fail. In order to respond to these new demands, we must know the reproductive biology and genecology of our species, including adaptive traits of families as well as the effect of environment on reproductive success and progeny performance. This is the challenge for future physiologists.

Reproductive Biology

The reproductive biology of forest trees forms the basis of our current and future studies. The reproductive biology of species includes the cycle of events starting from initiation of reproductive structures through to seed dispersal. For most conifers and temperate hardwoods these cycles have been at least partially, if not fully, described. In general, this information is lacking for tropical hardwoods but we expect to see this knowledge base expand rapidly over the next few years. Before a tree begins its reproductive cycle, it must first become sexually mature.

Sexual Maturation

All trees go through a phase of juvenility before flowering occurs and this period can be short (1–2 years) or long (greater than 30 years). There are specific phase changes associated with maturation in woody plants. These include morphological changes (decrease in growth rates, an increase in plagiotropism, a change in foliar morphology, and the onset of reproductive competence) as well as physiological and biochemical changes. While maturation is likely under genetic control, the effect of environment on gene expression is also significant. For example, many species of the family Pinaceae and Cupressaceae can become sexually competent in just a few years from seed. Using a combination of early growth acceleration (extended photoperiod and optimal growing regimes), applied stress (drought and heat during reproductive differentiation), crown-forming and growth hormones (gibberellins), flowering can be induced in just a few years and as low as 1 year. Sexual expression is a result of not only the attainment of ripeness to flower (maturation) but also the exposure to environmental/cultural conditions that stimulate flowering.

Physiology of Flowering

The anatomical and morphological description of flowering in conifers and temperate hardwoods has been thoroughly detailed. There are several critical stages in the reproductive cycle to know and they are most often referenced to calendar date. However, phenological development is mediated by environmental cues (photoperiod, temperature, soil moisture), making calendar dates too variable. Where possible, reproductive stages should be referenced to a readily observable phenological stage of development (i.e., bud burst and bud set) of the shoot or plant.

The reproductive stages of most interest are floral initiation and differentiation, meiosis, anthesis, fertilization, embryo development, and cone maturation. All reproductive structures of conifers and hardwoods differentiate from undetermined terminal or axillary apices. For all species of Pinaceae and Cupressaceae, initiation and differentiation are completed before winter dormancy, with the possible exception of soft (Haploxylon) pines where anatomical identification of seed cone structures does not appear until the spring following dormancy. However, in these species, the biochemical/physiological events leading up to differentiation and anatomical identification may occur prior to winter dormancy.

Conifer apices can abort, remain latent, or be determined as seed cones, vegetative buds, or pollen cones. The development sequence apices undergo is largely determined by their position on the stem and in the crown as well as the physiological state of the tree. Temperature and soil moisture conditions that put the trees into stress during periods of initiation and differentiation are the principal environmental factors determining the fate of apices. Light has also been implicated as a contributing factor but, aside from regulating shoot growth, light does not appear to play a direct role in the flowering of conifers. For tropical species, light (photoperiod) and temperature are important factors affecting flowering. Soil nutrient status (fertilizer) also affects flowering but the results are often conflicting and seldom predictable.

Mechanism of Flowering

We do not know the specific mechanism of flowering in trees nor why trees respond to specific inductive treatments. We do know, however, many of the environmental triggers that induce flowering in most Pinaceae and Cupressaceae species and some tropical hardwoods but we have yet to explain the mode of action of specific induction treatments acting either alone or in combination. Much of what we know today about flower induction in temperate conifers came from observations made in natural stands. Trees growing in open, more exposed sites on drought-prone soils are more conducive to flowering than those growing on sites that are shaded, cool, and moist. While some stress is essential for flowering to occur, it is stress applied at specific stages of phenological development that is important. Both low annual rainfall and above normal temperatures in the preceding year are associated with good flowering. However, we do not know how much (or little) drought and heat is required, although experience suggests that warm springs followed by warm, dry summers in temperate climates are best. We also know that growth in the years preceding flowering is important. Even if optimal meteorological conditions leading to stress differentiation occurs, flowering may not necessarily occur. Flowering the year following a particularly heavy crop year (mast) rarely occurs. For species that form their seed cones in the terminal position (i.e., spruce), then new growth must occur before another flowering event can occur.

Several hypotheses have been proposed to explain flowering in conifers. All implicate flowering in relation to shoot growth and plant hormone metabolism. A nutrient-diversion hypothesis contends that a higher concentration of nutrients is required for buds to differentiate reproductively and treatments which retard shoot growth will favor flowering. A second hypothesis relates bud (meristematic) vigor to flowering. Very-high- or very-low-vigor buds remain vegetative. Buds of moderate activity would preferentially promote female flowering in the upper crown (higher-vigor shoots) and male flowering in the lower crown (lower-vigor shoots). The effect of cultural stress treatments (root-pruning, root restriction, drought, and girdling) would be to slow the growth of vegetative buds and favor (enhance) the development of reproductive buds.

However, these hypotheses do not explain the results of gibberellin $A_{4/7}$ ($GA_{4/7}$) applications which not only promote flowering but can also enhance shoot growth (with no effect on apical bud activity). This suggests that the hormonal promotion of flowering and shoot growth are independent processes. Cultural treatments, such as root-pruning (in Douglas-fir), which also enhance flowering, did so by delaying development and not by increasing nutrient concentrations (total insoluble carbohydrate) in axillary apices. Root-pruning also reduces cell elongation and slows apical bud (mitotic) activity in both lateral and terminal buds.

A plausible hypothesis exists for the enhancement of flowering in conifers based on gibberellin biosynthesis and metabolism, although it remains largely untested. The effect of cultural treatment with and without $GA_{4/7}$ treatments suggests that flowering is under numerous biochemical/physiological controls, all of which must be 'permissive' if reproductive structures are to be differentiated and developed. Furthermore, cultural treatments (root pruning, drought, girdling, fertilizer, high temperature, root flooding) may all act through effects on GA metabolism. The effect of these six cultural treatments seems to increase the less polar endogenous GA-like substances ($GA_{4/7}$, GA_9) while at the same time decreasing the levels of more polar-like GA substances (GA_3). Results from labeled (tritiated and deuterated) GA_4 studies support this hypothesis and further suggest that GA activity is regulated in the shoot cell and their metabolites may be influenced by factors affecting root activity.

Roots may have a direct role in regulating flowering and it may involve cytokinins. The promotion of flowering by $GA_{4/7}$ alone and in combination with root flooding resulted in a marked decrease in cytokinin levels in Douglas-fir shoots harvested during the period of cone-bud differentiation. This led to the suggestion that actively growing roots export substances inhibitory to flowering. Since cytokinins are known to inhibit GA biosynthesis, the decreased levels of cytokinins found during flower promotion treatments may actually raise the levels of less polar GAs and, conversely, the higher levels of root-exported cytokinins during nonstress periods would result in lower GA levels and no flowering response.

While this hypothesis is intriguing, it must still be confirmed for the many species in which flowering has been promoted through application of stress treatments. While we do not have hard evidence that less polar GAs have a direct morphogenic role in the promotion of flowering in conifers, it is currently the best one we have. With the increasing knowledge of physiological processes under genetic control and the rapid expansion of molecular technique, new and innovative techniques can now be applied to test this hypothesis rigorously.

It is also interesting to note that flowering in the Pinaceae species only responds to the less polar gibberellins, $GA_{4/7}$, and species of the Cupressaceae families only respond to a more polar gibberellin, GA_3. For Pinaceae species, the effect is enhanced if treatments are combined with stress-inducing cultural techniques such as drought, root-pruning, and heat. Adjunct stress treatments for Cupressaceae species are less effective. Gibberellins do not seem to affect a flowering response in hardwoods but they do respond to photoperiod and shoot-growth retardation which may result in a reduction of GA concentrations. Applications of the growth retardant paclobutrazol have successfully induced flowering in *Eucalyptus* and in a dipterocarp (*Shorea stenoptera*).

Sex Expression

Because most conifer species produce large quantities of pollen that can be handled relatively easily *ex situ*, developing techniques to increase the ratio of seed cones to pollen cones would facilitate not only improved seed production but also the delivery of genetic gain through seed orchard management.

The management of seed production has long sought after sex-specific flower induction treatments. Most conifer species are monoecious and pollen cones are normally differentiated before seed cones. This has led to the possibility that both specific induction treatments and their timing may favor the response of one sex over the other. Cultural treatments are less specific but GA application may provide our best opportunity to control sex expression. However, the levels of endogenous GA normally applied are so large relative to exogenous levels (estimated to be about 5000 greater), it is difficult to expect such subtle responses at the cellular level. Furthermore, we know very little about other plant hormones and their role in sex expression. Certainly, the balance of gibberellins, auxins, cytokinins, and possibly growth inhibitors (i.e., abscisic acid) has been implicated in other plants (angiosperms) and to a certain extent in conifers but their mode of action in conifers is far from clear. Further, the interaction of known growth regulator response with cultural treatments and photoperiod must be very complex.

Regardless of these uncertainties, the value of sex-specific treatments remains. Current management practices that show promise are crown-pruning techniques that favor shoots with a high potential of pollen or seed cone response and treatment timing (specifically gibberellins) in relationship to shoot phenology. We also have the possibility of sex-specific gametocides, including chemical agents that inhibit pollen development.

Pollination Biology

Our knowledge of pollen biology and handling pollen *ex situ* has made pollen management of conifers an essential activity for breeding programs. Pollen management (supplemental pollination) can also be cost-effective in seed orchards where external pollen supply (contamination) can reduce the genetic worth of seed lots or in young orchards where pollen supply and distribution limit seed production. It can also be an effective tool for producing seed with specific traits (i.e., insect-resistant progeny).

Further restraints to seed production and optimal genetic gain include differential parental contribution and nonrandom mating. Some parents are more fecund than others and nonsynchronous flowering (seed cone receptivity and pollen shed) produce distinct breeding populations within orchard seed lots. Orchard activities to balance parental contribution and random mating among all parents include flower enhancement of selective clones, orchard cooling to reduce synchrony between external orchard pollen flight and within orchard pollen flight, and pollen management.

Pollen management involves the collection, extraction, storage, testing, and reapplication of pollen. To handle pollen successfully, we must be able to maintain and measure pollen viability *ex situ*. Pollen of all Pinaceae species is relatively easy to collect, extract, and store. Optimal storage conditions vary slightly among species. In general, pollen must be harvested as near to natural shedding as possible, dried at low humidity (30–40%) and warm temperatures (25–30°C) to a moisture content between 5 and 10%, and then stored in airtight containers at freezer temperatures (− 30°C or lower). For the few Cupressaceae species tested (i.e., *Thuja plicata*, *Chamaecyparis nootkatensis*), pollen must be handled differently. First, pollen must be extracted under high humidity (70–80% relative humidity) and cool temperatures (15–18°C). Under these conditions, pollen moisture content ranges from about 15% to 20% and pollen viability can be maintained at freezer temperatures.

However, conifer pollen quality can deteriorate quickly, especially under high temperatures and humidity. If pollen is exposed to a wide range of conditions, then it is important to test its *in vitro* viability before using. For conifers, three assays that provide consistently good estimators of field performance are respiration (a measure of oxygen uptake), electrical conductivity (a measure of membrane stability), and germination (pollen tube growth in a nutrient medium). Respiration and conductivity are straightforward assay procedures and yield the most consistent response for a wide number of species tested (Pinaceae and Cupressaceae). Germination can also yield good results but the procedure is very sensitive to assay conditions, in particular cultural technique, media components, and pollen prehydration.

Estimates of a pollen lot's fertility potential (ability to set seed) can be determined from assay response. Seed set rises rapidly with increasing pollen viability but quickly reaches an asymptote determined by the number of viable ovules per cone. Since most studies relating assay response to seed set are done using controlled crossing (isolation bags) procedures, the interpretation of these results is limited to this particular pollination technique. When using viability assay response for pollen lots to be used in pollen mixes (i.e., supplemental pollination), then competition between pollen lots becomes important. Since we expect equal contribution from each pollen lot within a supplemental pollination mix, variation in viability may lead to disproportionate contribution. Now that molecular fingerprinting techniques are routinely available, it is possible to measure paternal contributions and use this information to formulate mixes (equal volumes or adjusted to viability response) and to relate *in vitro* viability response to competition both within supplemental pollination mixes and between endogenous orchard pollen clouds.

Pollination Mechanism

Conifers and most temperate hardwoods are wind-pollinated (anemophilous) whereas most angiosperms are insect-pollinated. Most conifer pollen is shed by a wind shock and then air flow patterns around the receptive seed-cone bud not only aid the probability of pollen entrapment but may also favor pollination from its own species. While pollen capture is not specific (it requires over 1 million per ovule), the mechanism of pollen capture can be very efficient.

Once captured, the mechanism of moving the pollen grain into micropyle is quite different among conifer species. A pollination drop is actively involved in some species but not in others. There is considerable interest and, to a large extent, uncertainty about the actual role of the pollination drop. It has not been detected in species such as *Pseudotsuga*, *Larix*, *Tsuga*, and *Abies*. Where the drop does exist (i.e., *Pinus*, *Picea*, Podocarpaceae) and the micropylar arms of the ovule are inverted, the pollination drop can actively draw the pollen grain into the micropyle as it recedes. In some species, such as *Thuja* and *Chamaecyparis*, the pollination drop simply acts as a medium for the pollen landing on its surface to sink towards the nucellus. The various types of pollination mechanism are based on the presence or absence of a pollination drop and may have evolutionary significance.

The pollination drop may be a more recent occurrence but others argue that ovule secretions must have been part of the primitive pollination mechanism as well. Regardless of its evolutionary significance, conifer pollinations drops play an important role in not only directing the pollen towards the nucellus but also in preparing the grain for germination and, perhaps, even actively selecting the species' own pollen from foreign pollen and other microbes. The constituents of the drop include many simple sugars, amino acids, and proteins. With improving analytical technique, the complexities of ovule secretions and the role they may play in pollen germination, selfing and male selection will become clearer.

Cone Development

The description of conifer cone development from preanthesis to seed formation has been extensively reviewed. However, the effect of cultural and environmental conditions on these processes has been less studied, in particular seed cone development. Most temperate Pinaceae species develop their reproductive structures early in the season when temperatures are cool and soil moisture is adequate. However, development of ovules, pollen uptake, and fertilization may be affected by seed orchard environments prone to drought and high temperatures. Most often, the principal cause of poor seed set in conifers is unpollinated ovules. Even when artificial pollen is applied, on average seed yields do not normally exceed 50–60% potential yields. There are also a considerable number of immature or poorly developed ovules in each cone, typically at the base and tips of the cone. Certainly, cone development and early ovule development are under a certain degree of genetic control but the potential to increase the number of mature ovules through cultural techniques warrants a closer look. This is especially true in seed orchard environments where culture techniques can be easily applied.

Another factor affecting low seed set is cone and embryo abortion. *Pinus* species are most sensitive to pollen supply where a substantial percentage of first-year conelets can abort due to inadequate pollen. However, in mature seed orchards, pollen supply is seldom limiting and cone retention is high. However, under field conditions where drought, high temperatures, and low humidity occur, poor uptake of pollen in *Pinus* species may result in increased cone abortion. It is also possible that drought, high temperatures, and low humidity could restrict fertilization and early embryo development in all species.

Environmental Effects on Reproduction

Orchard environment can affect progeny performance. Progeny from parent trees growing in warmer southern seed orchard environments can display delayed flushing in the spring and extended growing periods and delayed growth cessation in the summer. They also developed frost-hardiness later compared to like genotypes derived from northern sources. This phenomenon has been termed seed orchard aftereffects and the effects can endure for several years, if not the lifetime of the tree. Similar effects have been demonstrated with progeny derived from like parents growing under greenhouse conditions compared to open orchard conditions. Further, progeny derived from seed reared under the warmer environment of greenhouses can also show lower spring and fall frost resistance.

We do not know the mechanism of this phenomenon, nor do we know at which stage of reproductive development the effect occurs. However, several hypotheses have been postulated. Since many of the genes expressed in the sporophyte are also expressed in the gametes, it is possible that gametophytic selection occurs. It is argued that pollination selection does not occur in conifers because the pollination mechanism allows too few pollen grains to enter the micropyle to provide sufficient selection pressure. However, three or four pollen grains in each of 100 ovules per cone and hundreds of cones per tree may provide a population sufficiently large to consider a directional selection of pollen under different temperature regimes. Furthermore, conifers have multiple archegonia (many egg cells) per ovule, which permits the possibility of temperature affecting the selection of many fertilized egg cells. Finally, the effect could also be non-Mendelian and represent a maternal effect that remains to be described.

Forests, Tree Physiology and Climate

M Rebetez and Michael Reinhard, WSL Swiss Federal Institute for Forest Snow and Landscape Research, Lausanne, Switzerland
Alexander Buttler, University of Franche-Comté, Besançon, France

Introduction

Climate can be defined as the long-term integration of atmospheric parameters such as temperature, precipitation, wind, insulation, air humidity, or snow cover. It is one of the key factors conditioning the growth of vegetation and it is impossible to dissociate the history of forests, and all flora and fauna, from the history of the earth's climate. Climate controls vegetation patterns and dynamics and, conversely, vegetation also influences the climate. These relationships occur over different spatial and temporal scales.

This article reviews the main aspects of the relationship between climate parameters and forests while the impacts of climate change and environment on forests as well as tree physiology and stress are covered in other articles within this publication.

The Energy Cycle and Vegetation Growth

The sun is the basic source of energy for the earth and the maintenance of its biological systems. This energy reaches the planet by means of electromagnetic radiation. The solar constant represents 2 cal (8.3 J) $cm^{-2} min^{-1}$, but the solar irradiance at the earth's surface, which is the driving force for the functioning of ecosystems, represents less than half of the solar constant (**Figure 1**).

The earth re-emits part of this radiation towards space (mainly in the infrared spectrum). Another part of it is trapped by the greenhouse gases in the atmosphere. The balance between the incoming, outgoing, and absorbed energy keeps the earth's climate virtually constant, at a mean temperature of about 15–16°C (warmer now, due to global warming, than it was a few decades ago). Without any greenhouse effect, which is brought about by the humidity and greenhouse gases such as CO_2 in the earth's atmosphere, the mean temperature on the planet would be −18°C. Thus, the total energy absorbed by the earth depends on the amount of greenhouse gases and of aerosols in the atmosphere. These depend in turn on different factors, including volcanic emissions, human sources linked to the burning of fossil fuels, and methane emissions from warming permafrost and agriculture. Only a small part of the sun's energy is used for vegetation growth, the photosynthetic yield, representing the transformation of radiation into chemical energy, being estimated at 1–1.5% for forest ecosystems. Primary

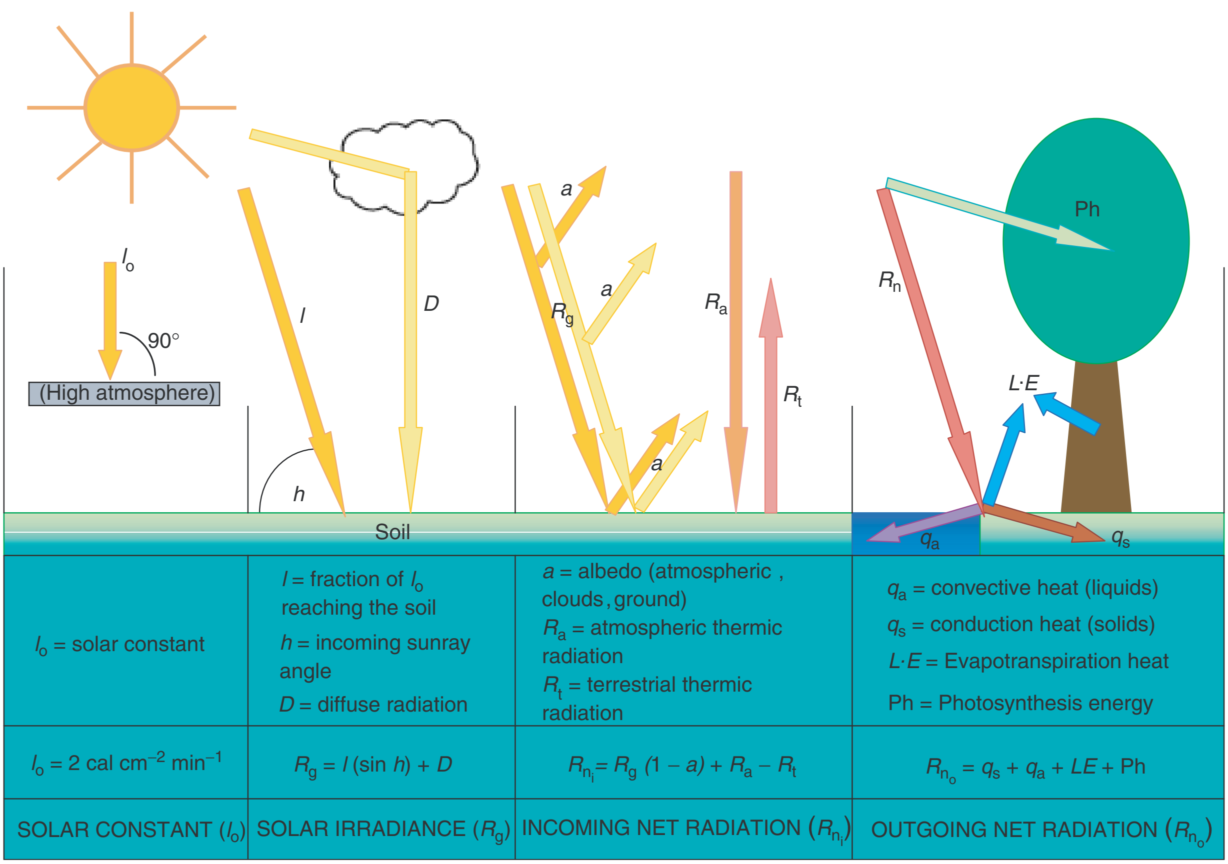

Figure 1 Incoming and outgoing net radiation at the earth's surface. The incoming and outgoing radiation depend on the thickness of the cloud cover, which can act as a shield for the sunrays. The total amount of intercepted radiation at the ground level depends also on the density and thickness of the vegetation canopy. About 98% of the intercepted radiation is reflected or used to heat the tissues and only about 2% is used for photosynthesis. Reproduced with permission from Ozenda P (1982) *Les Végétaux dans la Biosphère*. Paris: Doin.

production contributes to the carbon cycle, and sometimes this organic matter becomes trapped underground as peat, oil, or coal. Through its albedo, the vegetation cover also influences the amount of energy absorbed at the earth's surface.

The energy emitted by the sun is not equally distributed over the earth's surface and this leads to compensating ocean currents and atmospheric circulation. The earth's spherical shape implies a spatially uneven incidence of the incoming solar irradiance, and its intensity changes with latitude. Throughout the year, the intertropical zone receives more energy than polar regions. As the tilt of the earth's axis is not perpendicular to the planet's orbit, the amount of energy received also changes throughout the year, thus determining the seasons. The total amount of energy received by the earth yearly also varies with the amount of energy released by the sun and also with the elliptical shape of the earth's orbit and its eccentricity. These orbital parameters determine climatic cycles on the order of 20 000 to 100 000 years. These differences are relatively small, but important enough to explain major changes in the earth's ice, ocean, and vegetation cover in the past.

The Impact of Climate on Vegetation

Climate and the resulting distribution of vegetation over the earth's surface is primarily determined by the available energy. At a large geographical scale, climatic zones follow one another in parallel from the equator to the poles and determine zonal macroecosystem belts called biomes (**Figure 2**).

The strong warming of the earth's surface in equatorial regions causes air to rise. As the warm, moist air rises, it cools, resulting in frequent precipitation and allowing the development of rainforests. This air circulation pattern is linked to a belt of low atmospheric pressure upon which winds converge (**Figure 3**). The warm air masses circulate back the earth's surface north and south of the equatorial region, in a subsidence movement that is linked to high air pressures. During this process, the air temperature remains relatively high but the

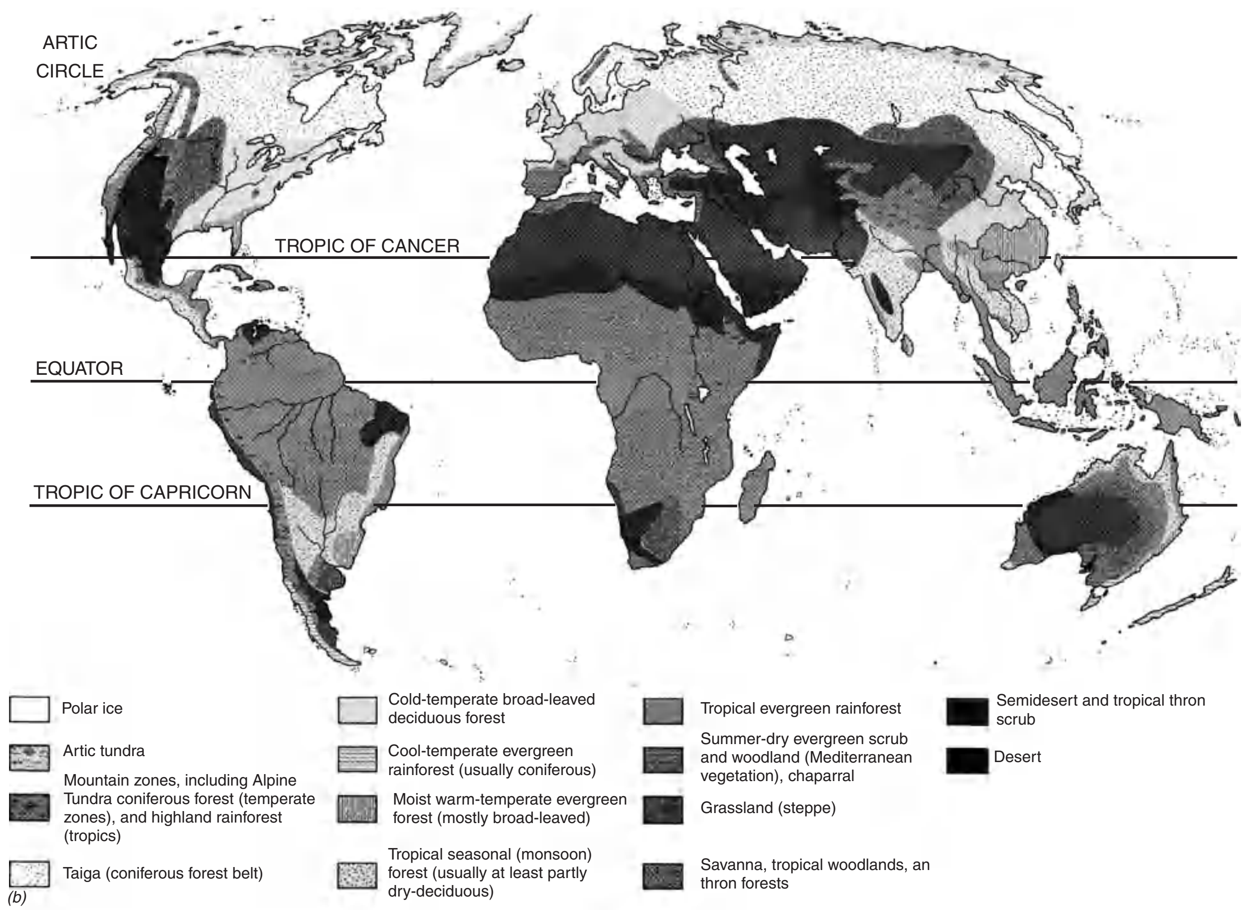

Figure 2 Distribution of the major vegetation types across the globe. Reproduced with permission from Aber JD and Melillo JM (2001) *Terrestrial Ecosystems*, 2nd edn. London, UK: Academic Press.

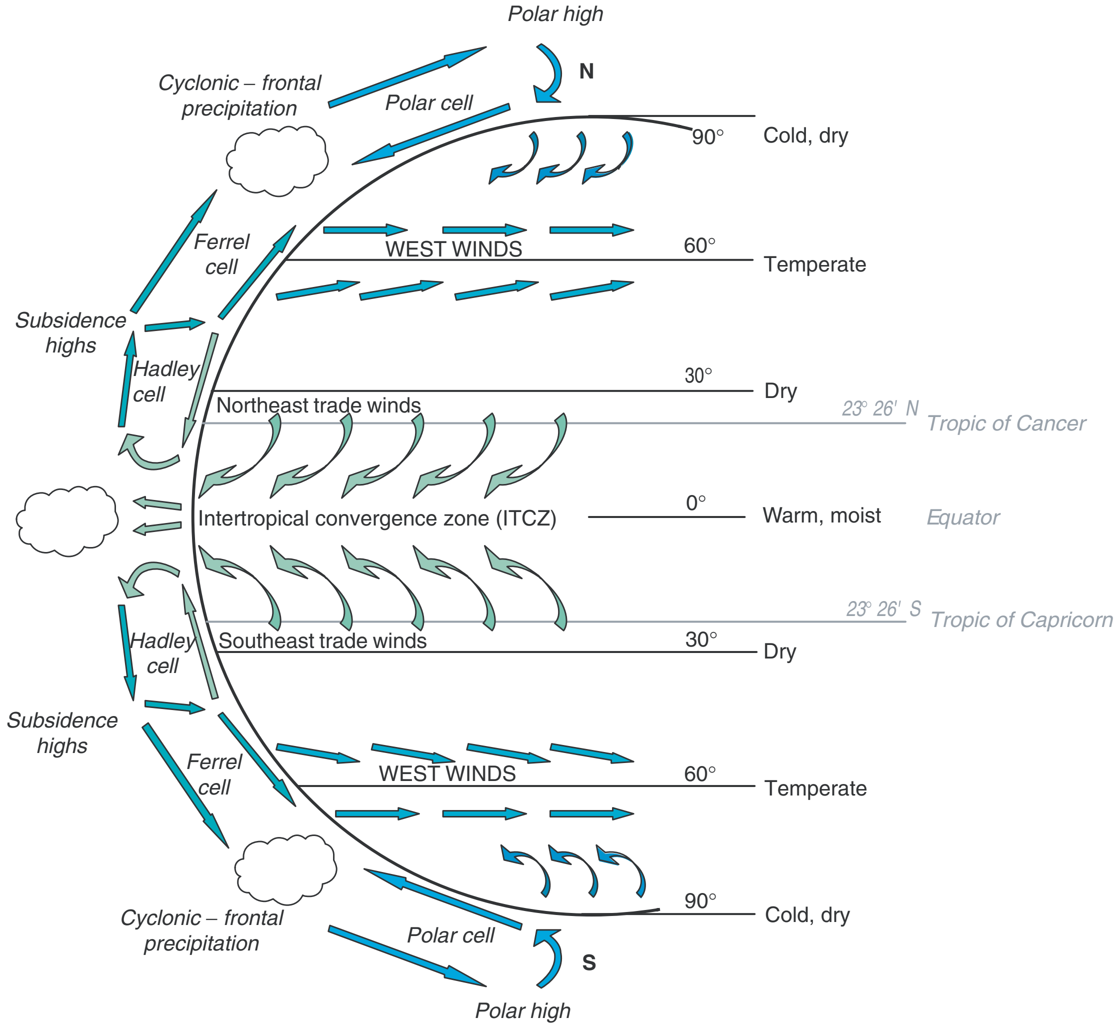

Figure 3 Global earth atmospheric circulation and main winds. The planet's surface receives decreasing solar radiation from the equator to the poles because of the spherical shape of the earth and its tilt. Heated air expands and loses density. There is thus a relation between the temperature gradient of the earth and the atmospheric pressure system. Hence, we would expect the air masses to move from the cold poles (dense air, high pressure) to the warm equators (dilute air, low pressure) to cancel out the pressure gradient. In reality, we observe various cyclonic (lows) and anticyclonic (highs) pressure systems leading to three main components (Hadley, Ferrel, and polar cells) in both hemispheres. Adapted from Whittaker RH (1975) *Communities and Ecosystems*. London: Collier Macmillan and Dincauze DF (2001) *Environmental Archaeology*. Cambridge, UK: Cambridge University Press.

moisture and precipitation decrease progressively, leading to drier climatic zones with more pronounced seasonality. A precipitation gradient of approximately 1 mm year^{-1} km^{-1} occurs from approximately 10° N to 18° N. Below a threshold of approximately 400 mm year^{-1}, the lack of precipitation shapes the steppe and desert vegetation. The Sahara Desert, the Sahel zone, and their transition zone have been defined as having the following rainfall values: Sahara Desert, 0–100 mm year^{-1}; Saharan–Sahelian transition zone, 100–200 mm year^{-1}; and the Sahel proper, 200–400 mm year^{-1}.

At higher latitudes, beyond these anticyclonic zones, the climate is dominated by westerly winds. The Mediterranean climate is characterized by dry and hot summers with wet and mild to cold winters. The temperate climate experiences air masses from the north or south at all seasons: warm air masses from the tropics alternate with cold air from the polar regions. Temperatures can consequently vary from one day to the next and vegetation must be adapted not only to cold winters and hot summers but also to rapid changes, including for instance a return to below-freezing temperatures during a mild spring. At the highest latitudes, temperature and light remain very low throughout the year. The vegetation is limited by the cold and partly by snow or ice cover, resulting in cold deserts. The broad pattern of world biome types can be represented in relation to humidity and temperature (**Figure 4**). The concept

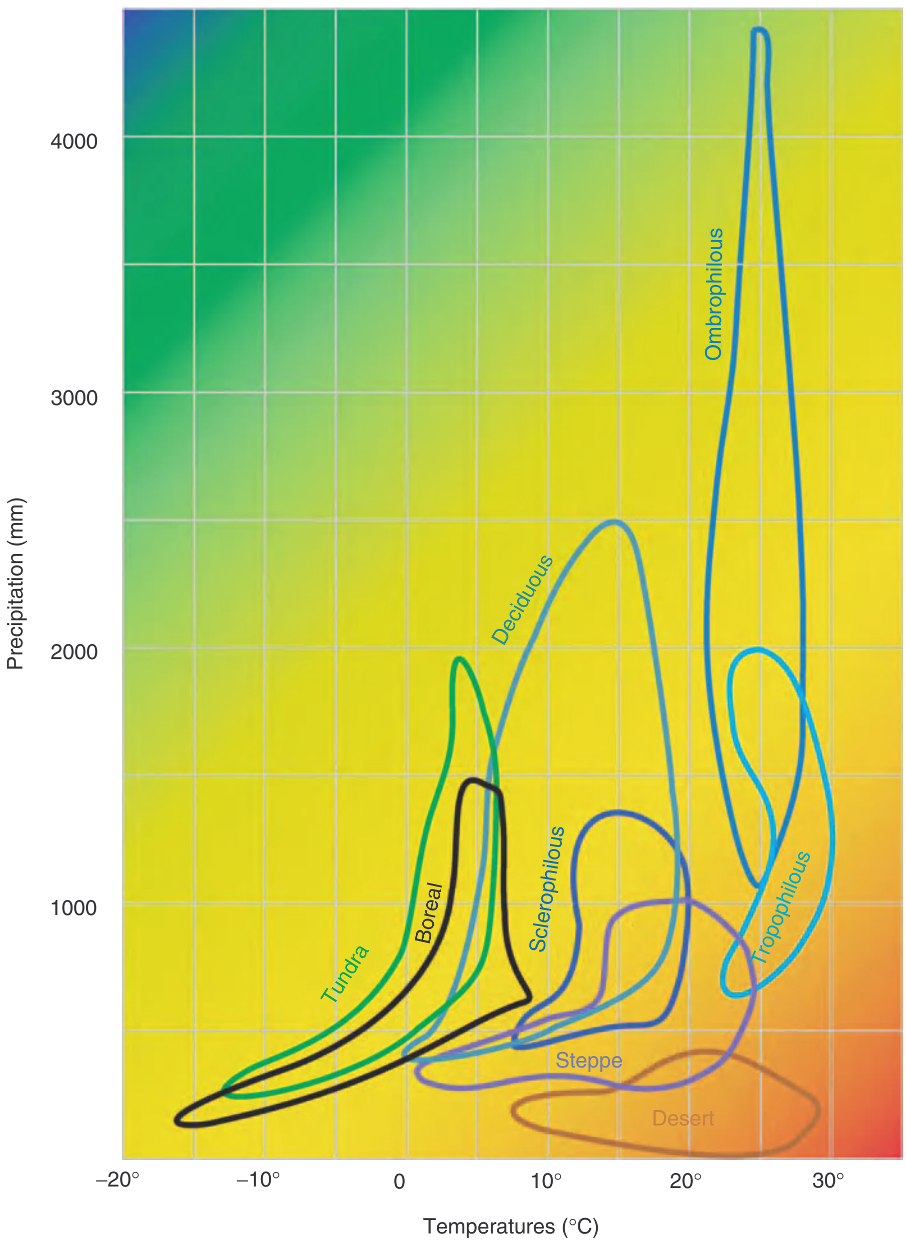

Figure 4 Distribution of vegetation types according to mean annual temperature and precipitation. The planet's vegetation cover is largely linked to temperature and precipitation gradients. This figure gives an insight into the coarse ombrothermic distribution of the major biomes. At finer scale, the species composition determines many other plant communities. Furthermore, the natural distribution and extension of the biomes is altered by human activities. Adapted from Whittaker RH (1975) *Communities and Ecosystems*. London: Collier Macmillan.

of the ecocline can be used to relate communities to climate on a worldwide scale.

The distribution of vegetation on the earth's surface is also influenced by other factors. Because of the uneven distribution of land and water over the globe, the biomes are distributed unequally between the northern and southern hemispheres (**Figure 2**). Regionally, they also depend on proximity to oceans, on the degree of continentality, or on topography. Temperate areas located near oceans are often referred to as 'oceanic,' as the oceans bring moisture and reduce the variation in temperature between summer and winter as well as between day and night. As air masses from the west move over the continent, losing moisture, the 'continentality' increases, which means longer drought periods and greater temperature fluctuations, and consequently the development of dry vegetation types such as steppes and deserts.

At intermediate scales, the regional climate setting can modify the general pattern of vegetation. Greater elevations can be considered as equivalent to higher latitudes. On Mount Kilimanjaro, Mount Everest, and Mont Blanc, the climate is comparable to that of the poles (cold deserts) although these mountains are in tropical and temperate regions. On the sides of these mountains, the climate follows a gradient determined by altitude. The temperature, in particular, decreases with altitude at a mean rate of approximately 0.7°C per 100 meters (depending mainly on the air humidity and pressure), and the vegetation communities reflect these changes (**Figure 5**). The vegetation changes that occur with altitude are similar to those occurring with latitude. For example, 100 meters change in elevation is equivalent to an increase of 1° of latitude. The degree of sun exposure and more generally the topography of the landscape can change the altitudinal distribution of vegetation communities (**Figure 6**). Features such as valleys where temperature inversions occur can host specialized communities and even reverse the altitudinal distribution of vegetation (**Figure 7**).

Light

Light is a fundamental climatic parameter providing the energy for photosynthesis and controlling the availability and production of vegetation. The amount of light and energy that penetrates the forest or is reflected depends on the species composition, which determines the canopy structure, and on other properties such as the color of leaves, their position and density, the age of the stand, and the season (**Figure 8**). The loss of light with increasing distance from the top of the canopy is termed light attenuation, and can be expressed by:

$$\mathrm{IL}/\mathrm{IO} = \mathrm{e}^{-k\mathrm{LAI}(L)}$$

where IL/IO is the percentage of light at the top of the canopy (IO) reaching depth L in the canopy, LAI(L) is the cumulative leaf area (in m^2 of leaf area per m^2 of ground area, called leaf area index) from the top of the canopy to depth L, k is a stand- or species-specific constant, and e is the base of natural logarithms (2.718).

The ground surface in a forest receives progressively less light as the forest grows; at the time of canopy closure, the ground in a pine stand will only be receiving approximately 7–8% of the ambient light. However, as a stand ages beyond this stage, the light penetration gradually increases, reaching approximately 30% of ambient by maturity. In the deciduous forests of temperate zones, the amount of light reaching the ground is highest in spring, being 5–10 times higher than that experienced in summer, when only 1–5% of the ambient light reaches the soil. Combined with the increase of temperature over the growing season, this change in light condition allows phenological shifts of the vegetation that are particularly obvious in the herbaceous strata.

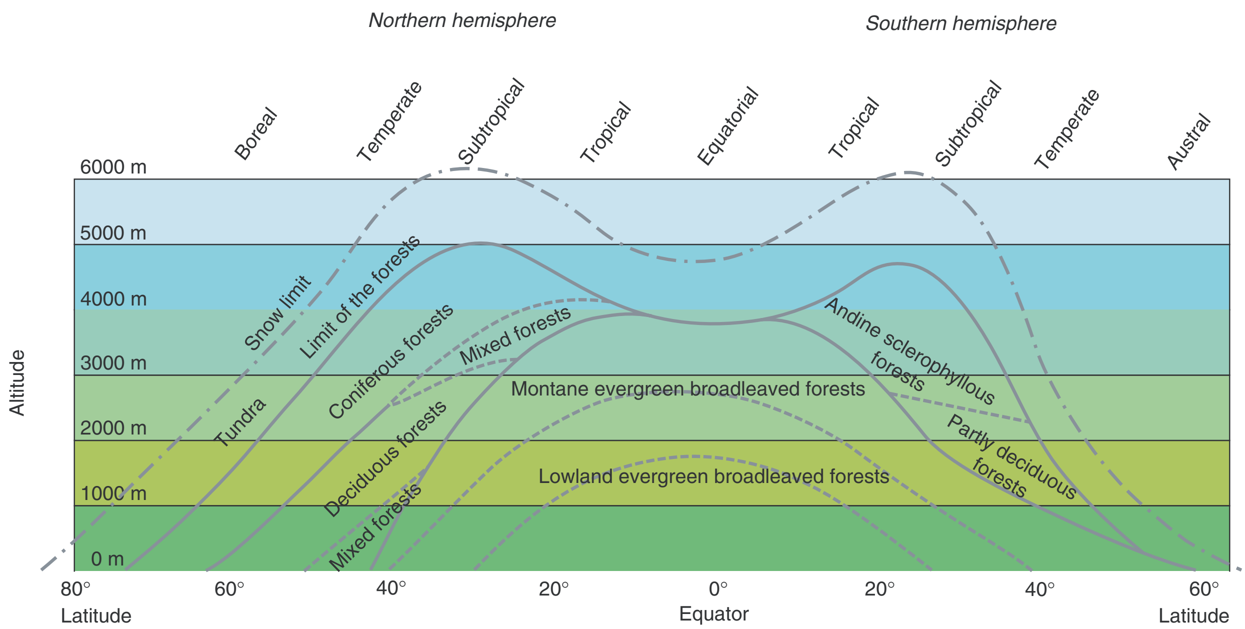

Figure 5 The relationship between altitude, latitude, and main forest types. The snow limit is lower at the equator because of the high precipitation and the related snow amount in comparison to the tropics. In general, coniferous forests mark the limit of the forests in the northern hemisphere, whereas deciduous forests do so in the southern. Adapted from Otto HJ (1998) *Ecologie Forestière*. Paris: Institut pour le Développement Forestier.

Modified from Gallandat JM and Landolt E (1994) Compte Rendu de la 2ème Excursion Internationale de Phytosociologie en Suisse (14–21 Juillet 1991). Veröffentlichung de Geobotanischen Institutes der Eidg. Tech. Hochschule, 119. Heft. Zurich: Stiftung Rübel.

Within the vertical strata of a forest stand, both the quantity and quality of light follow a gradient, which determines the ecological niches for species and contributes to the biodiversity of the stand. Hence, only a small amount of the direct light reaches the lowest forest strata and a distinction must be made between direct and diffuse radiation (**Figure 1**). Radiation within the forest canopy is characterized by the high transmission and reflection of green and infrared light, whereas blue and red–orange light, which are the most useful for assimilation, are depleted towards the lower strata. Photosynthetic assimilation in response to solar radiation has a hyperbolic shape. At the top of the curve is the saturation point (SP), or the light saturated rate of photosynthesis, beyond which plants cannot further increase light absorption. Some authors consider that if solar radiation increases beyond this point, photosynthesis diminishes in a process termed photoinhibition, and at very high levels of radiation photodamage occurs in the form of destruction of photosynthetic pigments and thylakoid structures. However, generally, leaves are well adapted to the local light conditions and their pigmentation allows for the dissipation of excess energy or the capture of energy when it is limited. This means that species growing under full-sun conditions generally show higher rates of photosynthesis and have higher saturation points than those normally growing under partial shade.

These processes play a determinant role in the plant composition of forests as different species have different light requirements. There are heliophyte plants, requiring high quantities of sunlight, and sciophytes, which prefer shade and sometimes still have a positive carbon balance, and finally species that have a rather large ecological amplitude. For instance, mosses and herbs on the forest ground have very low SPs. The amount of global radiation is the most important parameter for the definition of heliophyte and sciophyte types and hence for the vegetation composition in forests. Light conditions are also very heterogeneous horizontally. Light can directly penetrate into forest stands, creating light patches at the soil surface that are of particular importance for the regeneration of vegetation. Such light flecks can cover 20–25% of the ground surface at noon in a tropical forest, contributing 70–80% of the energy reaching the soil.

Plants do not only physiologically adapt to the light, they also do so morphologically. For example, the shape of leaves is smaller and thicker where insulation is important, whereas the opposite occurs in less exposed locations. The same tree species may show very different stature depending on whether it is growing in a dense or open stand. For example,

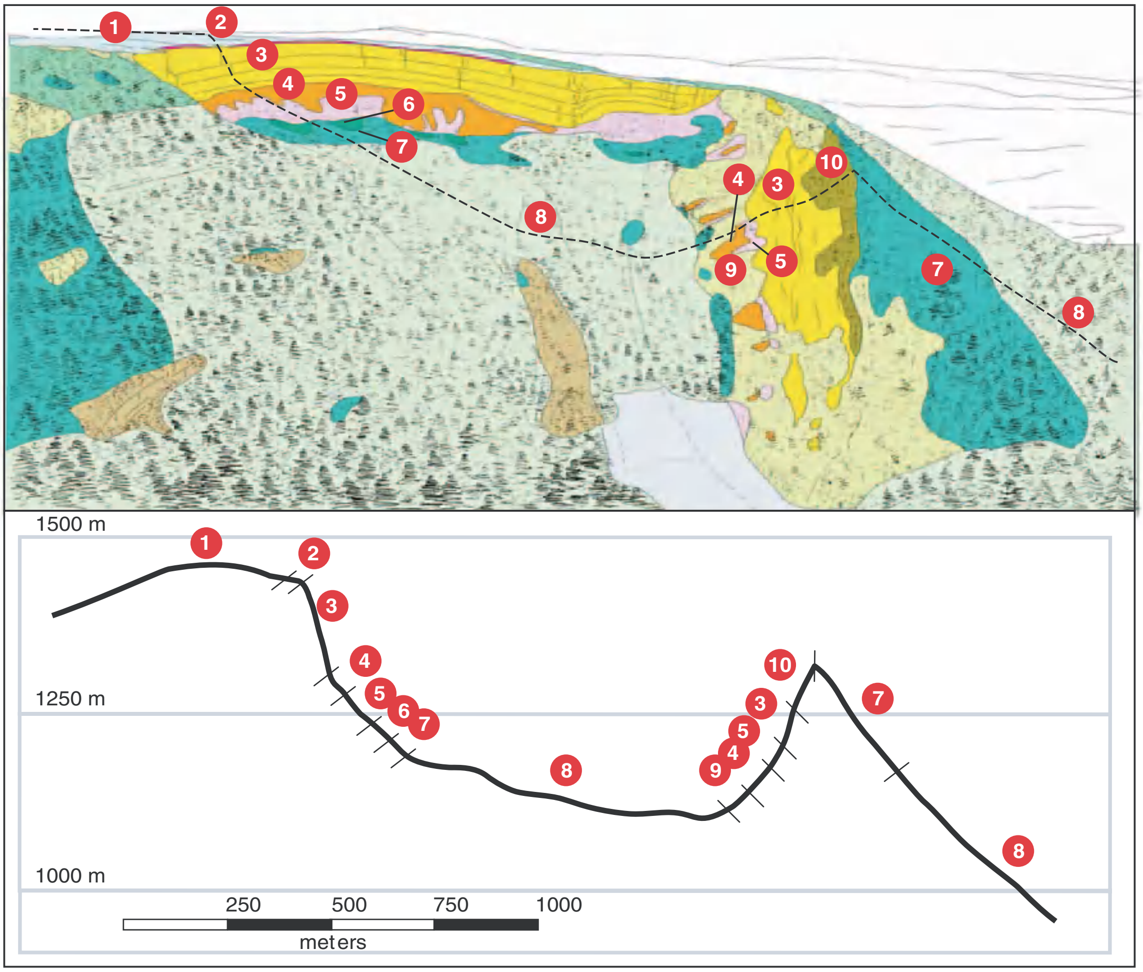

Figure 7 Distribution of the main vegetation types in the Creux-du-Van in the Swiss Jura Mountains. The site is shaped by a 200-m high cliff which encircles a semiclosed depression with a cold local climate. In the scree at the foot of the cliff, a permafrost has built up as a remnant of a local glacier. The figure shows that a spruce subalpine forest is developing in the cold depression and on north-facing slopes, whereas, on the contrary to normal vegetation distribution (see **Figure 6**) beech forests can be found at higher altitudes than the spruce forest. 1, Beech and maple forests, pastures; 2, Rock pioneer vegetation on the cliff; 3, Maple forests and pioneer vegetation on the scree; 4, Subalpine spruce forest on the scree, together with subalpine herbaceous species; 5, Beech and fir forests; 6, Thermophilous beech forest and pine forest. Figure 8 Relationship between the age of the stand and the relative amount of light received on the ground of the forest. On average, forests are thickest at about 20 years of age, which corresponds to the period when the smallest amount of light reaches the forest ground. Later, as the stand grows older, it loosens allowing for more light on the ground. Adapted from Flemming G (1995) *Wald, Wetter, Klima: Einführung in die Forstmeteorologie*. Berlin: Deutscher Landwirtschaftsverlag Berlin.

shaded leaves may have less chlorophyll per unit leaf surface area than sun-exposed leaves.

Temperature

Temperature is very important to poikilotherm organisms such as trees. Poikilotherm organisms assume the temperature of their environment. The lower the temperature, the lower the metabolic activity of the plant and the less the photosynthetic activity. Tree species all have different temperature optima for photosynthesis: a boreal forest tree conducts photosynthesis at far lower temperatures than tropical trees. On average, temperatures are harmful to vegetation when they rise above 50–60°C, which is the protein alteration threshold, and when they drop below 0°C, at the threshold for cellular structural deterioration. At both thresholds, the cell wall stability is critical. However, trees may adapt physiologically where temperatures frequently pass beyond these values. For example, in Siberia, trees have to cope with temperatures as low as −68°C.

Cold is a limiting factor that can cause freeze stress to trees unless they are acclimated. If the temperatures are too low and the growing season too short, trees cannot grow. Freezing damage is more important during daytime, when photoinhibition is also induced, and when vegetation is active, for example at the beginning of the growing season. Ice crystals form inside the plant cell and break the cell walls, which kills the cells. Extracellular freezing may also induce cell dehydration. Freezing within the xylem vessels can be followed, during melting, by the development of occlusions that hamper hydraulic conductivity. Trees therefore need to adapt to temperature, and they do this using particular strategies. In temperate climates, deciduous forests are dormant during wintertime. Trees lose their leaves, which cannot withstand frost, leaving only the relatively resistant dormant buds. Coniferous trees do not lose their needles during the winter season and overcome freezing stress through physiological adaptations. Intracellular freezing is avoided by chemical alteration of the liquids inside the cell, a phenomenon called supercooling. Supercooling is enhanced by partial rejection of water outside the cells, dropping the freezing point of the solute content of the cell. Water can freeze outside the cell, whose walls are able to deform. However, despite the use of both supercooling and extracellular freezing, most coniferous trees need a time to adapt and become frost resistant for the winter, a process called frost hardening. If the temperature drops too quickly, then even coniferous trees suffer from freezing stress, resulting in the development of injury to the foliage. Hence, winter temperatures set the broad geographic distribution of many tree species in both the northern and southern hemispheres. Under natural conditions, this ecological limitation can be recognized on mountains by the upper growing limit of the trees – the treeline.

High temperatures can also disturb or disrupt photosynthetic activity and harm the plant. The rate of photosynthetic activity depends on the species. Observations suggest that there is a relationship between latitude and the sensitivity of photosynthesis in a species to temperature. However, there is also evidence of considerable plasticity in this relationship. Several factors can lead to the decline of photosynthetic activity at high temperature, including the more rapid increase in respiration rate than photosynthesis that accompanies increasing temperature; the breakdown of temperature-intolerant enzymes thought to be critical for photosynthesis; the alteration of the cell structure, cell membrane thinning, and cell leakage; and stomatal closure and the inhibition of the carbon dioxide, water, and oxygen exchange essential for photosynthesis. Plants can adapt physiologically to high temperatures. For example, some leaves have a reflective coating. Other forms of adaptation concern the form or the orientation of the leaves, which may be vertical in order to reduce the exposure to the sun. For example, if a leaf orientated perpendicular to the sun absorbs 1.0 cal (4.19 J) of energy $cm^{-2} s^{-1}$, then one orientated at 60° to the sun will only absorb 0.5 cal (2.09 J) $cm^{-2} s^{-1}$. In cases when there is sufficient water available, another adaptive mechanism is to increase the transpiration rate, which then cools the leaves.

At a local scale, temperatures are controlled within forest ecosystems by the strong moderating effect of the stand on radiation. In deciduous forests, daytime temperatures are highest within the crown during the growing season, and highest at the soil surface once the leaves have been shed. Temperatures inside forests, and particularly at the ground surface, are of major significance as they have such a bearing on physiological processes. The temperatures inside forest stands are regulated, whereas the temperatures outside wooded areas can vary greatly between day and night, and over the seasons. Forests reduce the diurnal temperature range: days are cooler and nights are warmer than they are outside the forest. However, on average, temperatures are cooler in forests than in nearby open areas. The differences are greatest at the ground level. For instance, the average difference between field and forests is about 1 K at ground level, 0.7 K at about 2 m above the ground, and 0.3 K at the crown level. This is the result of the poor distribution of light and of the high rate of evaporation within the forests. Tree crowns retain cool air during the day, and at night, they capture the thermal radiation near the ground. In winter, snowless crowns have a lower albedo than the surrounding fields and, hence, temperatures are higher in the forests when there is snow on the ground. The spatial heterogeneity of the forest, and in particular the presence and distribution of larger gaps in the stands, can alter the thermal exchanges within the forest and its temperature gradients. This can be critical for the regeneration of trees.

Precipitation and Water Availability

Water availability at a particular location and the hygrometric condition of the atmosphere are of the utmost importance for terrestrial organisms, as their survival depends on the desiccation rate in conjunction with temperature. For many species, precipitation is a more important determinant of survival than temperature per se. Precipitation is a primary determinant of vegetation structure, with trees occurring only where annual precipitation is in excess of 300 mm. Vegetation needs water to achieve photosynthesis as much as it needs optimal temperatures and light. Moreover, plants need water for physiological activities such as protein synthesis or cell growth, and to maintain the rigidity (turgor) of the cells. Eventually, water is necessary for nutrient transportation in plants. Water is transported in vascular plants by physical processes: water moves from the high vapor pressure at the roots to the low pressure at the stomata. Water leaves trees through the stomata, which are usually located under the leaves, and this loss creates an upward water flux from the soil to the plant. The loss of water is termed transpiration, and the rate at which it occurs depends on the air temperature, humidity, and wind conditions, and on the particular stomata shape and behavior. Evapotranspiration is the total amount of water transmitted into the atmosphere by vegetation transpiration added to the total amount of evaporation from the plant and ground surfaces at the same location. The total yearly transpiration of a temperate forest stand ranges from 200 to 600 $l\,m^{-2}$. Thus, vegetation cover largely influences air humidity.

Observations indicate that there is a relationship between annual precipitation and the main vegetation types. This is particularly true for regions with extreme precipitation. However, this relation is blurred at regional and local scales. This is because of annual precipitation patterns, which regulate the available and usable water quantity for vegetation. Other parameters such as topography, soil, and the vegetation itself can influence the hydrological budget at a site. The fate of the rainwater depends partly on the forest stand. In temperate deciduous forests, the canopy can intercept between 10% and 40% of the annual precipitation, which is subsequently lost from the stand through evaporation. Higher interception rates have been reported for coniferous forests.

Trees need to adapt to hydrological conditions as well as to light and to temperature. Hygrophyte plants grow in environments close to the water saturation point while xerophyte plants live in dry environments. In water-saturated environments, trees are adapted to the poor oxygen availability in the soils; these include poplar (*Populus* spp.), willow (*Salix* spp.), alder (*Alnus* spp.), *Taxodium distichum*, *Nyssa* spp., mangroves, and a few palms, such as *Nypa fruticans*. The diffusion of oxygen in water-saturated soils is about 10 000 times slower than in dry soils. Consequently, plants need to adjust their roots to the conditions that they are growing in: aerial roots from stems, ventilating tissue (aerenchyma) along the stems, and longitudinal air spaces along roots are examples of observed adaptations.

Drought is also an important factor limiting vegetation. It influences the distribution of plants and occurs when a deficit develops between precipitation and evapotranspiration, leading to a reduction in the soil water content. Water stress occurs when, as a result of water deficit, the relative water content of the plant tissue decreases. Many plants cannot extract water from soils when the matric potential (a measure of the attraction between soil particles and water in the soil) falls below −1.5 Mega Pascals (MPa) – termed the permanent wilting point. Plants adapted to very dry conditions have permanent wilting points well below −1.5 MPa, such as the dryland vegetation described below. A lack of water will drastically disturb photosynthetic activity: the plant closes its stomata to avoid desiccation and to maintain the cell's rigidity and, hence, uptake of carbon dioxide for photosynthesis is halted. Trees that adjust to dry conditions are called water-stress avoiders because they develop particular resistance strategies. A general, long-term response to water stress is for the osmotic potential of leaf cells to be altered through an increase in the concentration of cations, sugars, and low-molecular-weight solutes in cells. This increases the differences in water potentials between leaf and soil and decreases the gradient between leaf and atmosphere, facilitating the movement of water from the soil to the leaf and reducing the rate of water movement from the leaf to the atmosphere. Other mechanisms also occur. For instance, the baobabs (*Adansonia* *digitata*) use their thick trunks to store water, which is then used during dry periods. They can store up to 120 000 l of water and at maturity have a circumference of about 20 m. Some shrubs develop a particularly deep root system that can reach groundwater located at considerable depths. For example, mesquite shrubs (*Prosopis* spp.) develop roots penetrating as deep as 53 m. Families such as *Olea*, *Myrtus*, and *Phillyrea*, which are fairly tolerant of fluctuations in water content, are termed hydrolabile. Families such as *Laurus*, *Arbutus*, and the evergreen *Quercus* species cope with water stress by adjusting transpiration rates; this behavior is termed hydrostable. Dormancy is another adaptation. Some trees adapt by shedding leaves during the dry season. However, plants retaining their leaves during the dry season are often adapted to water stress by having hard and waxy leaves, termed sclerophyllous leaves.

Precipitation and moisture in their solid form, snow and ice, are also important ecological factors in the mountains and in cold climates. They act as water reservoirs during the summer. Snow can protect against desiccation and against cold temperatures. However, snow can also harm trees because of its weight. The length of the snow cover season influences the spatial distribution of plant communities, and topography has an influence on the length of snow cover. A snow depth of 20 cm will prevent between 85% and 99% of the ambient light reaching the ground, depriving plants of the light necessary for photosynthesis. Fog and dew are other factors that can play an important role in some circumstances, for example in providing a significant source of water in what would otherwise be relatively dry ecosystems (*see* **Hydrology**: Hydrological Cycle).

Wind

Winds emerge from the atmospheric pressure system. Their strength depends on the difference between high- and low-pressure areas, modulated by topographical features of the earth's surface such as mountains and valleys. At ground level, air masses always move from high to low pressure at all the global, regional, and local scales, contributing to the precipitation distribution. As a result of the earth's rotation, winds in circular air movement patterns move to the left in the northern hemisphere and to the right in the southern hemisphere.

Within forest stands, wind influences temperature and moisture gradients. Where winds blow strongly and constantly, trees develop specific features reflecting the dominant wind direction. This phenomenon is called anemomorphism and is particularly frequent in coastal zones and some mountain regions. Where winds are too strong, arborescent species cannot grow and give way to shrubs and grass fields. Trees often grow up to a limit of 2300 m above sea level in the European Alps, for example, whereas because of wind they barely reach 1450 m in the French Auvergne, located only a few hundreds of kilometers away.

Locally, forests can act as windbreaks. Next to the forest boundary, turbulence is produced, altering the effect of the wind. For deciduous forests, this effect is most effective during the growing season. In many regions of the world, trees are used to shelter crops, buildings, and other features from wind.

Physiology of Vegetative Reproduction

R R B Leakey, James Cook University, Cairns, Queensland, Australia

Introduction

Vegetative regeneration is both a natural process and an artificial process. The artificial process is used by agriculturalists, horticulturalists, and foresters to capture and multiply individual genotypes, and so to produce cultivars and clones. Clonal approaches to forestry and horticulture have a history going back more than 800 and 3000 years respectively, originating in China. Typically the process is used to develop superior planting stock, although there are also many applications in research where clonal uniformity is a powerful tool in the separation of genetic effects from physiological and environmental impacts on growth processes in plants.

The level of understanding about vegetative regeneration using stem cuttings has progressed enormously since the 1970s, the period when clonal forestry was becoming a reality in Europe, USA, tropical Africa, and Latin America. Although the focus of this review is primarily on the physiology of rooting cuttings, some mention is also made of related issues in air-layering/marcotting, grafting/budding, and different *in vitro* propagation methods.

This contribution draws heavily on studies done with *Triplochiton scleroxylon*, a tropical hardwood of West Africa, because of the large number of relatively comparable experiments done using a similar type of material (single-node leafy cuttings) under similar environmental conditions, to seek some physiological principles of wider relevance. In addition, the review offers some suggestions on how future research should be implemented to enhance the identification of underlying physiological principles determining successful rooting of stem cuttings. The problem that needs to be overcome is the high level of interaction between the large number of factors preseverance, postseverance, and in the propagation environment.

Rooting Stem Cuttings

Stem cuttings can come in many forms but the two major groups are leafy softwood cuttings from relatively unlignified, young shoots (**Figure 1**), and leafless hardwood cuttings from older and more lignified shoots which typically have already shed their leaves due to the onset of winter or a dry season. It is important to understand that the factors determining the rooting of these two types of cuttings are very different: leafy cuttings depend on current photosynthates produced in the propagation bed, while hardwood cuttings depend on the hydrolysis and availability of carbohydrates stored within the stem tissues.

When trying to root leafy stem cuttings, there are four stages when a good physiological understanding of the factors influencing rooting ability is necessary: (1) in the propagation environment; (2) postseverance; (3) in cutting origin and environment; and (4) in the preseverance stockplant environment.

The Propagation Environment

The most important aspect of the propagation environment is that it encourages physiological activity (photosynthesis and transpiration) in the leaf to minimize the physiological stresses experienced by the tissues, from transpiration and respiration, and encourages meristematic activity (mitosis and cell differentiation) in the stem. The transport of assimilates and nutrients from the leaf to the base of the stem, and of water from the base of the stem to the leaf, are also important. Recent physiological measurements confirm general experience that the duration of physiological shock arising from severing a cutting from its stockplant and inserting it in a propagator can be minimized by controlling the propagation environment. Minimizing this shock enhances rooting.

There are many different types of propagation systems for stem cuttings, but the most common are: (1) fogging systems; (2) intermittent mist (**Figure 2**), controlled by a range of different sensors; and (3) airtight, watertight, high-humidity, nonmist propagators (**Figure 3**). These are all very effective, but vary in their cost and sophistication. The nonmist

Figure 1 A rooted cutting of *Milicia excelsa*.

Figure 2 A typical mist propagator.

propagators have the advantage of being very low cost and simple and so are highly suitable for use in developing country or rural situations where electricity and piped water are not available. The basic principles behind all these systems are that the cuttings are well supplied with water at the cutting base while the leaves are in a cool, shady environment with low vapor pressure deficit (VPD) to

Figure 3 A nonmist propagator – a watertight, airtight box when the lid is closed. Inset: cross-section of the propagation medium showing layers of saturated gravel and unsaturated but moist rooting medium.

minimize water stress. Moist leaves also keep the cuttings cool due to the evaporation of water from the leaf surfaces. While shading is beneficial, leafy cuttings need enough light to photosynthesize. Interestingly, the highest values of photosynthesis in severed cuttings have been found at relatively low levels of irradiance.

Comparative studies between different propagation systems for cuttings (e.g., mist and nonmist) found that nonmist propagators provided as good an environment for rooting as mist, if not better. Under mist, air and leaf temperatures and VPD were consistently higher than under nonmist systems. There were also differences in the frequency of peaks in VPD associated with peaks in irradiance. Peaks of VPD can also occur as a result of misting frequency, and its spatial distribution on the propagation bed. In a second study, using cuttings of four tropical trees (two from the moist tropics and two from the dry tropics), significant water deficits did sometimes develop in the leaves of the cuttings under both systems. The patterns of variation in relative water content (RWC) were similar to those of water potential and stomatal conductance. Interestingly, the species differences in RWC and stomatal conductance seemed to be more closely related to leaf morphology than to their environment of origin. Leaf morphology may also account for differences between the four species in optimum leaf areas, indicating the need to report full details of as many of the long list of morphological and physiological pre- and postseverance factors affecting rooting as possible if a good understanding of the vegetative propagation process is to be achieved.

Few studies have been done on the effects of the light environment on photosynthesis during propagation because of the difficulty of measuring gas exchange in cuttings with wet leaves; however, the use of a nonmist propagator has allowed measurements on the rates of photosynthesis, stomatal conductance, and chlorophyll fluorescence ratio to be made on cuttings with and without shade. A study on *Cordia alliodora* confirmed that photosynthesis does occur in severed cuttings in the propagation bed. Photosynthetic efficiency under two levels of irradiance (24–53 and 106–159 μmol m^{-2} s^{-1}) was found to be more closely related to rooting ability than photosynthetic rate, the latter being greatest at the higher irradiance, while rooting ability was either unaffected or reduced by irradiance, depending on the cutting's leaf area and presumably the balance between photosynthesis and transpiration. The number of roots produced was, however, closely related to photosynthetic rate. Further work is required to look at the interactions between propagation light environments and pre- and postseverance factors. The composition of the rooting medium, usually open compost or fine gravel, is often critical for rooting and can vary between species, and cultivars/clones. In addition to holding the cutting firm, it has to provide moisture and allow respiration from the tissues. Anoxia at the cutting base usually encourages rotting, so the gas-filled pore space (air-to-water ratio) of the medium needs to be optimized by the use of various-sized particles (sand and gravel) and a water-holding medium (perlite, peat, or other organic products). The oxygen diffusion rate also needs to be adequate for respiration. In *Milicia excelsa* the moisture content of the medium was positively related to the numbers of roots formed and negatively related to mortality and leaf abscission.

In temperate environments propagation beds, especially those for leafless hardwood cuttings, typically have some bottom-heat provided by heating pipes or cables to promote meristematic activity at the cutting base, while the leaves remain cool. Sprouting by cuttings in the propagation bed often has negative impacts on rooting, presumably by creating a competing sink for assimilates. Consequently a lower air temperature than bed temperature can be advantageous. This differential, although more difficult to achieve, can also be important in the tropics.

For successful rooting, cuttings have to have a positive carbon balance (i.e., producing assimilates faster than they are losing them through respiration). However, very little is known about the overall respiration rates of cuttings under different environmental conditions, or about the ways in which cutting origin, leaf area, and stem length/diameter affect respiration losses. This has, however, been investigated using an oxygen electrode to measure respiration in leafy, single-node cuttings of *Prosopis juliflora*. It was found that respiration rate per gram of dry matter decreased linearly down a shoot, as stem diameter increased. This can be attributed to an increase in nonrespiring lignified tissues, although the greater mass of cuttings with larger diameters more than compensated for these losses and the larger cuttings had a greater overall rate of respiration. Perhaps more importantly, however, the respiration rate of the cutting base (1-cm-long section) was greater than that of the stem above it. This, it has been suggested, provides a concentration gradient which drives assimilate transport basipetally to the cutting base and is a key factor in the rooting process.

Postseverance Treatments

There is probably a larger body of literature on the effects of postseverance treatments than on any other aspect of rooting cuttings. One characteristic of this literature is the apparent lack of consistent results between, and even within, species. This lack of any clear principles defining the rooting process has led to a plethora of papers reporting apparently situation-specific results, rather than to enhanced understanding. To reverse this process it is important to seek the factors that create the variability in responses to different treatments and factors affecting rooting ability.

Probably the most important of the postseverance factors are the application of auxins, leaf area, and cutting length/diameter. Consequently, to develop a practical rooting protocol for leafy stem cuttings of a previously unstudied species, it is first desirable to determine experimentally the optimal auxin application, optimal leaf area, and optimal cutting length and, if possible, to investigate experimentally their interactions within each propagation environment.

Auxin applications The application of root-promoting growth-regulatory substances (auxins) is the most common treatment to enhance rooting in stem cuttings. It is also probably the single most effective treatment to achieve successful propagation. In addition to effects on cell differentiation, auxins promote starch hydrolysis and the mobilization of sugars and nutrients to the cutting base, although increasing auxin concentrations does not result in respective increases in cutting dry mass. However, behind this apparently ‘cure-all’ treatment there lies a considerable body of evidence showing that auxin applications are interactive with other treatments, types of material, and the environmental variables affecting the rooting capacity of cuttings. This high degree of interaction is probably the reason why the literature is full of apparently contradictory statements about the precise physiological role of auxins in the rooting process, a situation that cannot be resolved when authors do not present definitive information about either the physiological condition of their material or the propagation environment used.

Typically cuttings treated with auxins root more rapidly and produce more roots, usually with a higher percentage of cuttings rooted. Usually, indole-3-butyric acid (IBA) is found to be the most effective root-promoting auxin, but occasionally α-naphthalene acetic acid (NAA) can be as effective, as in *Parkia biglobosa*. However, tree species and even clones can appear to respond differently to individual and mixed applications of auxin at differing concentrations, even when many other factors are constant. Interestingly, however, clones of *T. scleroxylon*, which appeared to have different dose–response curves, all rooted equally well at 40 μg auxin per cutting.

Leaf area Usually the rooting of softwood cuttings is dependent on the presence of a leaf, and indeed in the physiological processes of this leaf. Cuttings without a leaf very quickly become moribund, while the most common reason for these cuttings failing to root is the death of the leaf due to rotting, necrosis, bleaching, or leaf abscission. All these causes of failure are due to either the use of inappropriate tissues (too old (senescent), photosynthetically inactive (below compensation point; water-stressed; starch-filled), diseased, pest-infected), or to an undesirable rooting environment (too hot, too wet, too dry). The most common symptoms are leaf shedding, leaf rot, and stem rot.

Studies of the role of the leaf have indicated that rooting ability is maximized when the severed cutting is photosynthetically active and producing assimilates for the development and elongation of the root primordia, and when the leaf is not suffering water stress (**Figure 4**). Consequently, there often seems to be an optimum leaf area at which the balance between photosynthesis and transpiration is optimal. This varies between species and clones, depending on specific leaf area (leaf thickness), stomatal density, leaf morphology (waxiness, etc.) and the age of the leaf (node position). Optimizing the balance between photosynthesis and transpiration seems to be particularly important in difficult-to-root material, with easy-to-root species not being very sensitive to leaf area. Cuttings with a leaf that is too small rapidly decline in their carbohydrate (sugars and starch) contents, while those with an appropriate area increase in carbohydrate content (and hence dry matter), at least until the roots start to develop, creating a sink for assimilates. One study has found that there is a relationship, which develops after severance, in cuttings with differing leaf areas, between rooting ability and the content of reflux-extracted soluble carbohydrates, which suggests that rooting is promoted by the production of specific sugars during the period that the cuttings are in the propagator. Cuttings with an overly large leaf suffer from transpiratory water loss and stress, and close their stomata, thereby limiting their capacity to photosynthesize, and often triggering leaf abscission. As mentioned earlier, leaf area is an important variable interacting with the level of irradiance in the propagation environment. Consequently, statements about the optimal leaf area for rooting have to be linked to statements about the specific propagation environment.

Despite the importance of current assimilates for rooting in leafy softwood cuttings, there is evidence that the level of dependency does vary between species, with some species also being able to utilize stored reserves in the same way as hardwood cuttings, perhaps reflecting differences in stem anatomy. In *Larix* × *eurolepis* cuttings, for example, a dual ^{13}C and ^{15}N labeling approach indicated that more than 80% of total carbon in the roots was newly assimilated carbon, while 20% was from stored reserves.

Cutting length Cuttings can either be cut to a constant length (in which case they will usually vary in the number of nodes present) or can be cut to the available internode length of a predetermined number of nodes (**Figure 5**). The decision about which

Figure 4 Using a 'pressure bomb' to assess the leaf water potential of *Triplochiton scleroxylon* cuttings.

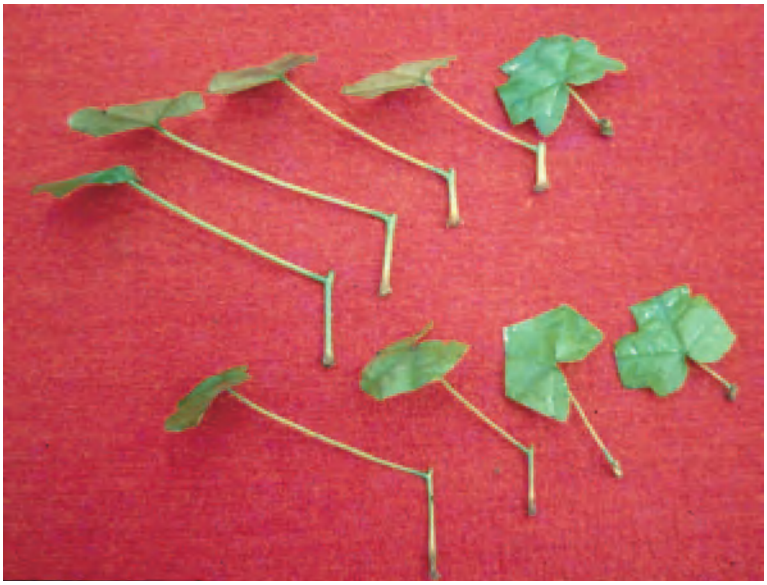

Figure 5 Variation in length and diameter in single-node cuttings from a two-shoot stockplant of *Triplochiton scleroxylon*, arranged in node order from the shoot apex. Top shoot: nodes: 1–5; second shoot: nodes 1–4.

option to take will have big impacts on the rooting ability, as long cuttings usually root best. From the practical point of view, the number of cuttings rooted is maximized by using a constant length, close to the optimum. This has the additional advantage that all the cuttings will penetrate the rooting medium to the same depth and that the leaf will be held the same height above the medium. From the research point of view, however, much can be learnt about the sources of variation by using a fixed number of nodes and utilizing the pattern of variation in internode length found within a stem (**Figure 5**). In the latter case, it is important to remember that internode length varies sequentially down a stem and thus is not an independent variable.

Stockplant Factors: Cutting Origin and Environment

There are two major sources of variation in stockplants. These are attributable to: (1) within-shoot factors and (2) between-shoot factors, both of which are strongly influenced by the stockplant environment. Additionally, there are other endogenously controlled growth changes, such as recurrent flushing, which can affect rooting ability.

Within-shoot factors Within any shoot there are numerous gradients of variation associated with the chronological aging of shoots as they grow longer. For example, from the top to the bottom, there is a gradient in age that affects the leaf size, leaf water potential, leaf carbon balance, leaf senescence, internode length, internode diameter, stem lignification, nutrient and stem carbohydrate content, and respiration. These gradients mean that no two cuttings are physiologically identical and, hence, no two cuttings have the same rooting capacity. Consequently, it is possible to use these gradients node by node as a diagnostic tool for how physiological factors affect rooting. For example, one of the unresolved issues that could be addressed is the importance of the relative concentrations of carbohydrates and nutrients in cutting tissues, which vary between node positions and over time. There is evidence of stored reserves being depleted early in the rooting process in *Larix* hybrid, and in *Khaya ivorensis*.

Comparing the typical with inverse relationships between cutting length and node position allows the study of within-shoot variation and has found that cutting length (in reality probably cutting volume) has a major influence on rooting ability. It seems that this may be due to the need for storage capacity for current assimilates until the new roots form a sink for these carbohydrates. The importance of this is supported by a negative relationship between leaf area and cutting length, suggesting that short cuttings cannot provide the storage capacity for assimilates coming from a large leaf.

Between-shoot factors Even in the simplest type of stockplant, a seedling that has been cut back once previously (**Figure 6**), there are considerable differences in rooting ability between the lateral shoots, with those from upper shoots being best. In *T. scleroxylon*, the percentage of cuttings rooted declines as

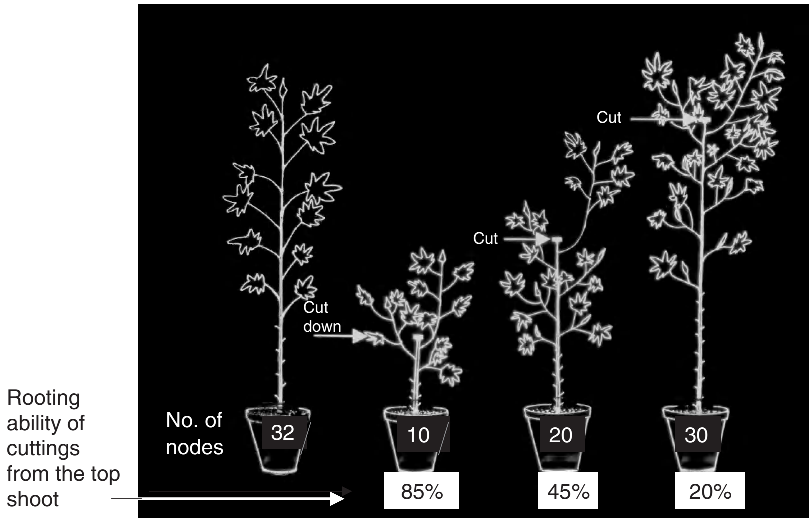

Figure 6 Effects of the number of shoots and stockplant height on rooting ability of *Triplochiton scleroxylon* cuttings from the top shoot. After Leakey RRB (1983) Stockplant factors affecting root initiation in cuttings of *Triplochiton scleroxylon* K. Schum., an indigenous hardwood of West Africa. *Journal of Horticultural Science* 58: 277–290.

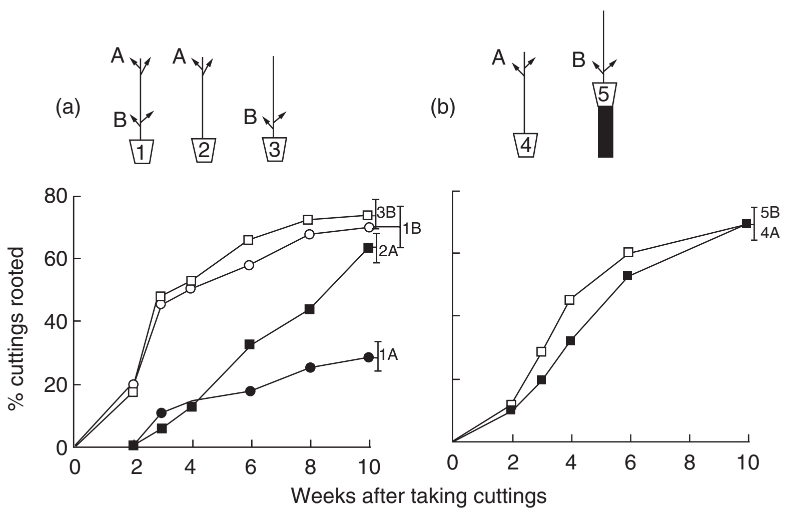

Figure 7 Effects of the number and position of shoots in stockplants of *Triplochiton scleroxylon*, relative to a light source. After Leakey RRB (1990) The domestication of tropical forest trees: a strategy for increased production and for conservation. In: Werner D and Müller P (eds) *Fast Growing Trees and Nitrogen Fixing Trees*, 1990 © Elsevier GMbH. Stuttgart, Germany: Gustav Fischer Verlag.

the height of the stockplant increases, there being a relationship between percentage rooting and the number of shoots per plant. The rooting ability of cuttings from lower shaded shoots can, however, be enhanced by the use of fertilizers, or by reorienting the stockplant (angled or horizontal) to alter the patterns of correlative inhibition. The rooting ability of cuttings from the upper shoots can be enhanced by removal of the lower shoots, implying that intershoot competition is a factor in determining rooting ability. Under situations of low but equal competition, basal shoots have a higher rooting ability than upper shoots. However, if basal and upper shoots are under similar light environments, their rooting ability becomes very similar (**Figure 7**).

In more complex stockplants, cuttings from first-order lateral shoots of *Cryptomeria japonica* rooted better than those from second-order laterals, indicating the need for better physiological and morphological understanding of such structural variation.

Preseverance Stockplant Environment

As seen above, both nutrients and light have been confirmed to have major effects as preconditioning agents on rooting ability, a finding confirmed in

Albizia guachapele. When this was tested experimentally in *T. scleroxylon*, it was found that there are complex interactions between nutrients and the quantity and quality of light, which affected photosynthesis and the carbohydrate status of cuttings. Photoinhibition and high starch concentrations in cuttings appeared to inhibit rooting, while active photosynthesis was associated with good rooting. Both low irradiance and low red-to-far-red ratios independently enhanced rooting ability, but in many natural systems these characteristics of shade occur together and probably have additive benefits. The mechanisms for this enhancement seem to be both morphological and physiological; cuttings from shaded stockplants of *Eucalyptus grandis* have longer internodes, greater specific leaf area, greater codominance between shoots, lower rates of preseverance net photosynthesis, lower chlorophyll concentration, but higher rates of net photosynthesis per unit of chlorophyll, and many other differences in gas exchange characters (**Figure 8**). These characteristics of preseverance physiology and morphology subsequently enhanced the cuttings' postseverance physiological status and promoted high rooting ability.

Figure 8 Using a portable gas analyzer to assess rates of preseverance net photosynthesis and transpiration in stockplants of *Zizyphus mauritiana*.

In *T. scleroxylon*, analysis of deviance indicated that the effects of light quality on rooting were entirely attributable to increased internode length. The changes in these stockplant factors are largely attributable to changes in the physiological condition of the shoots and are often related to vigor; thus they can be seen as a component of physiological aging.

The effects of preseverance light quality on rooting ability have now been demonstrated in a number of different taxa but, as expected, there are differences in stem and leaf morphology. Shoot etiolation under low irradiance and the preseverance elimination of light from the area of the cutting base independently and additively enhance subsequent rooting ability, having histological effects on stem development and retarded sclereid development. There is also some evidence of etiolation on levels of rooting cofactors and sugar concentrations. This newer understanding of preseverance factors is important as it involves easily overlooked differences in the ambient environment. This contrasts with the manipulative treatments like bark girdling, which have also been used to enhance rooting.

Stockplant Management

The importance of all of the above stockplant factors clearly indicates the opportunity to enhance the rooting ability of cuttings through stockplant management (especially a combination of pruning, fertilizer use, and light management) to promote the appropriate morphological and physiological conditions of the shoots. Field trials in the tropics have indicated that using nitrogen-fixing species like *Leucaena leucocephala* to provide a shading canopy above a stockplant hedge can be very beneficial. Hedging approaches have been tested over long periods, and found to be robust with no loss of rooting ability with time, although rooting success is affected by the height of hedges and the types of shoots used.

Efforts to improve stockplant management in *Larix* have included the extension of the photoperiod with artificial illumination in the fall, but without success, and the use of cytokinins to promote the outgrowth of short shoots. In *T. scleroxylon*, however, the injection of auxins preseverance was found to enhance rooting ability, with earlier injection dates enhancing the rooting ability of short cuttings.

Phase Change

The relative importance of ontogenetic and physiological aging is one aspect of the impact of stockplant physiology relating to rooting ability that is unresolved. As trees grow they develop a gradient towards reproductive maturity (ontogenetic aging) and after a time reach a threshold above which the newly developing shoots have the capacity to fruit and flower, while those below the threshold are still juvenile (**Figure 9**). The transition from juvenility to the state of maturity is called phase change. There are large numbers of reports in the literature that cuttings from mature shoots are very much more difficult to root than those from juvenile (seedling or coppice) shoots and attributed this to phase change. Increasingly, however, there are reports of old mature trees being propagated by cuttings, with reasonable success, especially in the early spring. However, a good understanding of the reasons why mature trees are difficult has never been achieved.

The importance of physiological aging in the rooting of cuttings from mature trees is illustrated by recent unpublished data in *Prunus avium* (**Figure 10**), which indicate that by comparison with leafy juvenile shoot cuttings, the rooting capacity of mature softwood cuttings was limited by the availability of stored reserves, while mature hardwood cuttings were constrained by leaf abscission. Other evidence that the poor rooting ability of mature shoots can be attributed to physiological aging rather than to ontogenetic aging is seen in the high rooting ability of ontogenetically mature and flowering plants formed when cuttings from mature tree crowns are successfully propagated and then used as stockplants (**Figure 9**). Although often plagiotropic, such plants have the vigor of juvenile seedlings and coppice shoots. To examine this experimentally within the crown of mature trees is difficult as it requires the formation of physiologically young shoots within an ontogenetically mature crown. This is not achieved by pollarding, but further research is needed to elucidate the relevance of phase change to rooting.

Observations of leaf shape and other morphological characters indicate gradients as trees grow older and these changes have been examined in detail, often using ivy (*Hedera helix*) as a model plant. This raises two questions: (1) are the changes in leaf shape relevant? (2) do we need to have a maturity factor, or are the conditions in mature cuttings just a severe case of the complex interactions arising from the sorts of stockplant variables examined above? Regarding leaf shape in ivy, there may be an error in the belief that the juvenile leaf form converts to the mature form as a result of ontogenetic aging, as the juvenile form is associated with the vine stems

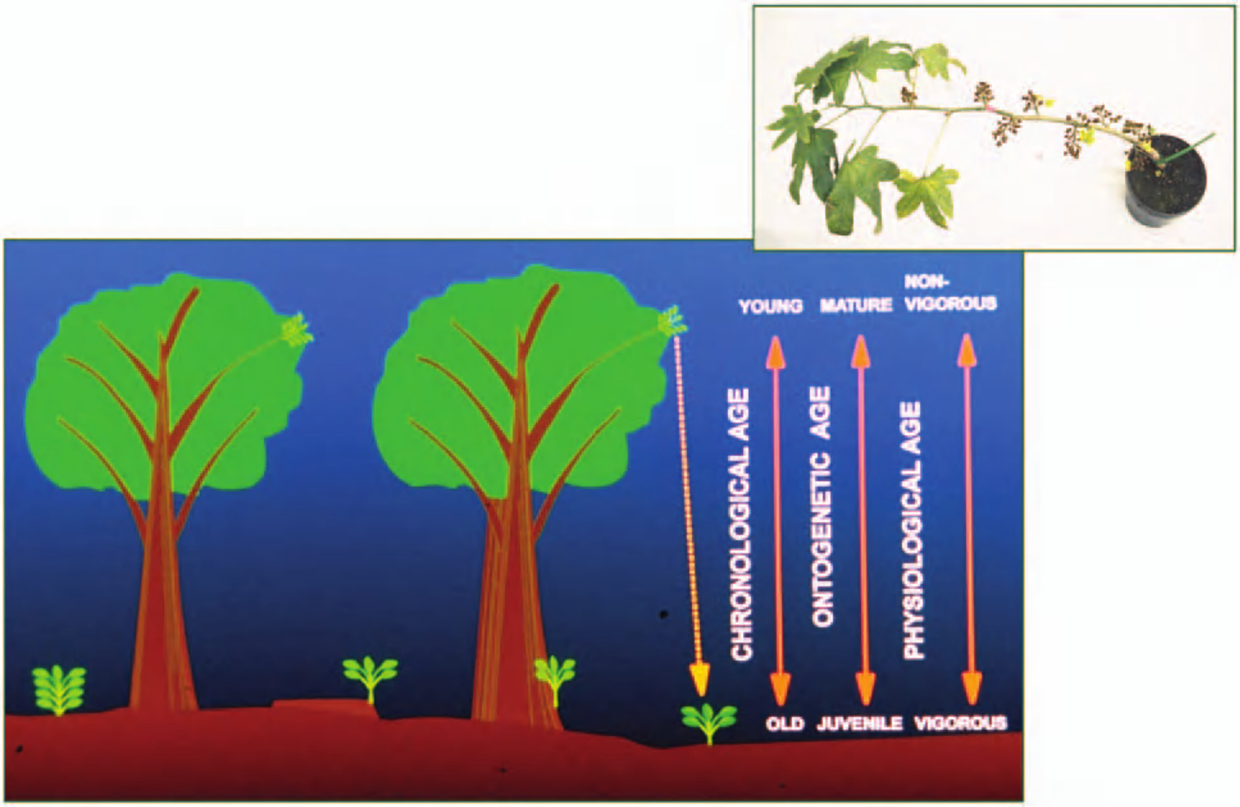

Figure 9 Gradients of aging and maturity in trees. Inset: an easily rooted mature cutting of *Triplochiton scleroxylon*, illustrating its plagiotropic habit and ability to flower.

Figure 10 Cherry (*Prunus avium*) cuttings from juvenile root suckers (1- and 2-year-old wood), young lateral softwood in a mature crown and terminal woody shortshoots in a mature crown.

(the mainstem) and the mature form is associated with free-standing branches, which happen to be where ivy, like many other woody plants, flowers. Different leaf arrangements and shapes in mainstems and branches are very common in woody plants. It is not clear therefore whether the reported differences in genetic material between these two tissue types is a result of ontogenetic phase change or to epigenetic differences between different tissues. In other species, there are changes in leaf morphology up the mainstem, as in *Acacia mangium*, in which the pinnate true leaf on seedlings changes to a mature phyllode. The unreliability of the phyllode as a marker of phase change was shown in a rooting trial from coppice stumps in which the rooting ability of cuttings with phyllodes was greater than that of cuttings with true leaves.

The felling and subsequent coppicing of mature trees are generally regarded as the best way to return to the juvenile state. However, while this was successful in *Milicia excelsa*, the rooting ability of cuttings from coppice shoots was still negatively correlated with the age of the stump. Similarly, in *Vochysia guatemalensis*, increasing stump diameter also had a negative effect on rooting, with larger stumps producing more shoots, and intershoot competition perhaps reducing rooting success.

There are some anomalies in the phase change literature. For example, in *Picea mariana*, cuttings from flowering crowns of 9-year-old trees rooted better than those from nonflowering trees of the same age and origin, while in *Cunninghamia lanceolata*, burying mature shoots horizontally in the soil apparently results in new juvenile shoots.

This topic of how to propagate mature tissues is the major constraint to many tree improvement programs focusing on cultivar development through vegetative regeneration.

Genetic Variation in Rooting Ability

Experience has suggested that there are genetic differences between species, and even between provenances and clones within species, which result in differences in rooting ability, although more and more formerly unrootable species and clones are now being rooted relatively easily as understanding improves. This suggests that, as the within-clone factors affecting rooting ability are optimized, the apparently innate genetic differences in rooting ability are actually attributable to genetic differences in the morphological and physiological factors that govern rooting ability. This view is supported by the use of stepwise regression to analyze data from rooting experiments, which commonly finds that the factors explaining much of the variance are cutting length, leaf abscission, and leaf area, and that the genetic differences between clones explain relatively little of the variance. This conclusion is in contrast to some recent studies, which have sought to detect quantitative trait loci affecting vegetative propagation. No very clear evidence has been found to indicate that there is genetic control of rooting ability *per se*. Some trees, like many herbaceous weeds, do regenerate vegetatively naturally (e.g., from root suckers), but it is difficult to see in evolutionary terms why there would be a genetic trait for rooting ability in detached shoots of trees.

Failure to Root

To learn more about the processes affecting rooting, there is also a need to pay much more attention to the causes of rooting failure. Some cuttings, as stated earlier, display different symptoms of death from leaf abscission to different patterns of rooting, which can be attributed to water stress, photoinhibition, anoxia, and negative carbon balance. Other cuttings neither die nor root. More information needs to be collected on all these responses to attempted propagation.

Integration by Modeling

The complexity of the rooting process in leafy stem cuttings alone makes it a very appropriate subject for modeling. Based on the *T. scleroxylon* data set, a mechanistic model of carbohydrate dynamics during the rooting process provides a framework for many of the other factors discussed above to be examined and compared with research results. Hopefully in future it will be possible to use this and other models to test differences in experimental methods and materials and so interpret the often contradictory experimental results.

Apparent Absence of Principles Determining Rooting Success

Recording Materials and Methods

On top of the highly interactive nature of the multitude of factors influencing the physiological condition of cuttings, there is an overarching methodological issue that needs to be resolved. Typically, people taking cuttings do not collect their cuttings in the same way, and more importantly, do not report what they have done precisely. Because of the impacts of all the interactive processes discussed above, two people propagating the same species under relatively similar conditions can obtain results that appear to be contradictory, while in fact their results are expressions of the different physiological and morphological condition of the tissues being propagated. Researchers need to address these deficiencies in their techniques and to address the impacts of all the variables experimentally before we can expect to understand fully the fundamental physiological principles determining the success of vegetative propagation.

Percentage Rooting – A Poor Measure of Success

To make matters worse, almost all research papers use the percentage of cuttings rooted as the prime measure of rooting success. Taking a simple example, even if auxin application, leaf area, and rooting environment are all optimized, when all the available cuttings are collected from a managed juvenile stockplant (**Figure 11a**), they are likely to have a fairly low rooting percentage and hence create a relatively low number of new plants. This is because of the inclusion of all of the inherent variations in cutting size and shoot position. If, on the other hand, the same people go to an identical plant and, because they know more about the species they are propagating and are aware that cuttings from the top two shoots are likely to have the greatest capacity to root (**Figure 11b**), restrict their collection to these shoots (so maximizing the use of their time and resources), they will root the same number of cuttings, but can claim an improved rooting percentage. In a third situation, where they have more understanding of stockplant management, and grow their stockplants under the shade of other plants and provide nutrients, the stockplant has greater codominance between shoots and produces more material to harvest. In this case, the shoots are morphologically and physiologically in a better condition to root well (**Figure 11c**). Consequently, more cuttings can be

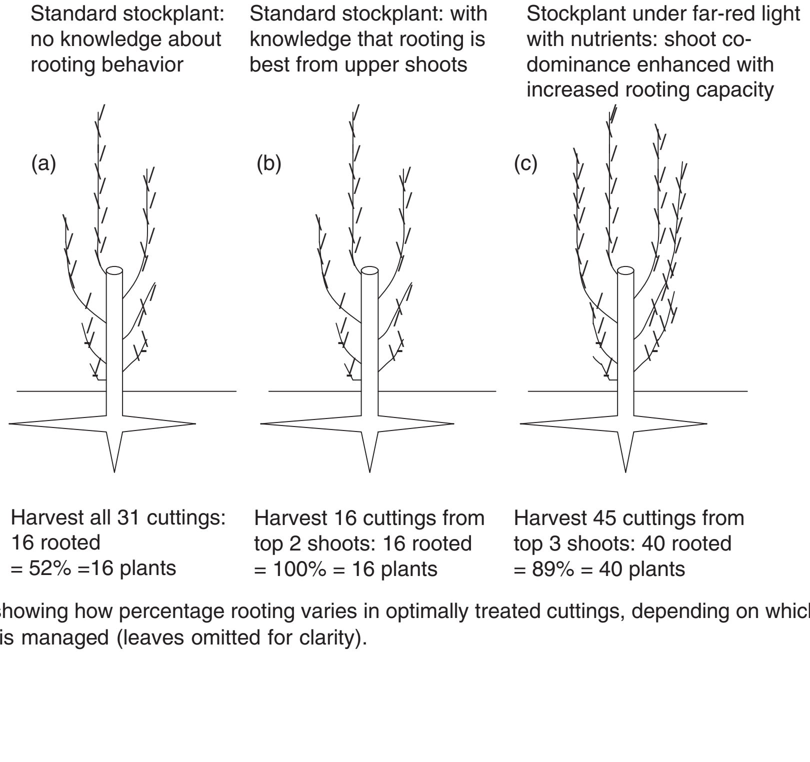

Figure 11 Diagram showing how percentage rooting varies in optimally treated cuttings, depending on which cuttings are used and on how the stockplant is managed (leaves omitted for clarity).

collected, and a third shoot can be included, resulting in a much larger number of cuttings rooted, but the percentage rooting may be lower than that in **Figure 11b**. Which of these results is of greatest practical value, and how well does the measure of percentage cuttings rooted represent the overall rooting capacity of the cuttings collected? Clearly, if the understanding of vegetative propagation is to advance, we have to be more rigorous in describing the source of our cuttings, and we have to improve the way we quantify rooting capacity.

Many authors do use additional measures of rooting success; for example, the number of roots per cutting, the mean or total length of roots produced, the mass of roots produced, and graphs often show differences in the rate of rooting. Interestingly, these measures of success are often unrelated to rooting percentage, and it is probably only when these different measures are well correlated that there is a good measure of rooting ability. These methods of quantifying rooting ability and their relationships require further research.

Other Propagation Systems

Grafting/budding, marcotting (**Figure 12**), root cuttings, and *in vitro* culture (**Figure 13**) are all systems that are used to multiply ontogenetically mature shoots that are very difficult to propagate by cuttings. This is especially important for the propagation of fruit trees or selected phenotypes in a forest tree seed orchard where ontogenetic maturity has to be retained.

In contrast with *in vitro* systems there have been relatively few major advances in grafting and marcotting in recent years, although they are still widely applied. Nevertheless, there is a need for improvements to make them more robust and reliable as low-technology options for mature tree propagation. Probably the most important area for future research is an investigation of how to use preseverance treatments and environment to enhance the rate and success of both the propagation and the subsequent establishment and growth of the young propagule.

Constraints on space here make it impossible to review fully the progress in other propagation systems. *In vitro* systems, which potentially have much greater multiplication rates and allow for biotechnological developments through genetic manipulation, continue to be an area of rapid development, meriting an independent literature review. Some easy rooting of shoots from mature *in vitro* cultures has been reported but the mechanism remains unclear. *In vitro* micrografting has also been used to improve the rooting ability of mature shoots. There is a need for better understanding of the use of these systems to promote easy propagation from a range of mature tissues. Evidence suggests that some physiological rejuvenation occurs after serial subculturing *in vitro* (with and without an assortment of culture medium supplements) but the physiological processes

Figure 12 Marcotting or air-layering on a tree of *Dacryodes edulis*.

Figure 13 *In vitro* micropropagation of (a) *Khaya ivorensis* and (b) *Nauclea diderrichii* showing the proliferation and rooting phases respectively.

involved are still unknown. Additionally, there is a need for more research on the role of preseverance factors on the opportunities for more robust *in vitro* propagation. For example, light quality has been found to be important for root formation in *Betula* shoot cultures *in vitro*, while darkness was important for micrografting *Picea* shoots *in vitro*.

Against the advantages of *in vitro* systems are the facts that they are costly and require specialist facilities and staff, making them inappropriate for some developing-country applications.

Conclusions

Within any of the numerous different types or systems of propagating trees, there are large numbers of factors that determine whether or not the propagule is in a good physiological condition, to form a functional plant and grow. For example, when propagating from single-node, leafy cuttings from juvenile shoots, the factors that will determine the level of success are:

stockplant environment × stockplant management
× topophytic variables × node position
× nursery management × postseverance treatments
× propagation environment

Each of these factors are themselves multifaceted and influenced by the ambient environment (light quality and quantity, water, temperature, nutrients) of the stockplant garden, the nursery, or the propagation bench. For example, in the stockplant garden the environment (light, water, and nutrients) and the management of stockplants can have both short-term impacts on rooting ability by determining the levels of water or heat stress experienced by the tissues being propagated before severance from the stockplant, or long-term impacts on rooting ability through their effects on the morphology or physiological condition of the shoots. Similarly, once the cuttings have been severed from the stockplant the environment of the nursery and the handling of the severed cuttings before and after insertion in the propagation bed will also determine the levels of stress that the cuttings experience. In addition, the cuttings are also affected by the activities of the person doing the propagation and particularly the care taken by this person to minimize the levels of stress experienced by the cuttings (e.g., maintenance in a cool, shady, moist environment; reduction of transpiration by leaf trimming). The human element in this is what is commonly called having 'green fingers' and reflects the person's sensitivity to the needs of the plant material.

TROPICAL ECOSYSTEMS

Contents

Acacias

S Harris, University of Oxford, Oxford, UK

Introduction

Acacias are emblematic landscape trees, whether they are the flat-topped trees that pepper the African savanna, the swollen thorn ant acacias of Central America or the wattles of the Australian outback. Many acacias are adapted to poor soils and disturbed conditions, often in hostile environments, where they are colonizers. It is these conditions that are often faced by tropical foresters, especially where human activities have modified the environment. Thus, acacias, particularly the Australian species, are important forestry trees and multipurpose tree species in the tropics. Acacias belong to the speciose genus *Acacia* and the monotypic genus *Faidherbia*. It is the purpose of the present article to introduce the basic systematics and distribution of the acacias, together with data on genetic variation and hybridization. The ecological and reproductive diversity of the acacias is presented, together with an overview of their utility.

Systematics

Acacia is a widespread genus of tropical–subtropical tree and shrub legumes distributed from Central/South America through Africa to Southeast Asia and Australia. Macrofossils (wood, leaves, phyllodes, flowers) attributed to *Acacia* have been reported from the Dominican Republic (Early Miocene/Late Eocene) and Australia (Early Pleistocene/Lower Pliocene). In contrast, microfossils (pollen) have been reported from Cameroon (Late Eocene), Puerto Rico (Oligocene), New Zealand, Patagonia, and Sudan (Miocene), and Australia (Late Middle Eocene to Quaternary).

Table 1 Characters that separate subgenus *Acacia* and the monotypic genus *Faidherbia* (*F. albida*, synonym *A. albida*)

Character	*Subgenus* Acacia	Faidherbia
Leaf phenology	Lost in dry season	Present in dry season
Seedling morphology	Pinnate eophyll	Bipinnate eophyll
Petiolar gland	Present	Absent
Stamen fusion	Free	Shortly fused
Polyad structure	Commonly 16	26–32 (rarely 16)
Pollen pores	Three	Four
Pollen exine	Smooth/reticulate	Areolate
Pollen size	23–64 μm	90–124 μm
Wood rays	Multiseriate	Uniseriate
Involucel	Present	Absent
Pod fibers	One layer	Two layers
Cotyledons	Petiolulate	Sessile

More than 5000 *Acacia* names have been described, comprising some 1300 species; more than 950 species occur in Australia, with approximately 230 species in the New World, 135 species in Africa, 18 species in India, and a few others in Asia and as island endemics. The genus *Acacia* is one of two members (the other is the African monotypic genus *Faidherbia*) (**Table 1**) of the mimosoid legume tribe, Acacieae. The Acacieae is closely related to the tribe Ingeae, although there appear to be no consistent characters that distinguish them.

Acacia species are woody trees, shrubs, or lianas which may have prickles. The leaves are bipinnate or modified as phyllodes (rarely reduced or absent). Petiolar glands are usually present, as are stipules that may be spinescent. Flowers are tetramerous or pentamerous, with white or yellow (rarely pink) petals and are either all hermaphrodite or a hermaphrodite–male mixture on a single tree. Flowers are organized into heads, and flower heads organized into axillary, racemose or rarely paniculate inflorescences (**Figure 1**). Flowers have free to united sepals, with numerous stamens that are usually free (rarely united at the base into a very short tube) and a single (usually), sessile or stalked ovary. Pods are dehiscent or indehiscent, usually flattened, and very variable in shape, ranging from straight to highly contorted. Seeds are unwinged and nonendospermous, usually with a hard seed coat and with or without an aril.

Acacia taxonomy has been in a state of flux since the genus was first described by Miller in 1754, although it was not until Bentham's work in the mid-1800s that the present generic limits were

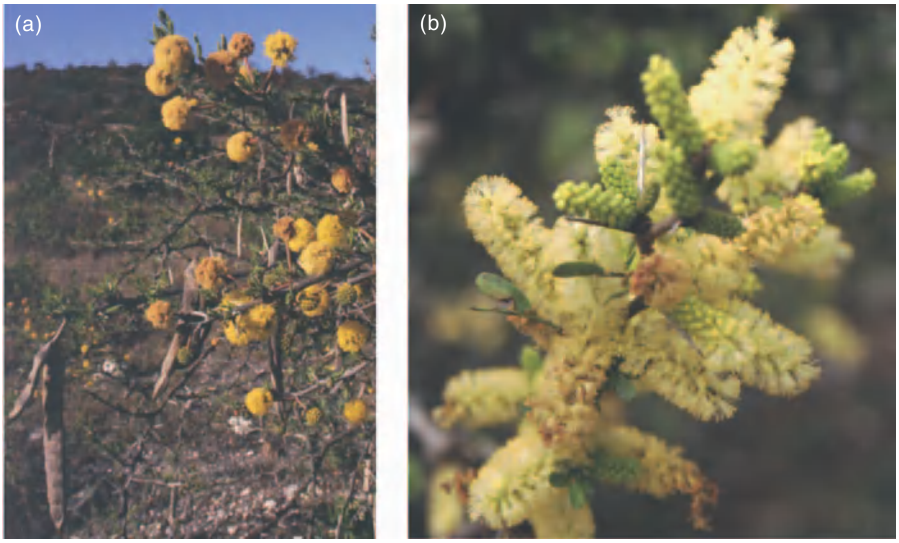

Figure 1 Globose and spicate inflorescences in the genus *Acacia*. (a) Globose inflorescence of *A. schaffneri* (Mexico); (b) spicate inflorescence of *A. amentacea* (Mexico).

established. Bentham divided *Acacia* into six series (**Table 2**), based primarily on vegetative characters (foliage and spinescence) and secondarily on inflorescence characters; fruit was largely ignored. In the 1970s, Vassal recognized three subgenera (*Acacia*, *Aculeiferum*, and *Phyllodineae*) (**Table 2**), and moved the African species *Acacia albida* to the monotypic genus *Faidherbia*. In the mid-1980s, Pedley concluded that the genus *Acacia* was too broadly conceived and three genera should be recognized (although most botanists have not accepted these changes): *Acacia* (=*Acacia* subgenus *Acacia*), *Senegalia* (=*Acacia* subgenus *Aculeiferum*), and *Racosperma* (=*Acacia* subgenus *Phyllodineae*) (**Tables 2** and **3**).

Most recent evolutionary studies, whether based on DNA or morphological data, concur with Pedley that the genus *Acacia* is not monophyletic. However, the appropriate division of the genus is unclear. Some workers suggest that subgenera *Aculeiferum* and *Phyllodineae* group together and are distinct from subgenus *Acacia*, others have suggested that subgenera *Aculeiferum* and *Acacia* group together and are distinct from subgenus *Phyllodineae*, whilst more radical still is the suggestion that the currently circumscribed *Acacia* should be split into five different genera. The formal splitting of the genus *Acacia* is likely to result in a large number of changes of scientific names.

Complex patterns of morphological variation, the paucity of material, poor understanding of distribution in some species and the recognition of numerous infraspecific taxa (e.g., *A. tortilis* and *A. nilotica*) can confound species delimitation. For example, *A. farnesiana* is prostrate in Mexican sand dunes, whilst *A. longifolia* subsp. *sophorae* shows a similar habit in the sand dunes of southwestern Australia. Some species have very wide distributions (*A. tortilis*, throughout tropical Africa and into the Middle East and India), whilst other species have very restricted distributions (e.g., *A. dorsenna*, known only from one area in Western Australia).

Ploidy	$2x$, $4x$, $8x+$	$2x$, rarely $4x$, $8x$	$2x$, rarely $4x$, $6x$
Mean 1C DNA content (standard error)	1.130 (0.032)	0.997 (0.074)	1.435 (0.011)

[a]Square brackets indicate that characteristic is rarely found.

Genetics

Chromosome number and structure varies across the genus from $2n=2x=26$ to $2n=16x=208$, with homogeneous to heterogeneous karyotypes, and nuclear DNA contents (1C, i.e., the amount of DNA in the haploid set of chromosomes) from 0.53 pg to 2.1 pg. Chromosome number in subgenus *Acacia* ($2x$, $4x$, $8x+$) is more variable than the other two subgenera, whilst 1C DNA content is greater in subgenus *Phyllodineae* than either of the other two subgenera (**Table 2**). However, variation in chromosome numbers can be found within species; for example, tetraploid individuals occur in populations of the normally diploid *A. dealbata*.

Differences in chromosome numbers would imply that polyploidy has been important in the evolution of the genus *Acacia*. The origin of the Australian allohexaploid *A. colei* is thought to have been through allopolyploidy, involving the diploid *A. neurocarpa* and the tetraploid *A. elachantha*, through a triploid, presumably sterile, intermediate. In the case of the African triploid *A. laeta*, this is thought to have arisen through hybridization between the two diploid species, *A. mellifera* and *A. senegal*. In general, natural hybridization between *Acacia* species appears to be relatively rare, although putative hybrids have been recorded from all the major areas of the genus's distribution. Furthermore, hybrids may have considerable potential in forestry; for example, the hybrid between the economically important species *A. auriculiformis* and *A. mangium*, has desirable commercial characteristics.

Few investigations of the distribution of genetic variation within and among natural populations of acacias have been conducted; those that have been undertaken have mainly used allozyme markers (**Table 4**). The occurrence of ploidy differences, particularly in subgenera *Aculeiferum* and *Acacia*, means that genetic diversity investigations are complicated by the possibility of more than two alleles at a locus within an individual and hence in the calculation of allele frequencies (e.g., high genetic diversity and low population differentiation in *A. karroo* may be a reflection of this problem). This may be one of the reasons that the majority of investigations of neutral marker diversity have focused on diploid Australian *Acacia* species. Furthermore, estimates of genetic diversity may be affected by population sampling and choice of loci (e.g., *Faidherbia albida*, *A. mangium*). Acacias tend to show high levels of genetic diversity and differentiation compared to other long-lived, woody perennials (**Table 4**). High genetic differentiation appears to be associated with disjunctions in genetic diversity, for example, the genetic differentiation of *A. melanoxylon* populations in eastern Australia into northern and southern types or the disjunction of genetic diversity between East and West African populations of *Faidherbia albida*. Such disjunctions have been interpreted as the result of changes in population size following major environmental perturbation. In the diploid *Acacia* species, low differentiation appears to be associated with restricted distributions (e.g., *A. anomala*).

Acacia mangium is one of the most widely planted and economically important *Acacia* species, yet very low levels of neutral genetic diversity and population differentiation have been reported. This illustrates the importance of having knowledge of both neutral

Table 4 Examples of the patterns of genetic diversity and population differentiation in natural populations of *Acacia* species sampled from across their native ranges and based on allozyme data

Taxon	*Number of populations*	*Number of loci*	*Mean population diversity*	*Total genetic diversity*	*Population differentiation*
Faidherbia albida	22–30	6–10	0.128–0.454	0.286–0.516	0.123–0.422
Acacia acuminata subsp. *acuminata*	6	16	0.237	0.266	0.108
A. acuminata subsp. *burkittii*	5	16	0.287	0.318	0.098
A. anomala	6	15	0.336	0.356	0.056
A. aulacocarpa	22	30	0.111	0.298	0.626
A. auriculiformis	13–18	18–22	0.098–0.122	0.134–0.149	0.181–0.270
A. mangium	11–13	18–30	0.017–0.064	0.025–0.070	0.086–0.311
A. mearnsii	19	22	0.179	0.201	0.108
A. karroo	12	10	0.84	0.88	0.050

A. oldfieldii	2	16	0.166	0.178	0.069
Long-lived, woody perennials	Mean = 9.2	Mean = 18.1	0.148	0.177	0.084

and adaptive variation before conservation and utilization decisions are made. Furthermore, *A. mangium* is the *Acacia* species for which the most comprehensive genetic map is available.

Ecology

The ecological diversity of the genus *Acacia* is reflected in its morphological diversity, where species occupy habitats as diverse as the arid centre of Australia and wet neotropical forests. *Acacia* species are important ecosystem components, especially in Australian and African savannas where they may be important colonizing species (e.g., *A. melanoxylon*). However, *Acacia* species tend to be more abundant in arid and semi-arid areas than in wet ecosystems. The majority of *Acacia* species show adaptations to water stress, for example, reduced photosynthetic surface areas (e.g., the Australian *Acacia* species *A. willardiana* of the Sonoran Desert), although some are adapted to periodic flooding (e.g., *A. xanthophloea*). Some species (e.g., *A. erioloba*), survive the extremes of the desert environment, including freezing, and may have very long (6–12 m) tap roots. The ant acacias show a mutualistic arrangement, where ant colonies protect the plant from herbivory and the leaves may produce Beltian bodies (protein-rich structures) as an ant food source. The association between ants and *Acacia* species appears to have arisen on more than one occasion, on at least two continents; the Central American swollen thorn ant acacias (e.g., *A. melanoceros*) support *Pseudomyrmex* colonies, whilst the African whistle-thorn acacias (e.g., *A. seyal*) support *Crematogaster* colonies. African and Australian *Acacia* species are also important hosts for members of the parasitic angiosperm families Loranthaceae and Santalaceae.

Dominant acacias (e.g., *A. aneura*) may have important roles in the landscape, although changes in human activities (e.g., pasture management) may cause considerable changes in an *Acacia*-dominated landscape; for example, the Central American ant acacia *A. melanoceros* is sensitive to forest fragmentation. In contrast, some species are very tolerant of human-mediated disturbance; for example, *A. dealbata* regenerates freely following windthrow. Such differences appear to be at least partially related to life-history traits. For example, *A. melanoceros* matures in 8–14 years compared to the 4–5 years of *A. dealbata*, whilst the resprouting ability of *A. melanoceros* is poor compared to the vegetative regeneration of *A. dealbata*. Furthermore, *A. melanoceros* seeds germinate quickly compared to those of *A. dealbata* that form a long-lived seed bank. Another major effect of humans on the distribution of acacias has been the intercontinental movements of species, for example, Australian species being moved to Africa and the New World and African species being moved to Australia. The consequences of such movements have been unpredictable; some species are highly productive (e.g., *A. mangium* in India), whilst others are very destructive (e.g., *A. nilotica* in Australia).

Distributions of *Acacia* species and range limitations may depend on soil and climatic factors; for example, *A. erioloba* is confined to soils of the Kalahari sand sheet in southern Africa, whilst the northern limit of *A. farnesiana* in the USA may be due to low temperatures. However, more complex interactions may occur; for example, phyllode size in the coastal species *A. melanoxylon* appears to be related to both distance from the coast (aridity) and seasonal rainfall patterns. Seasonality reveals additional patterns of ecological variation in acacias. Some species lose their leaves all at once, e.g., Sudanese *A. nubica* (at the end of the long dry season), whilst *A. tortilis* sheds its leaves progressively as the dry season advances. Most Australian acacias are adapted to fire; thus germination may be facilitated by fire or vegetative regeneration may be stimulated, as with some African acacias, where coppice growth is facilitated (e.g., *A. stolonifera*).

Acacias, as legumes, are generally capable of forming symbiotic relationships with the bacterial genus *Rhizobium*, producing root nodules and fixing atmospheric nitrogen. However, both nodulating and nonnodulating species are found in the genus *Acacia*. Nonnodulation is restricted to the southern USA, Central and South American, African and Asian members of subgenus *Aculeiferum* section *Monoacanthea* (e.g., *A. brevispica*); nonnodulation is unknown in Australian *Acacia* species. In addition to root nodules, acacias also have mycorrhizae.

Thirty-five *Acacia* taxa are listed as under threat by the IUCN, although this is likely to be an underestimate given that no Australian *Acacia* species are represented. Of those species under threat, the majority are threatened due to either agriculture or habitat degradation. Secondary effects of large mammal conservation may also have effects on *Acacia* conservation; as an example, the introduction of giraffes into South African savannas has driven accessible *A. davyi* populations to extinction.

Reproductive Biology

In *Acacia* species, the pollination unit is the flower head and pollen is released as polyads. Three mechanisms to promote outcrossing predominate in *Acacia* species:

1. Protogyny, where the stigma is receptive to pollen before pollen in the same flower is released.
2. Andromonoecy, where male and hermaphrodite flowers occur on the same plant, e.g., 17–50% male flowers are found per head in *A. suaveolens*.
3. Gametophytic self-incompatibility, where successful fertilization is determined by the genotype of the pollen, e.g., *A. retinoides*.

The structure of the *Acacia* inflorescence suggests that the majority of species are pollinated by insects, including Coleoptera, Diptera, Hymenoptera, and Lepidoptera, although others are pollinated by small mammals and nectarivorous birds; there is evidence that *A. nigrescens* is giraffe-pollinated. Genetic investigations of *Acacia* mating systems have shown that the species are highly outcrossed. However, reports of isolated individuals (e.g., *A. karroo*, *Faidherbia albida*) setting seeds imply that selfing may occur, whilst reports of polyembryony (e.g., *A. karroo*, *A. farnesiana*, *A. nilotica*) suggest that apomixis may also be important in some species.

In addition to sexual reproduction, some *Acacia* species also reproduce asexually by root suckering. For example, allozyme analysis of two disjunct regions of the rare Australian species *A. anomala* supports the view that one region is primarily outcrossing and the other is clonal, where each population in the latter region contains individuals with identical, multilocus genotypes.

Seed dispersal in acacias is usually by gravity or mechanical means. However, both insects and vertebrates may play important roles in seed dispersal and the facilitation of germination. In a few species, bird dispersal seems to be a common strategy. For example, the Central American ant acacias often have brightly colored fleshy arils that may attract birds, whilst the attractiveness of some species (e.g., *A. cyclops*) may be enhanced by seeds being suspended from the pod. In addition, it has been suggested that the aril of acacia seeds may be attractive to ants. For example, in the mechanically dispersed Australian species *A. linifolia*, secondary ant-dispersal may occur. Browsing vertebrates, particularly in Africa, play an important, if less selective role in seed dispersal; elephants and antelopes ingest large numbers of seeds which are then deposited in their faeces (e.g., *A. erioloba*). Such treatment scarifies the seed and provides a fertile germination medium. Other species, e.g., *Faidherbia albida*, appear to be dispersed by water, the fruits being buoyant, and deposit their seed when rotted, although the relative importance of water versus mammal dispersal in this case is unclear. Humans are an important means of long-distance dispersal of acacia seed, whether it is seed for establishing plantations, movement of multipurpose species with human migration, or transport by their livestock.

Many *Acacia* seeds have hard seed coats and need to be scarified before they will germinate; there are reports of acacia seed remaining viable in the soil for up to 60 years. The seeds of other species (e.g., *A. harpophylla*) lack impervious seed coats, lose viability rapidly, and have short lifespans. Despite their hard seed coats, many acacia seeds may be lost through infection of developing ovules by beetle larvae (Bruchidae) at the early stages of fruit development. Such losses are more significant in the New World and African acacias than in the Australian acacias, where the diversity of Bruchidae is relatively low.

Silviculture

Acacia diversity is reflected in the range of silvicultural practices applied to species management. The most widely planted *Acacia* species (*A. auriculiformis*, *A. mangium*, and *A. melanoxylon*) are generally light-demanding and adapted to a range of soil types. For example, *A. mangium* grows on acidic soils, whilst *A. auriculiformis* is particularly adaptable and grows well on sandy to heavy clay, often shallow soils. Furthermore, *A. auriculiformis* will tolerate flooding and very acidic soils, e.g., acid mine spoil in northern Australia.

Acacia saplings may be raised by vegetative propagation, although grafting may not be suitable for large-scale sapling production and stem cutting may only be possible from seedlings. Therefore, acacia plants are usually raised from seed. Acacia seeds can be stored for long periods, although they usually need scarification before they will germinate. Scarification may occur naturally by passage through animal guts, which has been promoted as a means of obtaining seed for plantation establishment. However, for most purposes other scarification treatments are necessary (e.g., mechanical or chemical damage to the seed testa or treatment with boiling water). Burning may also promote the germination of acacia seeds and is a common silvicultural practice, since accumulated litter is removed, even-aged stands are produced, and pests are destroyed. However, the practice may also increase the likelihood that some species become problem invaders, due to loss of seed dormancy (e.g., *A. brevispica*, *A. catechu*).

Acacia plantations are usually established from container-grown plants inoculated with rhizobia;

saplings are usually transplanted at about 6 months old. However, direct sowing of seed has been recommended in some cases, for example, *A. decurrens* in South Africa, where a well-developed taproot may be damaged during transplantation. Acacia seedlings are usually frost-sensitive, although once established species may be frost-hardy; for example, *A. melanoxylon* plantations will withstand frosts to $-7°C$.

Optimal spacing depends on the species and the products of interest. In order to produce high-quality *A. mangium* logs it is necessary to plant at densities that range from 900 to 1680 stems ha^{-1} which, combined with regular pruning and extensive thinning, will yield suitable timber after 15–20 years. In contrast, plantations for chipping, pulpwood, and firewood are not generally pruned or thinned and are harvested at 6–7 years.

Plantation management will depend on the species. *Acacia auriculiformis* responds well to pollarding and can be coppiced, whilst *A. mangium* is generally unsuitable for multiple rounds of coppicing. *Acacia melanoxylon* is susceptible to windthrow and must be sheltered if high-quality timber is to be produced; for example, in Tasmania it is grown with either *Pinus radiata* or *Eucalyptus* species. Rotation times will depend on the species; for example, *A. auriculiformis* produces stems of 15–20 cm diameter after 10–12 years, whilst *A. melanoxylon* will produce stems of more than 50 cm diameter after 70 years.

Utilization

Wood Products

In general, *Acacia* species have good biomass potential and, because of their high calorific value, are good fuelwoods. Large plantations of *A. mangium*, for paper pulp production, occur in Indonesia and Malaysia, where it is also an important building and furniture timber. *Acacia auriculiformis* is used for fuelwood, whilst the *A. mangium* × *A. auriculiformis* hybrid also has very good wood properties. *Acacia melanoxylon* is the best-known and highly valued temperate *Acacia* timber species, with harvesting from natural Tasmanian forests and plantations in New Zealand, South Africa, and Chile. *Acacia* species are important timber species in their native countries, e.g., *A. galpinii* and *A. nilotica* in Africa. In Western Australia, *A. acuminata* and *A. trachycarpa* are important *Santalum* hosts in commercial sandalwood production.

Tannin

Acacia mangium bark is a major source of vegetable tannin (used in leather and adhesive manufacture), the main producers of which are Brazil, China, Kenya, India, South Africa, Tanzania, and Zimbabwe. *Acacia decurrens* is also used, whilst historically *A. mearnsii* was planted for its tannin-rich bark.

Human Food

Acacia seeds typically have high nutritional values and few toxic or antifeedant compounds. Seeds of Australian tropical arid zone species, e.g., *Acacia colei* and *A. tumida*, are showing promise as a human food sources in semi-arid regions of the Sahel, where they were originally introduced for fuelwood and amenity planting. In Australia, *Acacia* (e.g., *A. murrayana*, *A. victoriae*) seeds are used as flavourings in the developing bushfood industry. African *Acacia* species (e.g., *A. senegal* and *A. seyal*) are important sources of edible gums.

Fodder

Acacia species are an important food component for African savanna mammals, whilst there are significant economic uses of *Acacia* foliage and green pods as livestock fodder, especially in times of drought (e.g., *A. tortilis*). In Australia, the *A. aneura* group is a particularly important fodder for sheep in the arid-zone rangelands, whilst *A. saligna* has been used outside Australia as fodder for sheep and goats in North Africa and South America. However, the foliage for some species is very toxic to livestock (e.g., *A. georgiana*). *Acacia* species may also be important fodder for wild species (e.g., *A. erioloba* in South Africa).

Ornamentals, Oils, and Medicines

In southern Europe, Australian *Acacia* species (e.g., *A. dealbata*, *A. retinodes*) have extensive ornamental value. In southern France, oil from *A. dealbata* and *A. farnesiana* flowers is used as a fixative and blending agent in perfume manufacture. Traditional medicines are extracted from some *Acacia* species, particularly *A. nilotica* and *A. catechu* in India.

Land Amelioration

Acacia species have been used for sand stabilization, *Imperata cylindrica* control, mine spoil rehabilitation, and improvement of soil quality. For example, *A. saligna* has potential for the mitigation of salinity, whilst *A. ampliceps*, *A. maconochieana*, and *A. stenophylla* have been very successful in highly alkaline, saline soils in Pakistan. *Acacia karroo* is an important species for land reclamation in southern Africa, and *A. dealbata* and *A. melanoxylon* are important species for sand dune stabilization in Chile.

Weediness

Some *Acacia* species have become serious weeds. Exotic Australian *Acacia* species (e.g., *A. saligna*, *A. cyclops*, *A. melanoxylon*, and *A. dealbata*) have caused serious weediness problems in South Africa, Portugal, and Chile, whilst New World and African *Acacia* species (e.g., *A. farnesiana*, *A. nilotica*) have caused problems in Australia. The weediness of *Acacia* species means that their use in agroforestry and amenity situations must be considered very carefully.

Bamboos, Palms and Rattans

I R Hunter and N Bystriakova, International Network for Bamboo and Rattan, Beijing, China

Taxonomy/Genetics

Bamboos: Poaceae (Gramineae)

The family Poaceae comprises about 12 000 species in about 700 genera. Twelve subfamilies are recognized, of which the Bambusoidea is one. This subfamily includes approximately 1200 species within the tribes Bambuseae (woody bamboos) and Olyreae (olyroid or herbaceous bamboos).

Bamboos are forest grasses. The most ancient grasses were tropical forest dwellers but, as the higher grasses diversified into open areas, the true bamboos were the only major lineage of the family to adapt to the forest habitat. Bamboos are set off from other grasses by the predominance of certain 'bambusoid' structural characters, many of which are considered to be 'primitive'. The most easily recognizable vegetative features that distinguish the bamboos are the prominent development of a rhizome system, the woodiness and strong branching of the culms, the presence of petioles on the leaf blades, and the difference in form between the sheaths clothing young culm shoots and those borne on the leafy twigs. To these may be added floral characters such as well-developed lodicules, in most species three in number, and a style consisting typically of a single column, bearing one, two, or three (rarely more) stigmas.

The bambusoid grasses are naturally distributed in all continents except Europe and Antarctica. Bamboos appear more or less prominently in the natural vegetation of many parts of the tropical, subtropical, and mild temperate regions. The approximately 1100 species of woody bamboos are distributed from 46° N to 47° S latitude and from sea level to 4300 m in equatorial highlands, whereas the approximately 110 species of herbaceous bamboos occur overwhelmingly in the New World, with only two Old World representatives. The herbaceous bamboos occur principally in moist forests between 29° N and 34° S latitude and are only occasionally found above elevations of 1000 m, rarely to 2700 m. The natural distribution of bamboo in the world has been greatly modified by human intervention.

Of the 60–70 genera of woody bamboos, only *Arundinaria* occurs in both the Old World and New World. Currently, 20 genera of solely New World woody bamboos are recognized, so there are 21 New World woody genera. Although nearly twice as many Old World genera are recognized, there are approximately 430 species of New World woody bamboos, compared with 500–600 Old World species.

In the Old World, the monsoon-belt of Southeast Asia with southern China is the main center of diversity of the bambusoid grasses. In the New World, Brazil (including the Amazon basin and the Atlantic forests) has the greatest diversity of genera and species, followed by the Andes (Venezuela to Bolivia) and Mexico and Central America.

Bamboos have a great industrial and cultural significance, particularly in East Asia, although fewer than 100 species are generally used.

Palms: Arecaceae (Palmae)

The family Arecaceae is a large group comprising approximately 2500 arboreal species to be found throughout equatorial, tropical, and subtropical areas of the world where they feature as a very peculiar element of the landscape. The main geographical areas having played the role of differentiation centers are Africa's equatorial coasts, the Indonesian region, the Sunda Isles, Oceania, Brazil's coasts, Amazonia, and the Antilles. It was during the Cretaceous period that this group had its largest diffusion and differentiation, leaving behind several fossil remains of trunks and leaves.

The family is traditionally divided into a number of subfamilies: (1) Phytelephasieae, characterized by flowers without a perianth, a large number of stamens in male flowers and female flowers bearing a multilocular ovary (4–9 locules), and infructescences (*Phytelephas*); (2) Coryphoideae, exhibiting floral characters typical of the family: free carpels, berry-like fruits, pinnate or fan-shaped leaves (*Phoenix*, *Chamaerops*, *Trachycarpus*, *Livistona*, *Sabal*, *Washingtonia*); (3) Borassoideae, characterized by fan-shaped leaves, perianth typical of the family, syncarpous ovary (*Hyphaene*, *Borassus*, *Lodoicea*); (4) Lepidocaryoideae, characterized by syncarpous ovary and fruits covered with imbricate scales (*Raphia*, *Metroxylon*, *Calamus*); (5) Ceroxyloideae, characterized by syncarpous ovary and pinnate leaves (*Arenga*, *Ceroxylon*, *Areca*, *Cocos*); (6) Nipoideae, characterized by male flowers bearing three connate stamens, and unilocular ovary (*Nipa*).

Habits of palms are quite typical, in that they are characterized by a tall, unbranched stem (up to 80 m tall in the genus *Cocos*) or, rarely, by a dichotomous branching stem (*Hyphaene*), and of the same diameter all along from base to top; at the apex they bear a rosette consisting of coriaceous, either palmate or pinnate, leaves, up to some meters long. The stem may remain quite slender, in which case it turns to a creeping habit (rattan/*Calamus*), or otherwise it may be very short in acaulescent species (*Phoenix acaulis*). Another feature peculiar to this family is that the stem reaches its ultimate growth in diameter before it starts its growth in height. Indeed, palms lack any secondary growth. Inflorescences are spadix-like, at first enveloped by a spathe or by leaf sheaths opening up at anthesis.

The fruit may be either a berry (e.g., *Phoenix*) or a drupe (e.g., *Cocos*). Only one fertilized locule carries on developing, whilst all others wither, so that the fruit contains one seed only. Pollination is mostly anemophilous; accordingly, the plant produces a large amount of pollen for this purpose.

The Arecaceae include plants of enormous economic importance for human beings, amongst them the coconut palm (*Cocos nucifera*) and the date palm (*Phoenix dactylifera*). Several species are employed in the production of vegetable fibers (*Sabal*, *Chamaerops*, *Trachycarpus*, *Borassus*). African oil palm (*Elaeis guineensis*) supports a huge industrial oil industry. Rattans are the basis of a large furniture and matting industry. Other palms with high potential as food sources include *Bactris gasipaes*, *Euterpe oleracea*, *E. precatoria*, *Jessenia bataua*, *Mauritia flexuosa*, and *Orbignya phalerata*.

Palms are also used in milder temperate-climate regions to provide trees for parks, gardens, squares, and avenues. Among the most widely used to this end are *Phoenix canariensis*, *P. dactylifera*, *Washingtonia filifera*, *W. robusta*, *Syagrus romanzoffiana*, and *Trachycarpus fortunei*.

Rattan: Calamoideae

Rattans belong to the Calamoideae, a large subfamily of palms. There are around 600 different species of rattan belonging to 13 genera and these are concentrated solely in the Old World tropics; there are no true rattans in the New World. All of the species within the Calamoideae are characterized by overlapping reflexed scales on the fruit and all of these climbing palms are spiny, a necessary preadaptation to the climbing habit. Of the 13 genera of rattan, three are endemic to Africa: *Laccosperma* (syn. *Ancistrophyllum*), *Eremospatha*, and *Oncocalamus*. Although some species within these genera are utilized locally and form the base of a thriving cottage industry, they have not, until recently, attracted much attention from commercial concerns.

The largest rattan genus is *Calamus*, with *c.* 370 species; it is represented in Africa by one very variable species, *C. deerratus*. *Calamus* is predominantly an Asian genus and ranges from the Indian subcontinent and south China southwards and east through the Malaysian region to Fiji, Vanuatu, and tropical and subtropical parts of eastern Australia. Most of the best commercial species of rattan are members of this genus. The remaining rattan genera, *Calospatha, Ceratolobus, Daemonorops, Korthalsia, Myrialepis, Plectocomia, Plectocomiopsis, Pogonotium,* and *Retispatha*, are centered in Southeast Asia and have outliers further eastwards and northwards.

Rattans can be clustering (clump-forming) or solitary; some species, such as *Calamus subinermis*, can be both. Other species are acaulescent, having no discernible stem at all. Clustering species sometimes possess up to 50 stems of varying ages in each clump and produce suckers that continually replace those stems lost through natural senescence or through harvesting. Some clumps can be harvested many times on a defined cycle if the light conditions are conducive to the remaining suckers being able to develop and elongate.

Rattans display two main modes of flowering. In one, a period of vegetative growth is followed by the simultaneous production of flowers. Flowering and fruiting are followed by the death of the stem itself. In single-stemmed palm species, the whole organism dies after fruiting. However, in clustering species of rattan the plant coppices from the base and it is only the individual stem that dies. In the other form of flowering, flowers are produced continually and flowering and fruiting do not result in the death of the stem. All the species of *Korthalsia, Laccosperma*, *Myrialepis*, *Plectocomia*, *Plectocomiopsis*, and a few species of *Daemonorops* flower and die. Furthermore, in many of these species, stems tend to be of low quality due to the presence of a soft pith which results in poor bending properties. Such stems are also more prone to subsequent insect attack due to increased starch deposition.

Rattan fruits are often brightly colored (white, yellow, orange, or red) and attractive to birds and mammals. Birds (e.g., hornbills) and primates are the main dispersers of rattan seeds. In the Asian taxa, the seed is often covered with a fleshy seed coat. Incomplete removal of this coat often results in delayed germination, suggesting that it contains some chemical germination inhibitors. However, once this outer layer is fully removed, the germination of commercial species such as *Calamus manan* and *C. caesius* is both rapid and uniform. In contrast, in African rattan species it can be rather prolonged and it may take between 9 and 12 months before germination commences.

Ecology

Bamboo

Bamboos range in height from a few centimeters to 20 meters or more. The shorter species exist either as understory to forest stands or as edaphic or climatic climaxes (particularly in altitudinal belts on mountains). They are associates of most temperate and tropical moist or dry forest types. Bamboos are generally very tolerant of poor soils. The minimum rainfall to form closed stands seems to be around 600 mm year^{-1}. Bamboo species vary greatly in cold tolerance; some will not tolerate any frost but others tolerate temperatures down to $-30°C$.

Bamboo understory species prefer light overhead shade. Bamboos may interact with fire in that they and grasses are reduced with fire exclusion. Soil impoverishment, through frequent burning, may promote development of a bamboo-dominated forest understory. Bamboo may aggressively colonize forest gaps and exclude light-demanding pioneer tree species. Under these circumstances forest composition can gradually change to be bamboo-dominant.

Pure bamboo stands occur naturally in several parts of the world. Altitudinal belts occur on East African mountains at 2400–3000 m. Bamboo forest, a type of open rain forest characterized by the dominance of arborescent bamboos of the *Guadua* genus, covers over 50% of Acre state in the southwestern Brazilian Amazon.

There is a close ecological link between bamboo forest and certain rare species – Amazonian bird species and, notably, the panda. However some bamboo stands may have a lower wildlife biodiversity than other natural forests.

Many bamboos are semelparous – they flower once after a long interval and then die. There are other plant genera with similar habits – *Agave, Ensete, Kalanchoe, Lobelia*, *Orchis*, and *Yucca*. It is not known what triggers such flowering or what benefit it is to the plant to behave in this way, although there are three main theories: bet-hedging, reproductive effort, and demographic models. Flowering seems to occur in waves, starting in one place and then migrating through nearly the entire species. The time taken to go through the wave may range from a few years to many decades. Contemporaneous flowering may occur even in ornamental bamboo plants continents away from their native range. For example, in the 1990s millions of plants of *Fargesia murieliae*, an ornamental bamboo, flowered in western Europe. As all plants were ramets of a single ortet introduced into Europe about 80 years ago, the simultaneous flowering of all these ramets constituted a single giant compound inflorescence. Species moved within their range retain the flowering pattern of their home range. One major cohort of *Bambusa arundinacea*, widely distributed in India, has been recorded as seeding in 1868–1872, 1912–1916 and 1958–1962. On the other hand, in *Melocanna baccifera* some populations have a flowering cycle of 30–35 years, and others may have a longer (45, 60, 65 years) or shorter (7–10, 19–21, 25, 26, 27 years) cycle.

Mass flowering and dying of bamboo are important events in the ecology of their associations leading variably to such consequences as enhanced tree seeding in gaps or to explosions of rodent populations. Flowering remains largely unpredictable, unless written or oral history has accumulated, and the subsequent dying is a major although infrequent problem in the management of bamboo as a crop.

Intensification of bamboo management leads to more diseases – particularly blights and rots. Some bamboos may form a nitrogen-fixing association with azotobacteria.

Palms

Palms exist as canopy constituents of forest associations; as understory species in forests and as edaphic or climatic climax, or more properly, survivor species. Many palm species are more tolerant of harsh conditions (salt, alkali soils, harsh temperatures, drought, permanent water-logging) and are hence sometimes, along an environmental gradient, amongst the last plants to be found on such highly degraded sites. In forest associations it has been noted that palms are often found on the poorer soils.

Rattan

With habitats ranging from sea level to over 3000 m elevation, from equatorial rainforests to monsoon savannas and the foothills of the Himalayas, there is a huge range of ecological adaptation among rattans. However, rattans are predominantly plants of primary rain and monsoon forest. Rattans are distributed in tropical and subtropical areas in the Asia-Pacific region and Africa. No rattans are found growing naturally in other tropical and subtropical areas, or in the temperate regions.

Throughout their natural range, rattan species are found in a wide range of forest and soil types. Some species are common components of the forest understory, whilst some rely on good light penetration for their development; hence several species are found in gap vegetation and respond very well to canopy manipulation, particularly that caused by selective logging. Other species grow in swamps and seasonally inundated forest whilst others are more common on dry ridge tops.

Despite this wide range of ecological conditions, the majority of rattans need adequate light for their full growth and development. Although the seeds will germinate under a wide range of light conditions, the resultant seedlings will remain for long periods on the forest floor awaiting sufficient light for them to develop, such as may occur after a tree fall.

Date Palm

The date palm is a native of North Africa but has been so extensively cultivated there for thousands of years that no natural stands are thought to remain and no information on its native ecology is available.

It is cultivated and naturalized throughout the desert regions between 15° and 35° N, from the Canary Islands and Morocco in the west to India in the east. It has been recorded from all the inland and littoral parts of North Africa, from the southern parts of the Balkan peninsula and Asia minor, from Syria, Palestine, Jordan, Iraq, Arabian peninsula, Iran, and Pakistan. It is cultivated as an ornamental in southern Europe, but seldom matures fruit except in extreme southern parts of Italy and Spain. The date palm is cultivated in Arizona and California, USA, and Queensland, Australia. There is evidence of date usage 8000 years ago in India as well as its cultivation in Sumeria and ancient Egypt.

Date palm is reported to tolerate annual precipitation of 30–400 mm – a full-bearing orchard requires only 250 mm of rainfall (by rainfall or irrigation). It is grown ideally where the permanent water table is within root-reach of the soil surface. Annual temperature should be warm temperate to tropical and soil pH slightly acid to strongly alkaline. Any good soil that is not too heavy will do. Dates do well even where there is a crust of salt on the surface. Daytime temperatures of 50°C are tolerated. For proper ripening of fruit, the mean temperature between the period of flowering and ripening should be above 21°C, rising to 27°C, for at least a month. There must be no rain during flowering time. Winter temperatures below −8°C are harmful.

Oil Palm

The oil palm (*Elaeis guineensis*) is originally a native of Africa but is now widely distributed as an exotic plantation species. It is widespread in the moist tropical forests of Africa. However, even in its native range its ecology has been greatly modified by domestication. Considerable attention is now directed to its genetic range. The Palm Oil Research Institute of Malaysia has the largest collection of *Elaeis guineensis* and *E. oleifera* germplasm in the world. Palms in over 1000 ha of germplasm gardens are being evaluated for oil yield, kernel content, height, harvest index, fatty acid composition, carotene, and vitamin E contents.

Raffia Palm

The raffia palm often occurs pure or in mixtures with mangroves and palms in wetlands and freshwater swamps in Africa. Although *Raffia regalis* is found on dry soils, and *R. farinifera* in lower mountain regions in Cameroon, the raffia palms in southern Benin are confined to freshwater swamps where the natural vegetation is forest. However, human activity has transformed this forest into a 'raphiale' where *R. hookeri* has become the main arborescent species. One sole species, *R. taedigera*, occurs in Latin America in a particular kind of swamp forest which is composed of a nearly pure stand of *R. taedigera*, growing in clumps. The leaves of *R. taedigera* grow to nearly 15 m in length and upon falling seem to eliminate the few other species of trees that might grow in water. There is conflicting evidence as to whether *R. taedigera* is actually native or introduced long ago from Africa.

Silviculture

Bamboo

Bamboos can be classified into two main types – sympodial (clumping and largely tropical) bamboos and monopodial (running and largely warm temperate bamboos). Monopodial bamboos spread by creeping rhizomes. They will naturally invade and thicken up. They can be very easily propagated by simple cuttings from the rhizomes. It is more difficult to make such cuttings from sympodial bamboo. However, techniques such as soil-layering, air-layering, and branch or culm cuttings are usually successful.

Bamboos do not suffer from a quality-degrading 'edge effect' like trees and so can be grown successfully in single clumps or in dense plantations. Bamboo shoots emerge and grow rapidly, reaching full height (which can be up to 20 m) in 40 days. In China a combination of edible shoot harvesting and respacing is used to keep a density of approximately 2500–3000 stems per hectare. Bamboo culms become mature at 4 or 5 years of age. Bamboo clumps therefore are best managed by selectively cutting the mature culms. Managed in this way, the evergreen canopy is never broken, thus maximizing soil and water conservation values. However, periodic clear-cutting has also been used successfully. Fertilizer and insecticide have been used to increase productivity. Managed conservatively, plants should last until the next flowering cycle, 50–100 years depending on species.

Bamboos have been planted in large-scale plantations; however, much of the 'bamboo seas' prevalent in China have resulted from an intensification of management in east coast monsoon forest scrub, by which farmers have gradually replaced all other species with bamboo.

Palms

In natural forests palms often occupy the poorest sites. Coconut palm lives on the edge of salty, wind-blown oceans. Date palms live in furnace-like deserts. Many palm species are extraordinarily tolerant of tough sites. Silviculture is not therefore usually problematical.

Oil palm From 1967 through to 1997, oil palm was one of the fastest-growing subsectors of the Indonesian economy, increasing 20-fold in planted area and showing a 12% average annual increases in crude palm oil production. The Malaysian oil palm industry has seen unprecedented growth in the last four decades to emerge as the leading agricultural industry in the country. From a mere 55 000 ha in 1960, the area under the crop grew more than 50-fold to 2.82 million ha in 1997. There are now, globally, 5.5 million ha of plantations. Oil palm grows well on desaturated ferrallitic soils of low fertility. Normally, however, the site is substantially, modified by cultivating, weed control, and fertilizing to achieve maximum growth. Oil palm silviculture is the subject of a highly focused and site-specific research effort. In that respect it has more in common with the major forest plantation genera such as *Acacia*, *Eucalyptus*, and *Pinus* than other palm species. Research reports indicate major efforts to control site-specific pests and diseases in monocultural plantations. Considerable effort is being applied to integrated pest management to reduce the use of pesticides. Oil palm cultivation is clearly associated with the destruction of primary or secondary rainforest and raises significant environmental issues.

Rattan Most of the rattan currently harvested comes from naturally occurring plants in tropical rainforests and is not managed silviculturally in any way. Some village communities have evolved indigenous management techniques. Generally, however, even known good practice techniques in cutting, such that the whole plant does not die, are not applied. Rattan can be grown in plantations. As a scrambling climber it does need overhead support. As a plant it also seems to need part shade in order to develop into a vine. There are many reports of it being grown in conjunction with and over other crops, such as old rubber trees. However, the cost of plantation-grown rattan is much higher than naturally grown rattan and the quality is sometimes poorer. Consequently, there is as yet little active silvicultural management. The global management of rattan could be described as in transition from weakly regulated exploitation of a natural resource towards some kind of resource management in the future as natural resources become depleted.

Rattan is usually grown from seeds collected from wild stands. The seeds of some species are slow to germinate, needing many months in specially prepared sandy seedbeds. Nursery technique therefore needs local experimentation and adaptation to be successful.

Coconut The coconut palm grows readily from the nut. It thrives on sandy, saline soils; it requires abundant sunlight and regular rainfall over the year. Coconut can be and is grown in plantations on a range of soils well away from the sea. It is often interplanted with other crops and sometimes with N-fixing crops to reduce fertilizer need.

Date palm The date palm is propagated by seed or offshoots. Seedlings are first planted in nursery rows and later transplanted to their permanent location. Normal healthy trees may produce 10–30 or more offshoots. These will root if their bases are encased in soil. Date palms are planted between 6 and 9 m apart, with one male per 50 or more females. Date palms are sensitive to cold. In early stages, manuring is productive and palms may be intercropped with low crops like barley, pulses, and wheat. When the palms are taller, fruit trees can be intercropped. Pruning of the leaves, artificial pollination, and thinning of the fruits are also recommended. Pollination is helped by placing cut portions of the male flower spikes in the receptive female inflorescence. In Egypt, dates usually flower in February and March, ripening in August and September. Precocious trees may start fruiting at 3 years, but full crops are not usual until 5–8 years old. Old or damaged trees can be rejuvenated by air-layering the top and retransplanting it. Trees may bear for a century or more.

Utilization

Bamboo

Bamboos are used for the widest range of products imaginable. As bamboo tubes they are used as structural members for housing, for water pipes, and for musical instruments. In the split form bamboo is used to make baskets and household containers. Split and made into mats it is further fabricated into plywood. Split and carefully squared, it is made into panels and parquet flooring. As a fiber it is made into fiberboard, paper, and (experimentally) textiles. The shoots are harvested in the spring, cooked and eaten.

There is a very large internal consumption of products in each producing country. There is a substantial trade in bamboo products between countries. World trade is known to be at least US $2 billion per year. Since many products are not identified as being of bamboo in the trade statistics, total trade can only be estimated, but is conservatively thought to be over three times greater. China is the world's largest producer and accounts for approximately half of the world exports. Indonesia, the Philippines, and Vietnam are significant exporters. The EC and USA receive nearly 80% of world imports.

Palms

Palm wine, an important indigenous product, is the fermented sap from numerous species of palm trees. In Ivory Coast, it is extracted from oil palm (*Elaeis guineensis*), borassus palm (*Borassus aethiopum*), and raffia palm (*Raphia hookeri*).

Rattan

The most important product of rattan palms is cane; this is the rattan stem stripped of its leaf sheaths. This stem is solid, strong, and uniform, yet highly flexible. The canes are used either in whole or round form, especially for furniture frames, or split, peeled, or cored for matting and basketry. Other plant parts of some species of rattan – fruits, leaves, roots, and palm heart – are also utilized and contribute to the indigenous survival strategies of many forest-based communities.

However, it is for their cane that rattans are most utilized. Rattan canes are used extensively across their range by local communities and play an important role in subsistence strategies for many rural populations. The range of indigenous uses of rattan canes is vast: from bridges to baskets; from fish traps to furniture; from crossbow strings to yam ties. It is estimated that 80% of the known rattan species is of limited commercial value due to inflexibility and being prone to breakage or possessing other poor mechanical properties, or due to biological rarity.

Coconut Palm

Coconuts are the main product of the coconut palm, and are used as whole fruits or for their parts: fibers, milk, kernel (or flesh), and husk. Coir mats are made out of coconut fiber. World production of coconuts exceeds 50 million tonnes. Indonesia, Philippines, and India between them account for over 70%.

Other parts of this plant are used too, notably its leaves to make baskets and roofing thatch. Apical buds of adult plants are an excellent palm-cabbage and an alcoholic drink known as toddy or palm wine is extracted from its sugar sap, tapped from the flowers.

Raffia

The leaves are the main products. Raffia fiber is used in floriculture and horticulture to make very tough ties, as well as a number of woven articles (mats, baskets, and hats). Raffia is tough yet very flexible and resilient leaf petioles are employed, instead of bamboo, to build houses and make various kinds of furniture. Sago, a kind of flour, is extracted from the stem pith which, before blooming, is extremely rich in starch.

Date

The fruit is the main product. Dates, due to their high sugar content, are the basic food for the people of North Africa, Arabia, and Iran. Hundreds of varieties are grown for commercial purposes. The individual varieties are recognized and prized much in the same manner as wines. Total world production exceeds 6 million tonnes. Egypt, Iran, United Arab Emirates, Saudi Arabia, Iraq, Pakistan, and Algeria (in that order) account for over 85% of world production. A considerable export trade exists to many other countries.

Palm Oil

The seeds are the main product. Prime oil, commercially known as palm kernel oil, is extracted from the seeds, which are first shelled and ground, then hot-squeezed. It is seldom extracted by means of chemical solvents. Oil content per seed ranges between 43% and 51%. This oil is very similar to coconut oil, from which it differs in its higher content of oleic acid; it is solid and buttery below 20°C, yellowish-white in color, pleasantly flavored, and it smells somewhat like coconut.

Palm kernel oil possesses a variable acidity degree, usually not exceeding 15%. It is employed for nutritious purposes as a kind of margarine or vegetable butter, or again as a partially hydrogenated oil; to this end, it is suitably refined and decolorized.

A kind of high-acidity oil, therefore of a purer quality, is extracted from the fibrous flesh of fruits after they have been hot-squeezed. This oil, whose content per fruit ranges between 40% and 70%, is mostly employed in making soaps and cosmetics or as a machinery lubricant.

During the last three decades world production of palm oil has increased from 0.9 million tonnes in 1967 to 17.4 million tonnes in 1997 from 5.5 million ha of plantations. Malaysia produces 50% of world production of oil palm fruit and Indonesia 29%.

Dipterocarps

B Krishnapillay, Forest Research Institute Malaysia, Kepong, Malaysia

Introduction

The dipterocarp forests of Southeast Asia constitute a dominant and particularly valuable component of the world's tropical rainforest. As a family of plants, Dipterocarpaceae may perhaps hold the distinction of being the best-known trees in the tropics. Their ecosystems are extremely diverse. They are uneven in their age and multilayered. They grow all the year round under warm temperatures and on sites where there is a large amount of rainfall. However, those growing in the seasonal forest are generally medium sized with the tallest trees being around 20 m with a maximum diameter of about 50 cm. Generally dipterocarps have been observed to occur on soils with very low fertility. Currently the dipterocarps dominate the international tropical timber market, and therefore play an important role in the economy of many Southeast Asian countries. In addition to timber, this family of trees also produces other non-timber products like resins and oleoresins.

Distribution

The present distribution patterns of dipterocarps are thought to reflect routes of colonization and past climatic conditions. They are distributed over the tropical belts of three continents of Asia, Africa, and South America (**Figure 1**). They occupy several phytogeographical zones that mainly conform to climatic and ecological factors. However, in Southeast Asia the Wallace line, which runs east of Philippines and between Borneo and Celebes, is a major phytogeographic boundary for dipterocarps. This phenomenon cannot be explained in terms of climatic differences but requires the intervention of continental drift.

Worldwide there are about 16 genera and about 580 species in the family. Seven main phytogeographical regions are classically recognized within this distribution area

1. Malesia, which constitutes Peninsular Malaysia, Sumatra, Java, lesser Sunda Islands, Borneo, Philippines, Celebes, the Moluccas, New Guinea and the Bismarks. The northern frontier of Peninsular Malaysia delimits this part.
2. Mainland Southeast Asia, which includes Burma, Thailand, Cambodia, Laos, Vietnam, and South China.

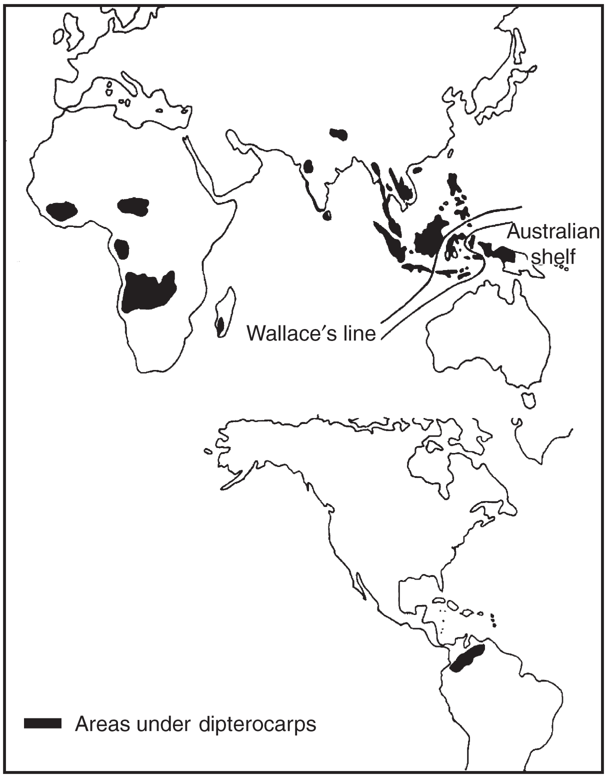

Figure 1 Phytogeographical distribution of the family Dipterocarpaceae worldwide.

3. South Asia, which constitutes India, the Andaman Islands, Bangladesh, and Nepal.
4. Sri Lanka.
5. The Seychelles.
6. Africa, which constitutes Madagascar, a narrow strip from Mali to Sudan in the northern hemisphere, and Congo.
7. South America, which constitutes Araracuara (Colombia), Venezuela, and Guyana.

The South American region corresponds to Guyana, Venezuela and part of the Colombian Amazon, which overlies the Guyana shield. The African region includes a continental area and an insular part in Madagascar. The Asian region corresponds to the Indo-Malesian area, which concentrates a high number of genera and species in the equatorial forest. This area is limited northward by the Himalayan foothills, then approximately by the borders of Assam, Arunachal Pradesh, Burma, Laos, and Vietnam and penetrating into South China including Hainan Island. On the extreme southwest the large belt of Asian dipterocarps reaches the Seychelles and covers India and Sri Lanka. Its eastern border corresponds to New Guinea. The Sundalands delimit the most southern part. No dipterocarp species are found in Australia.

In Asia, dipterocarps occupy a large variety of habitats. They are found from the coast to the inland, from riverine to swampy conditions. They occur on dry land on undulating to level terrain, on ridges, on slopes, in valley bottoms, on soils that are deeply weathered and shallow, from well drained to poorly drained conditions, and both on soils rich or poor in nutrients. This to a great extent shows the wide versatility of the species in terms of its ecology. In Peninsular Malaysia the altitudinal zonation of their main habitats types ranges from 0–300 m (known as lowland dipterocarp), 300–750 m (called hill dipterocarp forest), and 750–1200 m (known as upper dipterocarp forests).

The freshwater swamps, especially in drier parts, are rich in the species while in the true peat swamps occurrence is relatively poor. The dipterocarp flora is also poor on limestone and riverine fringes. Asian dipterocarps are limited altitudinally by climatic conditions and the conjunction of altitude and other natural barriers, such as large rivers and watersheds. These have obstructed the distribution of species in Borneo. For example the northwest and northeast of Kalimantan, Sarawak, Brunei, and Sabah are much richer in species than the rest of Kalimantan. The ever-wet areas are also richer in species than the seasonal ones as seen in Sri Lanka by the concentration of species in the southwest quarter, or in the Thai–Malaysian transition belt or from Java to the lesser Sundas.

The genera and species in Asia show much greater diversity compared to Africa and South America. As expected the higher numbers clearly occur in the ever-wet regions. **Table 1** shows the number of genera and species found in the different phytogeographical regions.

Ecological Distribution

For clarity in understanding the ecosystem of dipterocarps, the well-illustrated description from Peninsular Malaysia is referred to in this text. In the other parts of Asia, the ecological conditions are somewhat similar and with very minor variations. The ecosystems in which dipterocarp species are distributed can thus be divided into the following categories based on the altitude and forest type in which they occur.

Table 1 Distribution of genera and species of dipterocarps according to the seven phytogeographical regions

Phytogeographical region	*Number of genera*	*Number of species*
Malesia	14	465
Mainland Southeast Asia	8	79
Sri Lanka	7	45
South Asia	9	58
Seychelles	1	1
Africa and Madagascar	3	49
South America	1	1

The Lowland Dipterocarp Forests

These can also be classified as lowland evergreen rainforest formation. The bulk of the exploitable forests are in this category, which embraces all the well-drained primary forests of the plains, undulating land, and foothills up to about 300 m altitude. In most localities the dipterocarps form a high proportion of the emergent and dominant strata of the forest. Exceptionally, dipterocarps may be almost absent, while occasionally, over small areas, they may be so abundant that large trees of other families are few and scattered. In these lowland dipterocarp forests about 130 species of dipterocarps, representing all the main groups, occur. In any one forest reserve there may, exceptionally, be as many as 40 species, but between 10 and 30 is a more usual number. In most lowland reserves *Shorea* is represented by two or three species, and is the most conspicuous woody component of the forest. Usually one or two species of *Dipterocarpus* are also present.

The Hill Dipterocarp Forests

These too can also be classified as a lowland evergreen rainforest formation. They are the climax vegetation of the altitudinal zone immediately above the lowland dipterocarp forests. On inland ranges the altitudinal limits are approximately 300–750 m, but on isolated mountains, or on coastal ranges, this zone may be depressed to much lower altitudes. The lines delimiting the hill dipterocarp forests cannot be drawn strictly along the topographical contours; they descend the ridge and ascend the valleys, and the lower limit may range between 150 and 450 m on the same hill system.

The main difference between the hill dipterocarp forests and the lowland dipterocarp forests is in specific composition of the dominants of the upper strata of the vegetation. There is usually a slight diminution in size of the larger trees accompanied by a slight increase in number per unit area on ridge tops and towards the upper limits of the hill dipterocarp forests. Many of the lowland dipterocarps are represented in the hill forests, although they become scarce towards the upper limits of these forests, but many species appear in the hill forests that never, or only very exceptionally, occur in the lowland forests. Predominant among these is *Shorea curtisii*, one of the *Shorea* group that tends to be gregarious on ridges; it is readily distinguished in the forest, and is a useful indicator of hill dipterocarp forest. Where this species is abundant the light-colored crowns of the *S. curtisii* trees mark the hill dipterocarp forest zone as a blue–gray band along the mountainsides.

In these forests all the main dipterocarp groups, except perhaps *Dryobalanops* and *Pentacme*, are represented. At the lower levels of the zone, where many of the lowland dipterocarps still persist, the forests are the richest both in species and volume of dipterocarps. Beyond the limits of the lowland species the number of dipterocarp species represented is usually less per unit area than in the lowland forests, although *Vatica* is usually better represented. This reduction in species, however, is often more than offset by the greater number of individuals, thus fully maintaining the predominance of the dipterocarps in these forests.

In the hill dipterocarp forest zone on coastal hills, or on hills that the geologically recent recession of the sea has rendered inland, several dipterocarps are represented, which are absent or rare on ranges remote from the sea, for example, *Shorea glauca*, *S. lumutensis*, *S. gratissima*, *Dipterocarpus rotundifolius*, *D. penangianus*, and *Cotylelobium malayanum*. These hill forests too represent a great potential wealth.

The Upper Dipterocarp Forests

These are also classified as tropical lower-montane evergreen rainforest subformation, which is a transition zone between the tropical lowland evergreen rain forest and the tropical upper montane rainforest of the higher mountains. This is the zone into which the hill dipterocarp forests blend. It is represented only on the higher mountains, the altitudinal limits being approximately from 750 to 1250 m altitude on inland ranges, but on isolated mountains or coastal ranges, where the vegetation zones tend to be depressed and telescoped, it may be represented by a narrow belt lying between 600 and 900 m altitude.

There is a marked difference in floristic composition of the vegetation as one passes from the hill dipterocarp forests into the upper dipterocarp forests. Almost all the lowland forms are absent and the montane forms, which predominate in the next highest zone, become more and more in evidence. The dipterocarps are represented by only a few species, but these are so characteristic, and sometimes so abundant in these forests, that it is desirable to recognize a separate forest zone of which they are the chief indicator species. The predominant, typical species is *Shorea platyclados*. However, *S. ovata*, *S. ciliata*, *S. submontana*, *Hopea montana*, *Dipterocarpus retusus*, *D. costatus*, and *Vatica heteroptera* are also characteristic. These forests are mainly of value for soil protection, but limited areas rendered accessible by the roads to hill stations may produce commercial timber.

The Montane Oak Forests

These forests can also be classified as tropical lower-montane evergreen rainforest subformation. The upper dipterocarp forests form the lower levels of this subformation, and the montane oak forests the upper. The altitudinal range of the montane oak forests is usually between 1050 and 1500 m. These altitudes are above the normal range of dipterocarps.

Peat Swamp Forests

These are classified as tropical woodland formations but they are most closely allied to the tropical freshwater swamp forest. They belong to a vegetative formation that occupies vast alluvial flats along the northwest and southwest coasts of Borneo, around the coasts of the Rio and Lingga archipelagos, on the east coast of Sumatra, and on the west, and to some extent the east coast of Peninsular Malaysia. All the chief timber-producing families of the lowland dipterocarp forests are represented in the peat swamp forests, but the number of species of each is comparatively small. These species are, with very few exceptions, entirely different from any found on dry land, but most of them are widely distributed throughout the peat swamps. Dipterocarps are important components of the peat swamp forests. The number of species is small, but they show a marked gregarious tendency and frequently form a high proportion of dominant and emergent trees of the forest. Species like *Shorea albida*, *S. rugosa*, *S. teysmanniana*, *Anisoptera marginata*, *S. platycarpa*, *S. dealbata*, *Dipterocarpus coraceus*, *D. chartaceus*, *Hopea resinosa*, *H. mengarawan*, and *Vatica wallichii* are commonly found in this habitat.

Riparian Fringes

The narrow strips of vegetation found along, and characteristic of, river courses are regarded here as riparian fringes. These have also been classified as tropical riparian woodland formation, but it is perhaps more appropriate to regard them as a series of edaphic formations zoned from river mouth to source. A constant supply of telluric (rising from the soil) moisture is the predominant edaphic factor, while the zones are determined mainly by the incidence of tidal influence, width of stream, rate of flow, and altitude. At the mouth of a stream, the first zone, which is under saline influence, is inhabited mainly by mangrove swamp species. Further upstream a transition zone occurs, which is still under tidal influence but in which the water is mainly fresh. This riparian zone is not normally inhabited by dipterocarps, but *Vatica wallickii* has been reported to occur towards its upper limits. Beyond tidal influence there is a pronounced change in specific composition of the riverbank flora. Many of the species are particularly adapted to this riparian habitat. Some have narrow leaves to reduce resistance to flood water, the so-called stenophyllous plants, while some have fruits specially adapted for dissemination by water or capable of germinating and establishing themselves under water. Several dipterocarps are characteristic of these communities. The best known and most abundant is *Dipterocarpus oblongifolius*, but in the same category *Shorea sumatrana*, *S. palembanica*, and *Hopea odorata* could also be placed. The gnarled trunks of these trees overhang the streams, forming what have been called gallery forests. The following species also frequently occur in this zone of riparian vegetation, but they are less characteristic of the differentiated riparian fringe than of any damp soil in the vicinity of streams or of land subject to periodic inundation. These would include *Shorea assamica*, *S. macrantha*, *S. hemsleyana*, *Hopea kelantanensis*, *H. mengarawan*, *H. sangal*, *Dryobalanops oblongifolia*, *Vatica bancana*, *V. lobata*, and *V. wallichii*. The upper reaches of the larger rivers are in the montane forest zone and no dipterocarps are represented in the riparian fringes.

Heath Forests

In Borneo there are large areas of lowland primary forest to which the provisional name 'heath forest' has been applied. These forests are an edaphic climax type, developed on pale, light-textured, acid sandy soils that seem to resemble a European podsol. *Shorea glauca* occurs gregariously in this forest type. The only dipterocarps in addition to *S. glauca* found in this zone are *Hopea semicuneata* and *Vatica odorata*.

Limestone Rocks

The limestone rocks, which are such a striking feature of the Asian landscape, bear a very different vegetation from that of the surrounding forest. This vegetation contains a calciphilous, or chalk-loving, element, as well as a cremnophilous, or cliff-dwelling element. The small trees and shrubs that dominate this vegetation can mainly be classed in the latter category. It has been stated that dipterocarps shun chalk, and it is true that they are absent from most of the limestone hills. This is probably because xerophyllous, adaptable dipterocarps have lacked access to them. On the limestone hills of Langkawi, Perlis, and the north of Kedah in Peninsular Malaysia, several dipterocarps, that have adapted and that withstand seasonal desiccation in territories to the north, have established themselves. These are *Hopea ferrea*, *Pentacame siamensis*, *Shorea talura*, and *Vatica cinerea*. All these species are also the inhabitants of the semi-evergreen or moist deciduous forests of Burma and Thailand. All these species occur also on soils other than limestone, but *H. ferrea* seems to show a distinct preference for limestone, or perhaps it would be more correct to say that it is unable to maintain itself in competition with other species except on limestone.

BRIS Formations

This is the name adopted to describe a type of vegetation that is occasionally found on the coasts of Borneo, Sumatra, the Malay Peninsula, and the intervening islands. BRIS is the abbreviation for Beach Ridges Interspersed with Swales. These BRIS formations are stretches of white sand, deposited by a combination of river and tidal action. They are most common immediately behind the beaches, but the older formations may occur inland as islands among more recent and dissimilar alluvial deposits. The vegetation of these areas is typically sparse grassland, interspersed with shrubs, among which *Rhodomyrtus tomentosa* is usually conspicuous, and solitary or grouped, small, frequently gnarled, dwarfed trees. Two species of dipterocarps have been reported to grow in such sandy formation. These include *Shorea talura* and *Cotylelobium* sp.

The Family of Dipterocarps

The family of dipterocarps contains 16 genera and 580 species. The genera have further sections and subsections. Details up to the section level are given in **Table 2**, which shows that there is a largely discrete distribution of this family in the neotropics, Africa, and Asia.

Non-Timber Products

Production of oleoresins is characteristic of most members of the family. The volatile portion consists mainly of sesquiterpenes that are used for caulking and varnish. Also, the fruits of many *Shorea* and sometimes *Dryobalanops* are boiled as vegetables. The fruits of *Shorea* section *Pachycarpae* and some others are rich in fat. The seeds contain up to 70% fat, which is similar to cocoa butter but has a higher melting point and is favored for manufacturing

chocolates and cosmetics. Camphor is another product from dipterocarps especially from *Dryobalanops*, which is used as incense (*see* **Non-wood Products**: Resins, Latex and Palm Oil).

Diversity and Conservation in Dipterocarps

Chromosome number is one of the genetic mechanisms responsible for diversification at intraspecific and specific levels. It has been found that dipterocarp species and genera are remarkably uniform with respect to chromosome number. Polyploid species are known only in two genera, namely *Hopea* and *Shorea*, while aneuploidy has been observed only in the genera *Anisoptera* and *Dipterocarpus*. These two ploidy levels assist in diversification at the species level. Breeding systems is another primary determinant of the pattern of genetic diversity in natural populations of dipterocarps. Studies indicate that in this family self-incompatibility exists in a large number of the species and hence most of these species are outcrossers. This mechanism provides the populations to have a high level of genetic diversity (*see* **Genetics and Genetic Resources**: Genetic Systems of Forest Trees).

Concerning conservation, as exploitation of these species for timber has been going on at a rapid phase in the Asia-Pacific regions, national governments have come to the realization that conservation of samples of relatively intact forest is necessary for balanced land use. National parks and other forms of protected area are some of the most universally adopted mechanisms for conservation of the species in this family (*see* **Ecology**: Biological Impacts of Deforestation and Fragmentation).

Conclusion

As can be seen the dipterocarps form an intricate part of the natural forest system in the tropics. The family exhibits a wide variation of characteristics in its growth and occurrence over a range of habitats.

As a forest ecosystem, the dipterocarp forests are a habitat for hundreds of thousands of animal and plant species that form an intrinsic network of interactions. The question being asked all over the world is whether such a complex ecosystem can tolerate anthropogenic disturbances such as timber extraction. However, to date there is still no clear answer to the long-term effects of logging of such forest on species diversity and continued sustenance of such an ecosystem. There is an urgent need to quickly bridge these gaps in knowledge to ensure that this natural treasure so vital to the well being of our planet is conserved and sustainably used to ensure perpetuity of these valuable resources.

Eucalypts

R J E Wiltshire, University of Tasmania, Tasmania, Australia

Eucalypts and the Australian Vegetation

Eucalypts are remarkably prevalent in the woody vegetation of Australia, dominating an estimated 127 million ha of forest, comprising nearly all vegetation types in Australia (302 communities) and occurring as codominants in a further 30 communities, with the exceptions of rainforest, the vegetation of the central arid zone, and higher montane regions. This natural distribution includes a wide variety of habitats from sea level to the alpine treeline, from the tropics to below 43° S latitude. Although this natural distribution is almost exclusively confined to Australia (except for a handful of tropical species to the north), eucalypts have been introduced to more than 90 countries where they have a multitude of uses, including industrial plantations conservatively estimated at 9.5 million ha in area (*see* **Tree Breeding, Practices**: Genetic Improvement of Eucalypts).

The genus *Eucalyptus* (family Myrtaceae) was named in 1788 by Charles-Louis L'Heritier de Brutelle, from a specimen of *E. obliqua* collected in 1777. Since then over 700 species have been recognized, derived from 13 main evolutionary lineages. The current taxonomic status of the eucalypts is still debated, especially the inclusion of the bloodwoods (*Corymbia* and *Angophora*) within *Eucalyptus*, or as separate genera (*see* **Tree Breeding, Practices**: Genetic Improvement of Eucalypts).

Eucalypts are highly variable in form, ranging in habit from forest trees, generally of between 30 and 50 m in height, but in some species more than 70 m (*E. deglupta*, *E. diversicolor*, and *E. grandis*, with the tallest flowering plant in the world *E. regnans* approaching 100 m in height), to woodland trees 10–25 m high, largely single-stemmed but spreading, to mallees that are multistemmed from the ground level, usually less than 10 m in height, and to some eucalypts that grow as shrubs less than 1 m in height, such as the subalpine yellow gum *E. vernicosa*.

Classifications of Eucalypt Forests in Australia

Most classifications of Australian vegetation are derived from Specht's structural classification, based on the life form and height of each stratum and the foliage cover of the tallest stratum. Eucalypts are not a major component of the closed forests (tropical and temperate rainforests) that comprise 3% of the Australian forest, but do dominate an estimated 78% of the forested area in Australia (from the most recent estimates of the National Forest Inventory or NFI). The NFI classification includes four broad classes of eucalypt forest: tall, medium, and low eucalypt forest, and mallee (**Figure 1**).

Tall Eucalypt Forests (Tall Open Forests)

Tall eucalypt forests (tall open forests or wet sclerophyll forests in previous classification schemes) are those that exceed 30 m in height with a projected foliage cover of 30–70%. These forests occupy

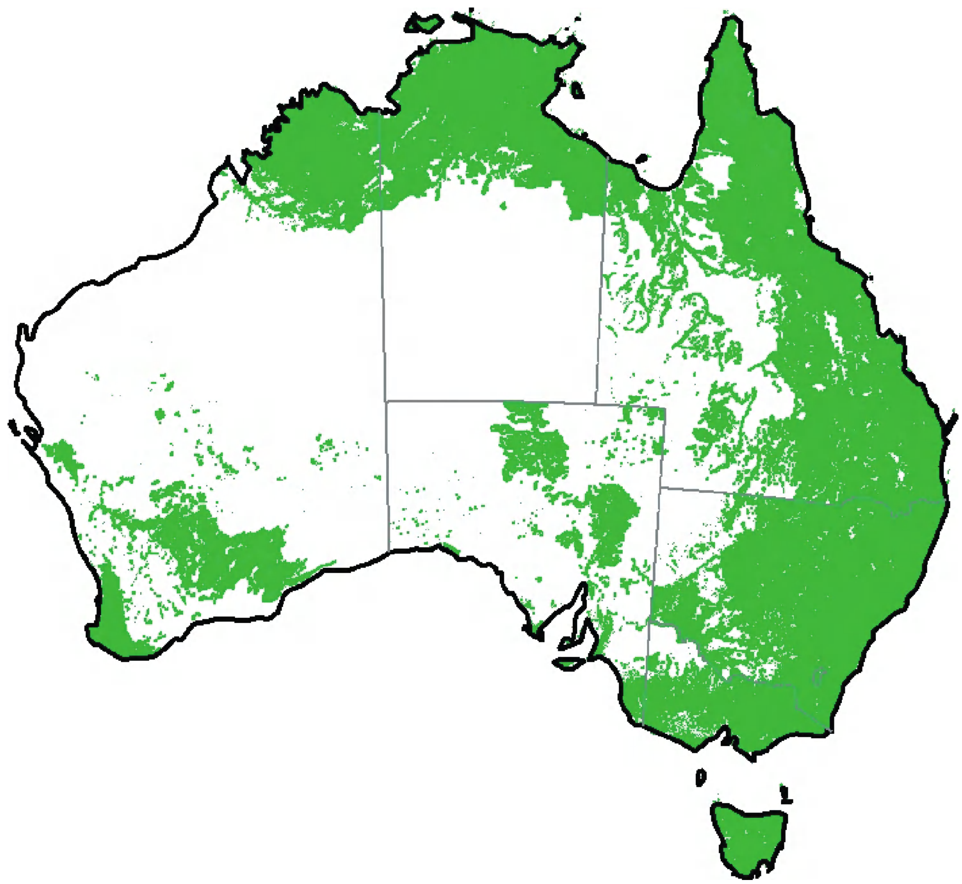

Figure 1 The distribution of eucalypt forest Australia (National Forest Inventory 2003).

8.7 million ha (5% of the total forest area) in Australia and can be extremely productive, with mean aboveground biomass estimates of 492 t ha^{-1} for *E. regnans*. One estimate of standing merchantable volume of 60-year-old unstocked, unthinned stands of *E. regnans* in Victoria was 839 m^3 ha^{-1}. These forests reach their greatest heights (>70 m) in areas of relatively high rainfall (>1000 mm year^{-1}) on soils of reasonable fertility in southeastern Australia (Victoria and Tasmania) and in the karri forests of southwestern Australia.

The understory vegetation in the southeastern tall forests is comprised of mesomorphic shade-tolerant trees such as *Bedfordia salicina* and *Olearia argophylla* (Asteraceae), *Pomaderris apetala* (Rhamnaceae), and some *Acacia* species (e.g., *A. dealbata* and *A. melanoxylon*). Beneath this layer, light is extremely limited and the vascular plants are restricted to tree ferns (*Cyathea* spp. and *Dicksonia antarctica*) and groundcover ferns (such as *Blechnum*, *Histiopteris*, and *Hypolepis*). The understory of the southwestern karri (*E. diversifolia*) forests lacks the tree ferns and the closed forest species, with the dominant understory species often more scleromorphic shrub species of the Rhamnaceae (*Acacia*); Casuarinaceae (*Allocasuarina*); Myrtaceae (*Agonis*); Proteaceae; (*Banksia*, *Persoonia*); Rutaceae; and Fabaceae.

These tall open forests are often comprised of a single cohort of eucalypts (**Figure 2**), recruited after a devastating fire. In an elegant model proposed by Gilbert in 1959, eucalypt tall forest can be viewed as a disclimax vegetation type, dependent on disturbance by fire within the lifespan of the dominant species (350 years). *Eucalyptus regnans* in southeastern Australia, for instance, is killed by wildfire but releases vast numbers of seed (perhaps more than 1 million ha^{-1}) into an ash-enriched seedbed devoid of competitor species, except for soil-stored seeds, such as *Acacia* species, and seed dispersed from adjacent unburnt areas. There is intense competition between individuals as the density decreases from a reported count of 494 000 seedlings ha^{-1} to 400 stems ha^{-1} at 40 years to as few as two trees ha^{-1} 350 years after fire. Seedling establishment is virtually impossible for eucalypts beneath the light-limited conditions of the dense canopy and is restricted to very shade-tolerant rainforest species. Consequently, there is a successional transition from the eucalypt dominants over an understory of short-lived (<100 years) *Acacia* species, to a forest of

Figure 2 Tall open forest (wet sclerophyll) with even-aged *Eucalyptus regnans* over *Acacia* spp. *Bedfordia*, and *Pomaderris*. Sandspit Reserve, Tasmania.

emergent eucalypts (perhaps 70 m in height) over a canopy of shade-tolerant rainforest species (such as *Nothofagus cunninghamii*) if fire is excluded from the community for more than 150 years. If 350 years elapse without fire, the eucalypts senesce and the community becomes a closed forest or cool temperate rainforest. In Tasmania, these transitional forests (**Figure 3**) are termed 'mixed forest' by foresters, to distinguish them from the politically sensitive 'cool temperate rainforest,' although environmental groups have countered with the term 'old-growth forests.' Therefore, it has become a largely political argument whether such forest should be classified as 'eucalypt with rainforest understory' or 'rainforest with eucalypt emergents,' while the reality is a transitional form between the eucalypt forest and rainforest.

Medium-Height Eucalypt Forests

Medium-height eucalypt forests are those ranging between 11 and 30 m in height. The NFI estimates there are 83 million ha of medium eucalypt forest, or 51% of the total forest cover. Most of these forests are woodlands (64%), where the crowns of the trees do not touch, the canopy is very open, and there is often a significant grassy understory, so that in the past they have often been described as 'savanna'. These forest types contain about 80% of all eucalypt species and occur in four main areas: (1) the warm temperate southwest; (2) a broad band across tropical northern Australia; (3) subtropical and warm temperate eastern Australia; and (4) cool temperate southern Australia. The NFI has classified these medium-height woodlands on the basis of the understory: tall, low, or grassy.

Medium-height woodlands with tall understories These communities extend across northern Australia and occur inland in the east and southeast of the continent. Depending on whether the forests are in the northern or temperate regions, the understory includes palms (*Livistona*) and cycads or sclerophyllous shrubs such as acacias, banksias, and casuarinas. In the temperate regions, the natural distribution of these forests has been severely reduced by clearing for agriculture and most only exist as remnant patches in an agricultural landscape. In southern Queensland, central New South Wales, and northern

Figure 3 'Mixed forest' or tall open forest *Eucalyptus regnans* over a rainforest understory. Tahune Forest Reserve, Tasmania.

Victoria, they occur in dry areas (400–600 mm annual rainfall) and are often referred to as box and ironbark woodlands.

Medium-height woodlands with low understories These communities have also been extensively cleared in the Western Australian wheatbelt, where the jarrah (*E. marginata*) forest gives way to *E. wandoo* (wandoo) that may be 12–18 m tall and *E. salmonophloia* (salmon gum) woodlands that may reach 30 m in areas that receive little more than 200–300 mm rainfall annually. In the east, *E. largiflorens* often dominates the areas bordering the floodplains of the Murray Darling basin. In addition to a sclerophyllous shrub understory, these woodlands often have a succulent saltbush (Chenopodiaceae) understory.

Medium-height woodlands with grassy understories The grassy understory woodlands have undergone considerable floristic change in many areas due to the combined effects of grazing by introduced animals, altered fire regimes, nutrient enrichment, and plant species introductions. The understory of some *E. melliodora* (yellow box) woodlands of the southern tablelands of New South Wales, for example, is now composed nearly entirely of species of Mediterranean origin, due to the intense grazing pressure.

About one-quarter of the medium-height forests have a dense canopy. Like their sparse-canopy (woodlands) counterparts, these forests have been classified by the NFI into three types depending on the height and nature of the understory.

Medium-height open forests with a tall sclerophyllous understory These forests occur where annual rainfall is between 600 and 1000 mm. Understory components tend to be similar to those in medium-height woodlands with a tall understory.

Medium-height open forests with a low understory This vegetation type is often called 'dry sclerophyll' to differentiate them from 'wet sclerophyll' or tall eucalypt forests. The 'dry sclerophyll' refers to the often xeromorphic leaf type of the understory species, by comparison with the broader, softer leaves of the taller forests. These forest types are also 'dry' in that they usually occur in areas receiving less than 600 mm of rain a year, and on poorer soils, and are widespread throughout temperate Australia, although small areas also occur in the tropics.

Medium-height open forests with a grassy understory Grassy understory may develop on more fertile soils. These types of forest occur predominantly in north-east New South Wales and eastern Queensland. Smaller areas also occur on soils derived from igneous substrates in Tasmania, on the floodplains of the Murray River (in the form of *E. camaldulensis* forests), and in tropical Australia.

Low Eucalypt Forests

22 million ha of forest, or 14% of total forest cover, is nonmallee eucalypt forest less than 10 m tall. Most of these forests occur in arid regions in association with *Acacia* species. Generally they contain a similar range of eucalypt species to that in adjacent medium-height forests, including *E. baxteri* in South Australia, *E. populnea* and *E. largiflorens* in western New South Wales, *E. populnea* in southern Queensland, and *E. alba*, *E. brevifolia*, *E. miniata*, and *E. tetradonta* in northern Queensland, the Northern Territory, and the Kimberley region of Western Australia. Low eucalypt forests also occur in the subalpine regions of New South Wales, Tasmania, and Victoria. The best known of these are the subalpine snow-gum forests of Tasmania and the Snowy Mountains in southeast Australia *(E. coccifera* and *E. pauciflora,* respectively).

Mallee

Mallee is a unique type of vegetation consisting of low-growing, multistemmed eucalypts generally 2–10 m tall, with a low canopy coverage. These even-sized stems arise from a large lignotuber, or mallee root, after the crown is killed by fire, drought, or herbivore damage. Over 100 species of eucalypt have a mallee form, with the greatest number occurring in Western Australia. Mallee forests have a wide distribution across the south of the continent (about 15 million ha or 9% of Australia's forests), primarily in regions with 250–400 mm of rain a year. South Australia has 40% of Australia's mallee forests. A further 32% are found in Western Australia and the remainder mostly occurs in southwest New South Wales and northwest Victoria. In more arid areas, mallee is usually replaced by acacias and at the upper rainfall limit by single-stemmed forms, sometimes of the same species. Mallee understories may include hummock grasses, sclerophyll shrubs, and semisucculent shrubs.

Ecological Processes Controlling Distribution

Nutrient Availability

The Australian continent is a very old landscape, produced by extensive erosion and weathering, with exposed portions of the Precambrian shield (600–400 million years ago) strongly influencing the western two-thirds of the continent. Due to tectonic stability, there has been little rejuvenating activity since the beginning of the Tertiary, about 60 million years ago, except volcanic activity during the Oligocene along the eastern and southeastern ranges, and glaciations in the southeast and Tasmania during the Pleistocene. Many of the parent materials are sedimentary and so have undergone one or more cycles of weathering and erosion. The smaller-size fractions of the soil, most closely associated with nutrient elements, are lost during these processes. Consequently, the soils in Australia are generally very low in nutrients, particularly phosphorus and nitrogen, but also sulfur and potassium, and the trace elements molybdenum, copper, zinc, boron, and manganese. The average P concentration in Australian soils is 0.03%, but can be as low as 0.003%, compared with a range of 0.04–0.09% for soils in North America (**Table 1**).

Table 1 Nutrient pools in some eucalypt ecosystems in Australia: chemical content in soil 0–100 cm depth

Annual rainfall (mm)	*Parent material*	*Eucalypt community*	*N ($g\,m^{-2}$)*	*P ($g\,m^{-2}$)*	*Ca ($g\,m^{-2}$)*	*Mg ($g\,m^{-2}$)*	*K ($g\,m^{-2}$)*

Reproduced, with permission, from Keith H (1997) Nutrient cycling in eucalypt ecosystems. In: Williams JE and Woinarski JCZ (eds) *Eucalypt Ecology: Individuals to Ecosystems*, pp. 197–226. Cambridge, UK: Cambridge University Press.

Climate

The broad floristic and structural distribution of eucalypt communities is strongly influenced by climate but, within a climatic region, soil nutritional properties (nutrients, soil moisture, aeration, and root penetration) and topography (elevation, aspect, and slope) strongly influence local patterns of distribution of eucalypt species. These factors are interrelated. For example, on a uniform granitic parent material, the vegetation in wetter forests of southeastern Australia may vary from cool-temperate rainforest in gullies, to wet sclerophyll forest on southerly aspects, to dry sclerophyll forest on the warmer, drier northerly aspects. The deeper soils of the rainforest and wet sclerophyll forests may have twice the P content of the dry sclerophyll forest topsoil because of the warmer microclimate and increased weathering of the parent material, and greater erosion associated with more frequent fires.

Eucalypts and Fire

Fire is an integral part of the Australian environment and has played a pivotal role in shaping the forest ecosystems, greatly expanding the range of eucalypts across the continent. Even prior to the arrival of humans in Australia (an estimated 60 000 years ago), eucalypts were an extensive part of the forest vegetation, especially in the arid and semi-arid areas with a high incidence of lightning strikes. With extensive use of fire by the indigenous Australians (for hunting and the creation of specific vegetation types), eucalypt forests have expanded further at the expense of other forest types, such as tropical rainforest, cool temperate rainforest, cypress pine (*Callitris* spp.), *Casuarina* spp., and araucarias.

The arrival of Europeans with their different attitudes to the use of fire have led to further changes to the Australian landscape, as farmers and graziers used fire to clear bush and stimulate grass regrowth; miners used fire to clear vegetation indiscriminately while prospecting; and foresters have used frequent, low-intensity fires for hazard reduction to protect timber resources. The use of fuel reduction burning regimes is currently widespread throughout Australia, not only by forestry agencies, but also by nature conservation bodies, local councils, and private property owners. However, the use of fire as a means of minimizing damage requires further sophistication, or wider application, as attested by recent (January 2003) catastrophic fires in which 500 homes were destroyed in the national capital, Canberra, and surrounding areas.

'Natural' fire regimes (although many are lit by humans) vary in different parts of Australia due to variation in climate, soil, and vegetation. In the seasonally wet northern savannas, less intense fires may occur every 1, 2 or 3 years, whereas in the wet southern forests, severe fires may occur only after one, two, or three centuries. The intensity of the fire is a consequence of the nature and amount of fuel, although this is moderated by the weather, wind direction, and topography. Eucalypts produce large amounts of fuel that accumulates with time since the last fire until it reaches equilibrium. Those litter loads may be relatively low and consist largely of annual grasses in arid and semi-arid northern low eucalypt forests, or may accumulate to $40\,\mathrm{t\,ha^{-1}}$ of eucalypt leaves, bark, and litter in the wetter forests of southern Australia. Thus, the intensities of eucalypt fires can vary from $10\,\mathrm{kW\,m^{-1}}$ of fire edge in light litter fires to $100\,000\,\mathrm{kW\,m^{-1}}$ in firestorms – 25 times higher than the maximum for forest fire control. The temperatures in such extreme fires may reach 1000°C and, if the fuel load beneath them is high, the tree crowns will become involved in the flame front and explode as the essential oils are vaporized. Under the worst combination of dry, hot weather and high winds, such fires are uncontrollable and exacerbated by 'fire-spotting' many kilometers in advance of the fire-front as ribbons of eucalypt bark and glowing embers are caught in the high winds and updrafts caused by the fire.

Unsurprisingly, much of the Australian flora shows adaptive responses to fire. This includes stimulation to flower after fire, as in some orchid species and the grasstree genus *Xanthorrhoea*. A more common response to fire is seen in serotinous species of *Banksia*, *Casuarina/Allocasuarina*, and most species of *Eucalyptus*, to release seed stored in woody, aerial fruits in response to heat and/or desiccation. The postfire environment is optimal for germination, with litter, pathogens, herbivores, and competitors removed, and a readily available source of nutrients from the ash. In other genera, most notably the acacias, fire provides a heat shock that stimulates germination of soil-stored seed, and it has been shown that smoke provides a germination cue for many other species. Many eucalypts, and other genera, are also capable of regenerating vegetatively after fire, either from epicormic buds buried beneath bark in the stem tissue or from buds at the base of the stem (lignotubers). Gill has classified these adaptive responses to fire as 'seeders' that are killed by the fire, and 'sprouters' that regenerate vegetatively after fire. Most eucalypt species exercise both options of massive seed release after fire and sprouting from epicormic buds or lignotubers.

Eucalypt–Plant Interactions

Given the extent of eucalypt forest distribution, it is not surprising that a large proportion of the approximately 25 000 native vascular plant species of Australia are found in communities dominated by eucalypts. The species-richness of the 300 or so eucalypt communities varies widely from 93 species of vascular plants recorded in $128\,m^2$ in grassy woodlands in the Grampians, Victoria, to perhaps three vascular plant species in an equivalent area of mixed forest in Tasmania.

There is no real evidence of obligate associations between eucalypts and the associated plant species; indeed, evidence seems to suggest that eucalypt species have distributions that are largely independent of the distributions of the understory species at the larger scale. Nevertheless, canopy species can profoundly affect the distribution of the understory vegetation in terms of understory biomass, cover, or diversity, by either suppression or facilitation. The predominant effect of a eucalypt canopy in the Australian flora is one of suppression that produces a sparser, lower, less diverse but more xerophytic understory vegetation. These circular zones of altered growth around trees, or halos, are often conspicuous on aerial photographs and to the ground observer. Various biophysical factors have been implicated in these tree-understory patterns, including alteration in light, temperature, moisture, soil nutrient levels, litter, allelopathy, and subcanopy fauna. These effects are not always negative, however, for eucalypt canopy species may ameliorate the minimum and maximum temperatures for understory species and so reduce the combined effect of low temperature and high light intensity, i.e., cold-induced photoinhibition, on understory species, particularly in forests occurring at higher altitudes, such as *E. delegatensis* forests of Tasmania's Central Plateau.

Eucalypt–Fungal Interactions

Fungi are an integral part of all eucalypt ecosystems, with roles as pathogens, decomposers, and mycorrhizal symbionts, but relatively little is known about these important organisms. About 15 000 fungi are currently known from Australia, but based on estimates of the number of species of fungi to hosts in better-studied groups (about 10 : 1), about 250 000 species can be expected in Australia. Therefore, the 700 eucalypt species are likely to have 7000 species of associated fungi, although so far only 600 species of fungi have eucalypts recorded as the host of the type collection.

Major Fungal Parasites

Some fungal parasites of *Eucalyptus* have been studied due to their detrimental impact on forest productivity, especially species of *Phytophthora*, *Armillaria*, and canker fungi. *Phytophthora cinnamomi* is a soilborne oomycete that causes root rot and consequent dieback of many host species over a wide geographic and ecological range, but is particularly destructive in southern Australia since its recent introduction. In southwestern Australia alone, there may be as many as 2000 susceptible host species. Of the eucalypts, *Monocalyptus* species tend to be more susceptible, although the economically important plantation species *E. nitens* (*Symphyomyrtus*) is also highly susceptible. *Armillaria luteobubalina* is also a root-rotting fungus that causes widespread death and decline in native and exotic host species (including *Eucalyptus*), but is a basidiomycete and can persist in stumps and other dead wood, or form rhizomorphs and, with mycelial spread, can occupy areas of up to several hectares.

Cankers of dead bark are formed by a number of ascomycetes as the fungus invades the phloem tissue of twigs, branches, stems, and roots. Canker-causing fungi of eucalypts include species of *Botryosphaeria*, *Cytospora*, *Cryphonectria*, *Endothelia* and *Endothia*. Leaf blight fungi, such as *Mycosphaerella*, have also been studied because of their deleterious impact on forest productivity; mean damage by fungi can be as much as 30% of leaf area. Some fungi are specific to juvenile or adult foliage; some are restricted to one or other leaf surface (such as *M. molleriana* on *E. globulus*). The host-specificity of such parasitic fungal species varies widely, with *M. molleriana* found only on *Symphyomyrtus* whereas *M. cryptica* infects at least 24 species from both *Symphyomyrtus* and *Monocalyptus*. A single eucalypt leaf may be host to several fungal species with a range of interactions. A biotroph like *Ophiodothella longispora* may weaken the eucalypt host and allow the invasion of necrotrophs, such as *Fairmaniella leprosa* or *Macrohilum eucalypti*, leading to a succession of leaf decay species on a single leaf while it is still on the tree.

Mycorrhizal Fungi

Mutualistic associations between fungi and the roots of plants are widespread but, in the nutrient-impoverished soils of many eucalypt ecosystems, the increased supply of nutrients, particularly phosphorus and nitrogen, in exchange for carbohydrates, may be even more crucial to the host species. Fungi form both ectomycorrhizae and endomycorrhizae in association with eucalypts. The ectomycorrhizal habit occurs in several distinct lineages in three divisions of the Eumycota. In the basidiomycetes alone, some 470 epigeal species and 200 hypogeal species are putatively ectomycorrhizal with eucalypts, as are species of *Endogone* in the Zygomycota and *Elaphomyces*, *Muciturbo*, and *Tuber* in the Ascomycota. There is no strong evidence for specificity of ectomycorrhizal fungi among different supraspecific taxa of *Eucalyptus*.

The vesicular-arbuscular mycorrhizal (VAM) associations are a very common form of endomycorrhizal associations, possessed by 30–75% of species. Other endomycorrhizal associations, the ericoid mycorrhizae found in the Australian Epacridaceae, and the mycorrhizal fungi associated with orchids, are more specific to those groups. The VAM fungi (all zygomycetes) show low host-specificity and are also present in many ectomycorrhizal plants (13–24%), including *Eucalyptus*, where both types may be present on the one plant simultaneously, or they may vary in time or space.

An individual fungus may form mycorrhizae with one or several plants of the same or different taxa and, therefore, relationships can become complex. For example, nutrient transfer has been demonstrated between plants connected by mycorrhizal mycelium. A species of *Rhizoctonia* forms ectomycorrhizae with *Melaleuca uncinata* and also stimulates the germination of the orchid *Rhizanthella gardneri*, so it is possible that there is a transfer of nutrients from the *Melaleuca* to the orchid. In a natural ecosystem there will be many potential associations between mycorrhizal fungi and plants and the interactions certainly affect the distribution of hosts, their mycobionts, and other species at scales that vary from the individual plant to the community level.

Eucalypts, Fungi, and Animals

Mycophagy (fungus consumption) is another crucial and complex part of eucalypt forest ecosystems. Fungi comprise part of the diet of at least 37 species of Australian mammals, and are an important source of food for bettongs (*Bettongia*) and potoroos (*Potorous*) in eucalypt forest in eastern and western Australia. At least 100 species of fungi are consumed from unrelated groups in the Ascomycota, Basidiomycota, and Zygomycota; most are hypogeal (below-ground), putatively ectomycorrhizal, and dependent on mammals for spore dispersal. Sporocarp production may be linked to fire in eucalypt forests to enhance spore dispersal of ectomycorrhizal fungi by bettongs at the height of seedling recruitment (following fire). Invertebrates such as mites, collembolans, and earthworms may also be important in dispersal of fungal propagules, especially in dry climates. Macrofungi provide food and habitat for a great diversity of invertebrates, including nematodes, collembolans, mites, earwigs, millipedes, slugs, snails, moths, flies, and beetles. Some species are primary fungivores but other relationships are more complex. The ambrosia fungi in the Ascomycota, for example, are mutualistically associated with some wood-boring Coleoptera (ambrosia beetles in the Lymexelidae, Platypodidae, and Scolytinae in Australia) that attack living eucalypt trees. The ambrosia fungi cause soft rot and reduce the strength of wood, and form specialized structures and mycelium on the walls of tunnels made by the beetles. Adults and larvae feed not on the wood, but on the fungi, which are transmitted to new sites as a yeast-like single-cell state in specialized organs (mycetangia). Again, the relationships between the fungi, the host plants, and the animals are often complex and undoubtedly pivotal in shaping the eucalypt communities.

Reproductive Strategies in Eucalypts

Eucalypts generally produce large numbers of flowers, with conspicuous anthers attracting pollinators. There is extensive variation in floral traits, such as: inflorescence structure (bud number and arrangement); flower size (from 3 mm in diameter in *E. diversicolor* to 40 mm in *E. macrocarpa*); filament color and nectar production; and breeding system. The eucalypt inflorescences are produced from the current season's shoots in the outer crown, usually in groups of 3, 7, 11, 15, or more buds, that may take several months to 2 years to mature. At anthesis, the covering operculum (fused calyx and/or corolla) is shed to reveal the filaments unfolding from the outside whorl. Eucalypts are protandrous and, although the pollen is viable and available to pollinators at this stage, the stigma remains dry and unreceptive for 2–14 days after anthesis, depending on the species. Epidermal cells lining the hypanthium produce nectar from early in anthesis. The base of the ovary is divided into two or, more usually, three or four locules, with vertical rows of sterile ovulodes above fertile ovules borne on a placenta in each locule. Fertilization of the ovules occurs several days (5 in *E. regnans*, 10 in *E. woodwardii*) after the pollen grains germinate at the stigmatic surface and the pollen tubes grow down the transmitting tissue of the style.

After fertilization, the seed develops within the locules in a woody capsule. In addition to the viable seed, mature fruits also contain inviable seed (abnormal or unfertilized ovules) and chaff (the sterile ovulodes). The mean number of viable seed per capsule varies between species, individuals and seasons; the relatively large *E. globulus* capsules average 20 viable seeds per capsule (up to 100), but the average number of viable seeds in smaller capsules may be only 1–5 per capsule.

Flowering Phenology and Pollination

The majority of eucalypts produce small white or cream flowers grouped into large inflorescences, which are visited primarily by insects, a range of birds, and bats. Others develop fewer larger, colored flowers that are especially attractive to birds. Many temperate forest and woodland eucalypts rely on opportunist pollination, primarily by a diverse insect fauna, with patchy bird and mammal pollination. In contrast, many mallees and tropical woodland eucalypts appear to be adapted to pollination by nectar-seeking birds or mammals.

Specialization and coevolution with one type of pollinator (insect, bird, or mammal) undoubtedly has consequences for pollen-dispersal distances (and outcrossing rates), and flowering intensity and phenology. For example, in bird-specialist eucalypts with relatively low flowering intensity, visitors are encouraged to move between trees. Such a strategy may be associated with eucalypts with clumped, patchy, or disjunct distributions. However, a universal strategy appears to be production of many inflorescences, each presenting flowers at different phases, encouraging repeated visits by a variety of vectors.

Pollination by Insects

Insect pollinators include a wide range of taxa that depend on pollen and nectar in the adult stage, although the larval stages may be dependent on wood-boring (Buprestidae), insect predation (Ichneumonidae), or carrion-feeding (Calliphoridae). Some insect visitors to flowers are predatory or parasitic on other insects, and some forage for pollen, but the majority of species are seeking nectar. The effectiveness of these insect visitors as pollination vectors varies, however, with feeding strategies. For example, although many families of beetles contain anthophilous species, with scarab and jewel beetles identified as important pollinators of *E. leptecophylla* and *E. cylindriflora* in southwestern Australia, most beetles have gnawing mouthparts and are destructive feeders. Flies are also common and regular visitors to flowers for nectar, with half of the Australian dipteran families containing anthophilous species. Flies may be more effective pollination vectors than beetles, with larger flies carrying as many as 80 000 pollen grains. It has been estimated that medium to large calliphorid, syrphid, and tachinid flies are responsible for 11–23% of faunal pollen transfer in *E. regnans*.

The majority of Australian native bee species are largely dependent on the family Myrtaceae, including *Eucalyptus*, as their main source of floral nectar and pollen, and the medium and larger species may also be significant pollinators of tall open-forest species, such as *E. regnans*. The introduced honeybee (*Apis mellifera*) is also a common visitor to many eucalypt species (eucalypts are an important resource for the honey industry in Australia); however its effectiveness as a pollinator is not clear. Similarly, although ants are often present in eucalypt flowers, they are unlikely to be effective pollinators, and may even deter other pollinators.

Pollination by Birds

Birds may be more effective in cross-pollination than insects due to their higher energy requirements and higher rates of flower visitation. It has been estimated that more than half of the eucalypt species may be pollinated by nectar-seeking birds. Twenty-five species of honeyeaters, wattlebirds, spinebills, rosellas, lorikeets, pardalotes, and white-eyes are frequent visitors to eucalypt flowers in southern and southwestern Australia. It has been suggested that 26 of 102 Western Australia eucalypt species visited by nectivorous birds have adaptations not only to encourage bird pollination but also to limit insect access to stigmas. In these species, the flowers are large and aggregated into a ball; they are pink, red, or yellow rather than cream. This preponderance of bird pollination in south-western Australia is attributed to the large number of species with restricted distributions, climatic extremes that are often unfavorable to insect activity, but with long growing and flowering seasons providing nectar and pollen throughout the year.

Pollination by Mammals

A range of nectar- and pollen-feeding mammals visit, and may pollinate, eucalypts, including: the sugar glider (*Petaurus breviceps*); yellow-bellied glider (*P. australis*); feathertail glider (*Acrobates pygmaeus*); northern blossom-bat (*Macroglossus minimus*); Queensland blossom-bat (*Syconycteris australis*); gray-headed flying-fox (*Pteropus poliocephalus*); spectacled flying-fox (*P. conspicillatus*); red flying-fox (*P. scapulatus*), and black flying-fox (*P. alecto*). In northern Australia, *E. porrecta* and *E. confertiflora* appear to be adapted to the nocturnal visitations of the two latter species, with the majority of flowers opening after sunset and more nectar being produced after sunset. Flying-foxes appear to be important long-distance pollinators of eucalypts in a variety of eucalypts in tropical Australia, but also over considerable distances, with seasonal migration in southeastern, coastal eucalypts such as *E. tereticornis* and *E. paniculata,* and *E. maculata* in northern New South Wales.

Herbivory of Eucalypts

Eucalypts act as hosts to a wide variety of vertebrates and invertebrates, feeding not only on pollen and nectar, but on bark, foliage, flowers, seeds and exudates, as well as on each other. Because most eucalypts are evergreen (with the exception of some eucalypt species of the monsoon tropics) and retain their leaves for more than 1 year, there are quite marked differences in herbivory of eucalypts and deciduous, northern hemisphere forests. By comparison with short-lived leaves of winter-deciduous trees, leaves of evergreens generally have lower photosynthetic rates, lower nutrient contents, higher concentrations of secondary metabolites, and greater leaf thickness and specific mass. Therefore, eucalypts have foliage that is similar to that of conifers: of low nutritional quality but available over a long period. In addition, eucalypt leaves and many of the understory plants associated with them have high concentrations of lignin and carbon-based secondary metabolites, especially phenolics (including condensed and hydrolyzable tannins and a range of simpler phenol-based compounds) and terpenoids (essential oils). Collectively, these substances decrease the digestibility of proteins and cell-wall carbohydrates for vertebrate and invertebrate herbivores, although the significance of each is contentious. Some of the *Symphyomyrtus* species further reduce the digestibility of their foliage by producing cyanogenic glycosides.

For insects, the low concentrations of nitrogenous compounds and leaf toughness appear to be the most limiting factors for herbivores on eucalypts. Similarly, mammalian herbivores are limited by the availability of protein and energy in eucalypt forests. Because of the energetics of a eucalypt leaf diet, the majority of both invertebrate and vertebrate eucalypt folivores prefer young, actively growing foliage.

Herbivory by Insects

Insects have a great diversity of styles of herbivory on eucalypts: eating whole leaves, grazing on leaf surfaces, or mining their internal tissues; tunneling through bark, boring into or chewing wood; sucking sap from leaves, stems, bark, wood, or roots; and making galls. The insects occupying these niches on eucalypts differ from those in many other forest systems. For example, beetles dominate the leaf-chewing guild on eucalypts of temperate regions, whereas caterpillars dominate the leaf-chewing and mining guilds in the northern hemisphere. Similarly, psyllids are very common sap-sucking insects in eucalypt forests but aphids, which occupy the same niche in northern hemisphere forests, are totally absent. Beetles (Coleoptera, particularly the adult Christmas and other scarab beetles, Scarabaediae, and the chrysomelids, Chrysomelidae) and stick insects (Phasmatodea: Phasmatidae) can cause massive defoliation. The chrysomelid beetle, *Chrysophtharta bimaculata*, is one of the most notorious forest insect pests, attacking regrowth forests and plantations of *E. delegatensis*, *E. obliqua*, and *E. regnans*, from their earliest stages through to advanced stands, and can cause extensive defoliation. Other insects, usually caterpillars (such as the gum leaf skeletonizer, *Uraba lugens*) remove all the soft tissues from whole leaves, leaving a skeleton of the harder parts.

Psyllids or lerp insects (Psyllidae: Hemiptera) are one of the major groups of sapsucking insects found on eucalypts. The sedentary nymphs cover themselves with a starch shell (lerp) and feed by inserting their stylets into the leaf phloem. Although widespread, the psyllids apparently cause little damage at low densities, but at high densities whole leaves and canopies become necrotic and are shed prematurely, resulting in severe dieback. The white lace lerp (*Cardaspina albitextura*), for example, periodically causes severe defoliation and sometimes death of its host plants, *E. blakelyi* and *E. camaldulensis*, in south-eastern Australia.

Gall-forming insects (mostly wasps, but also flies and many psyllids) use the actively growing tissues of the eucalypt host to form protective layers that vary from simple deformations in leaf tissue to complex galls on virtually all plant parts. Wood-boring insects usually attack stressed or debilitated trees. Termites are the main wood-eating insects in eucalypts and are widespread in the tropical open woodlands. Termite invasion follows damage to the tree, usually by fire, and results in 'piping' that structurally weakens the tree and, following an intense fire, can indirectly cause mortality rates of 6–21% for some tropical open-forest eucalypt species.

Herbivory by Mammals

Many of the small arboreal marsupials and bats that feed on eucalypt nectar and pollen have been mentioned above. There are, however, many other species that eat insects, nectar, gums, and/or fruits, or any of the preceding combinations, such as the insectivorous *Antechinus* spp. There are a smaller number of leaf-eating marsupials, including: common ringtail possums (0.7–1 kg) that eat up to 50% mature eucalypt foliage; greater gliders (1–1.7 kg) that only eat young foliage; and koalas (5–13 kg) that eat *Eucalyptus* spp. leaves almost exclusively, and can survive on mostly mature foliage, when young foliage is unavailable. There are also intermediate feeders, such as the common and mountain brushtail possums (*Trichosurus* spp.) that do eat eucalypt leaves but supplement this diet with ground-story herbs and grasses, fruits, and insects. These arboreal leaf-eating mammals are relatively common in the eucalypt forests and woodlands of southeastern Australia, perhaps due to the more reliable production of young foliage, but uncommon or absent from the eucalypt forests of tropical northern Australia. There are also terrestrial mammalian herbivores in the eucalypt forests, feeding on eucalypt seedlings, roots, seeds, or other shrubs or groundcover plants or fungi. This includes the familiar marsupial kangaroos and wallabies (family Macropodidae), wombats (*Vombatus ursinus*), and bandicoots (family Peramelidae), but also placental granivorous rodents.

Impacts of Herbivory

Eucalypts are well adapted to cope with extensive defoliation by fire, drought, and herbivory, with leaf growth renewed from the naked buds in the leaf axils, from accessory buds in the leaf axils if the naked buds are damaged (as they often are), or from epicormic buds in the larger branches or the main stem of the tree if crown death is complete. In this way, most eucalypts can rapidly reestablish the leaf canopy in a single growing season. A few eucalypt species are less capable of resprouting, such as the tall ash species, *E. regnans* and *E. delegatensis* and, hence, are vulnerable to outbreaks of insect pests such as phasmatids. Death of mature eucalypts due to grazing by mammals such as koalas or common brushtail possums is usually associated with limited abundance of food trees due to clearing for agriculture or unusually high population numbers. However, grazing by brushtail possums and macropods may be important in excluding seedling regeneration by selective predation in some natural eucalypt communities and can pose serious problems for the establishment of eucalypt plantations. Strategies to reduce the impact of browsing on plantation species, such as *E. nitens*, have been tested, including: repellent sprays; coplanting with repellent species such as bitter lupins; different plantation sizes, shapes, and associated vegetation; but the principal preventive method remains the use of 1080 poison, which is currently a serious source of dispute between the forestry industry and environmental groups.

Conservation Status and Trends

The sustainable management of Australia's eucalypt forest ecosystems is a major challenge facing all sectors of Australian society. There have been dramatic changes to land use over the past two centuries since European settlement, with widespread vegetation clearance (perhaps 500 000 km^2 since 1788), grazing by introduced livestock, and consequent changes in hydrological and fire regimes affecting nearly all eucalypt forest ecosystems.

At the most fundamental level, the remaining eucalypt forests are the major source of unique terrestrial biodiversity. At more pragmatic levels, the wise management of eucalypt forests will be essential to addressing problems of greenhouse-gas pollution, degradation of water quality, widespread soil salinization and degradation that have resulted from forest clearance, poor agricultural practices of overgrazing and excessive tillage of fragile soils, and introduction of highly destructive pests.

Tenure of Eucalypt Forests

The 127 million ha of eucalypt forest in Australia are divided by tenure as follows: leasehold land 46%; private 24%; conservation reserves 13%; other crown land 8%; and multiple-use 7%.

However, the tenure over eucalypt forest varies significantly from state to state, as shown in **Table 2**. In the southeastern Australian states of Victoria and Tasmania, large proportions of the eucalypt forest (*c.* 35%) are in conservation areas with a similar proportion in multiple-use (timber-producing) forests, so that the majority of eucalypt forest is under government authority control. This is in contrast to the situation in the states with larger areas of less productive forests and woodlands (New South Wales, Queensland, South Australia, Western Australia, and the Northern Territory) where the majority of eucalypt forest is leasehold or privately owned.

As a consequence, the eucalypt forest types differ in the level of conservation, with the tall and medium open forests being relatively well reserved, in comparison to other structural types of eucalypt forest, such as the medium woodland eucalypt forests (6%) and low eucalypt forests (6% within conservation reserves), although 35% of eucalypt mallee forests are in conservation reserves.

Clearance of Eucalypt Forests

These differences in land tenure in different states and different forest ecosystems have implications for

Table 2 Tenure of eucalypt forest in Australian states ('000 ha)

	ACT	*NSW*	*NT*	*QLD*	*SA*	*TAS*	*VIC*	*WA*	*AUST*

the nature of land clearance, largely because land clearance is under state government, rather than Commonwealth government control. Estimates of forest clearance across Australia vary widely, but the magnitude of deforestation is massive by any scale; it is claimed that Australia has the sixth highest land-clearing rate in the world. During the period 1990–1995, the net woody vegetation loss was 863 090 ha, or 172 620 ha $year^{-1}$, although estimates of clearing are much higher. Most of this clearing is in Queensland and New South Wales (**Table 3**). In Queensland clearing rates averaged 289 000 ha $year^{-1}$ during 1990–1995, but accelerated to 340 000 ha $year^{-1}$ in 1995–1997 and 425 000 ha $year^{-1}$ in 1997–1999. The vast majority of clearing was for pasture (86%), some cropping (10%), and small areas for forestry, mining infrastructure, and settlement (4%). This acceleration may be attributable to a rush by landowners to clear land before effective control measures are in place. In spite of changes to Commonwealth environmental law brought about by the Environment Protection and Biodiversity Act 1999 (EPBCA), the Queensland government has been reluctant to apply controls under its own Vegetation Management Act 1999 in the absence of a Commonwealth contribution to a compensation fund to landholders potentially affected.

In recent years, a number of governments in Australia have brought in legislation in an attempt to regulate the clearing of native vegetation. However, the success of such legislative controls is questionable. In a 2002 audit of the effectiveness of the Department of Land and Water Conservation (DLWC) of New South Wales in regulating land clearance since the introduction of the Native Vegetation Conservation (NVC) Act 1997, the Auditor-General was condemnatory. Amongst the findings were:

1. There are currently no objectives or targets to measure progress in conserving native vegetation. Only one of a possible 22 regional management plans has been approved since the Act commenced.
2. The DLWC does not have an adequate information system and operational capacity to regulate native vegetation in NSW efficiently and effectively.
3. The likelihood of breaches of the NVC Act is high. The number of alleged breaches is steadily increasing.

Since the commencement of the NVC in 1998, the annual clearing approvals have not decreased (**Table 4**). It should be pointed out that these figures understate the area cleared because illegal clearing and clearing under exemption are not included. Illegal clearing is a significant issue, with reported breaches of the NVC increasing steadily to more than 200 per year, with only seven prosecutions commenced out of more than 700 alleged breaches from 1998 to April 2002.

There are many implications of the changes to the eucalypt forests across Australia. The clearing of native habitat is the single most threatening process for biodiversity loss and species extinction in Australia. The loss of species in Australia over the past two centuries due to human impact is conservatively estimated at 97 plants, 17 species of mammal, and three birds. However, several hundred vertebrates, several thousand plants, and an untold number of invertebrates are threatened with extinction due to loss of habitat. The extent and rate of deforestation in Queensland are comparable to that in Western Australia and Victoria in the past, which has given rise to significant salinity problems in these states, both in terms of dryland salinity and salinization of drinking and irrigation water. The release of carbon into the atmosphere by clearing operations also contributes significantly (13% in 1996) to Australia's greenhouse-gas emission, and there is a net loss of carbon dioxide equivalent to a ratio of 3 : 1 compared with that captured by vegetation acting as a sink. Although many of these consequences of the loss of eucalypt forests have been known for decades, and have been recognized by governments and addressed in recent policy initiatives, clearing of eucalypt forests continues.

Ficus spp. (and other important Moraceae)

J K Francis, Jardín Botánico Sur, San Juan, Puerto Rico, USA

Introduction

Moraceae is a family of mostly tropical trees containing 37 genera and about 1100 species. The most important genus, both in terms of numbers and benefit to humans, is *Ficus*. The family is characterized as having milky or sometimes watery latex. Leaves are mostly alternate, simple, entire, and pinnately veined. The flowers are unisexual but variable in form, as are the inflorescences. The fruits are commonly drupaceous, embedded in a fleshy receptacle forming a syncarp. The seeds are large without endosperm or small with endosperm. Although a few of the species produce timber, bark, and yield medicinal products, the greatest benefit to humans and animals is from the fruits that many produce. Except for a few of the fruit-producing species, three or four timber species, and a number of *Ficus* and other species planted for ornament and shade, members of the family are little planted or actively managed.

Taxonomy/Genetics

Note: The following treatment is based on taxonomy that predates the publication of the Angiosperm Phylogeny Group's higher-level classification of the angiosperms. Moraceae (used here in the narrow sense) is one of the ewosid families of Rosales.

Moraceae is part of the order Urticales, which is believed to have descended from a single ancestral line. Because of morphological and molecular similarity, it has been suggested that Moraceae, Celtidaceae, Cecropiaceae, and Urticaceae should be merged. The genera of Cecropiaceae appear under Moraceae in older references. Moraceae currently contains 37 genera and about 1100 species (**Table 1**).

Table 1 Details of genera and species within Moraceae

Genus	*No. sp.*	*Range*	*Life forms*

t, trees; s, shrubs; c, climbers; h, herbs.
Information source: Kubitzki K, Rohwer JG, and Bittrich V (1993) *The Families and Genera of Vascular Plants*, vol. 2. Berlin: Springer-Verlag.

The family Moraceae consists of trees with lesser numbers of shrubs, climbers, and herbs, most of which are tropical. All (except for the genus *Fatoua*) secrete milky (sometimes watery) latex from laticifers in parenchymatous tissues in stems and sometimes leaves. Leaves are alternate or rarely subopposite, most frequently simple, entire, and pinnately veined. Stipules are present, although often fused and forming a cap over the bud. Inflorescences take various forms. Flowers are unisexual, often four-merous. Plants may be monoecious or dioecious. Although some species have dry fruits, most have drupaceous or achene fruits embedded in fleshy receptacles. The family is further divided into the tribes Moreae (*Morus*, *Broussonetia*, *Milicia*, *Maclura*, *Trophis*, *Streblus*, *Bleekrodea*, and *Fatoua*), which have 'urticaceous' stamens; tribe Artocarpeae (*Artocarpus*, *Paratocarpus*, *Triculia*, *Prainea*, *Hullettia*, *Antiaropsis*, *Sparattosyce*, *Batocarpus*, *Bagassa*, *Sorocea*, *Clarisia*, and *Poulsenia*), with generally unisexual inflorescences and seeds almost without endosperm; tribe Castilleae (*Perebea*, *Maquira*, *Castilla*, *Helicostylis*, *Pseudolmedia*, *Naucleopsis*, *Antiaris*, and *Mesogyne*), with spontaneous abscission of branches; tribe Dorstenieae (*Utsetela*, *Bosqueiopsis*, *Helianthostylis*, *Trymatococcus*, *Brosimum*, *Trilepisium*, *Scyposyce*, and *Dorstenia*) usually with uncinate hairs; and tribe Ficeae (*Ficus*), which have syconia enclosing the flowers.

The family follows various growth models. In Troll's model the architecture is built by the continual superposition of plagiotropic branches, each division alternating between main-line axis and determinate branch, and is followed by *Milicia excelsa*, in Rauh's model, a monopodial trunk grows rhythmically and develops tiers of branches and the branches are morphologically identical to the trunk, is exemplified by *Artocarpus heterophyllus*, *Ficus aurea*, and *Musanga cercropoides*. The architecture in Cook's model results when a monopodial trunk with spiral or decussate phyllotaxis adds branches phylomorphically. *Castilla* follows this model. Roux's model, followed by *Antiaris welwitschii*, *Milicia regia*, and *Perebea guianensis*, occurs when a monopodial orthotropic trunk meristem grows continuously and has plagiotropic branches that are inserted continuously. *Dorstenia* and *F. theophrastoides* grow by Corner's model in which vegetative growth of a single aerial meristem produces one unbranched axis with lateral inflorescences.

Sex determination in *F. carica*, and probably other members of the subgenus *Ficus,* is different from the XX/XY method used in most other life forms, from mosses through humans. It is believed to be determined by two pairs of alleles located on one pair of homologous chromosomes. Eleven possible combinations of dominant and recessive genes result in plants that produce caprifigs (with separate staminate male flowers and female pistillate flowers), and plants with edible figs (with only female flowers).

Members of the family have $n = 12$, 13, 14, or more (sometimes much more) base numbers of chromosomes. Some notable genera are as follows: *Dorstenia* $2n = 24$–48; *Brosimum* $2n = 26$; *Broussonetia* $2n = 26$, 39; *Ficus* $2n = 26$; *Castilla* $2n = 28$, *Artocarpus* $2n = 28$–81; *Morus* $2n =$ mostly 28 with oddities up to 308.

Ecology

Species within the family Moraceae are tropical and subtropical, with a few exceptions such as *Maclura pomifera*, *Morus alba*, *M. rubra*, and *M. serrata*, which are warm temperate. Although a wide variety of soil, topographic, and precipitation conditions make a suitable habitat, most members of the family grow in humid, fertile conditions at low to middle elevations. They vary from highly intolerant of shade to shade tolerant. Most require full or at least partial sunlight to establish themselves, grow well, flower, and bear fruit. Many Moraceae species occur in primary remnant forests while others grow in secondary forests; a few are pioneer species. One group colonizing an unusual habitat are *Ficus* species that grow in the crowns of other trees, and on rocks, cliff faces, and masonry structures.

Form, structure, and life history are usually inexorably linked with the niche each species occupies in the forest ecosystem. *Dorstenia* are perennial herbs, subshrubs, or shrubs with rhizomes or tuberous subterranean parts. They usually grow in mesic habitat in the understory of primary and secondary forests. All, or nearly all, of the Moraceae rely on animals for seed dispersal. The form and presentation of the fruits and seeds help facilitate the particular disperser. *Morus* and the small-fruited figs, such as *F. citrifolia*, present their fruits near the ends of slender branches, ideal for small birds and fruit bats. Other species, such as *Artocarpus heterophyllus*, *F. racemosa*, and *F. heteropoda*, flower and fruit on their stems and major branches (cauliflory), where the fruits are more accessible to climbing mammals and large birds. Several figs bear fruits on pendulous branches near the ground (*F. capensis*, *F. ribes*, and *F. minahassae*), at least one at the base of the trunk (*F. auriculata*), and at least *F. geocarpa* and *F. cunia* produce fruits on underground branches (geocarpic fruiting) at a distance from the parent tree, where they are uprooted by deer, pigs, and other animals. Most species of the family have small seeds that easily pass through the gut of the dispersing animal. On the other hand, the *Artocarpus* spp. have large seeds that are mostly discarded by the dispersing animal as they consume the fruit pulp.

Most Moraceae species follow the common plant life history of seeds, being deposited by dispersers on soil or superficial organic horizons, germinating, and growing into adult plants. A significant part of the genus *Ficus* develops in a different way. The seeds, which are tiny, are deposited by birds or mammals through defecation in crotches or bark crevices of trees, or in irregularities in large rocks, cliff faces, or masonry structures. They germinate during rainy periods and grow slowly, developing short roots to attach themselves and absorb moisture and nutrients. After they have grown a few leaves they begin growing a vinelike root toward the earth. The process may take a few months to several years. After the long aerial root has reached the soil, it thickens and stiffens to become the plant's stem. Cutting the vine-size roots will not kill the epiphytic plant. Additional roots to the earth may be added and lateral roots begin to surround the host tree or interlace the stone surface. Some species remain vinelike but most become trees, often very large, smothering or sometimes strangling their hosts. Some species actually have modified roots that encircle their host's trunk for the purpose of strangling them. The aerial roots that become stems eventually coalesce to form a massive trunk.

The seedless variety of *Artocarpus altilis* (breadfruit) is totally dependent on humans for long-distance transport. Once established, it suckers from the roots, sometimes as much as 30 m away from the parent tree. The variety thus reproduces and competes successfully in secondary forests that develop after farm abandonment.

The flowers of *Ficus* are pollinated by tiny wasps. The female wasps normally pass from their birth syconia, carrying pollen from male flowers that are located near the apical pore of the syconia to syconia on other trees where they oviposit in short-styled pistillate flowers. Long-styled flowers are pollinated without being parasitized. The male wasps emerge first to inseminate the females before they emerge to repeat the process. The relationship is obligately mutualistic for both the wasps and the figs. Most species of fig have their own endemic wasps. For this reason, exotic *Ficus,* which leave their endemic pollinators behind, rarely produce seed and do not become invasive. An exception to the rule, *F. microcarpa*, has naturalized in several counties in southern Florida. Members of the Moreae tribe with 'urticaceous' stamens that propel pollen into the air are wind-pollinated. Research is needed to determine how pollination is accomplished in other genera.

Silviculture

The cultivation of *Ficus*, *Morus*, and *Artocarpus* species for fruit, *Ficus* species for potted ornamentals, and *Morus alba* for silkworm fodder is well documented and beyond the scope of this silviculture treatment. Methods used for the production and establishment of seedlings for yards, streets, parks, greenbelts, and shelterbelts are similar to those used in restoration and plantation forestry. The large-seeded species and some of the small-seeded species are started from seed in nursery beds or germination trays, usually without pregermination treatments. The seedlings are then grown as bare-root or containerized seedlings by conventional methods. At least the small-seeded *Ficus*, while easy to germinate on wet peat or blotter paper, are difficult and slow to develop into plantable seedlings. They are routinely propagated vegetatively by stem or root cuttings or by air or ground layering. Field planting is done by conventional procedures. While none of the Moraceae are planted in large monocultures for timber, a few, for example *Bagassa guianensis* and *Brosimum alicastrum*, have been tested or are being cultivated in small plantations and may possibly find a place in major plantation silviculture in the future.

An alternative to monoculture plantations is enrichment planting and treatments to promote natural reproduction. *Milicia excelsa* has been produced in nurseries and outplanted. Because it is fire-sensitive, it can only be employed in enrichment planting where complete fire protection is maintained. In harvested areas in Mozambique where large *M. excelsa* were left as seed trees, reproduction occurred in the openings.

Management of *Ficus* species in natural stands is an extremely important issue but little studied and reported. One of the reasons that it is so important is that the wild figs are an important source of food (fruit) for mammals and birds in native forests, and they are dependent on those animals as dispersers of their seeds. If the principal disperser of the seeds of a species is eliminated from an area by hunting or critical habitat destruction, the *Ficus* species must eventually decline. The impact is greater because in most tropical forests, wild figs occur in low densities. The *Ficus* species, which are of low timber value, are also likely to be eliminated during timber stand improvement treatments. While killing large *Ficus* trees is difficult by cutting and girdling, and moderately difficult with herbicides, they can be eliminated with a determined effort.

Enrichment planting of *Ficus* species will probably not be much different from the establishment of ornamental figs or enrichment planting of other forest species: providing an opening with enough light for vigor of newly planted seedlings and protection from weeds and encroaching overhead shade until the planted trees show promise of reaching a codominant position in the canopy. Except for the one previously cited for *M. excelsa*, reports of successful treatments to encourage natural regeneration are not known to the author. A logical treatment for ground-seeding species would be to create openings with scattered patches of exposed soil near fruit-bearing *Ficus* trees. Treatments to encourage epiphytic species may not be possible other than the protection of potential seed trees and their animal dispersers.

Utilization

Probably the most important species in an economic sense is *F. cerica* (common fig), a low, bushy tree or large shrub. It apparently originated in western Asia, was domesticated in ancient times, and spread to the Mediterranean and to most subtropical areas of the world. Today, annual fruit production is an estimated 1 million tonnes. The fruits are eaten raw, dried, preserved, candied, made into jam, used in baking, brewed into wine, and toasted for a coffee substitute. The wood is used to some extent for boxes, small articles, and fuel. There are at least 87 other *Ficus* species whose fruits and vegetative parts are eaten by people in various parts of the world. A number are used in herbal medicine. The tissue used depends on the ailment treated. Maladies most commonly treated are skin lesions, ulcers, and other skin problems, and diarrhea and dysentery. Although used locally for lumber, crafts, and fuel, *Ficus* species do not figure in international commerce for wood. This could change with wider use of medium-density wafer board and similar products. However, great benefit is derived from many *Ficus* species as ornamentals and shade trees. A few should be noted. *F. benjamina* (benjamin fig) is one of the most common large indoor potted plants for homes and institutions. It is also grown outdoors as a street, yard, and park tree in frost-free climates. If allowed to grow freely, it may reach 30 m in height and assumes a banyan-like habit.

Ficus elastica (Indian rubber tree) is used in much the same way indoors and becomes even larger in outdoor settings. Its tapped latex was once an important source of natural rubber, but has been almost completely replaced by latex tapped from *Hevea brasiliensis*. The banyan fig (*F. benghalensis*), although an interesting curiosity, eventually covers so much area by its expanding crowns and aerial roots that become trunks that it cannot be extensively used. *Ficus microcarpa*, *F. lyrata*, and *F. religiosa* are all beautiful and manageable figs planted in parks, estates, and along streets, and loved throughout the tropics. A large number of other *Ficus* species are occasionally planted as ornamental and shade trees. *Ficus pumila*, a climber that clings to surfaces by means of adventitious roots, is used like ivy (*Hedera helix*) to cover masonry walls.

Most of the *Ficus* species are relatively common but rarely abundant in tropical forests. However, many are important sources of food (mainly the fruits) for wildlife. Over 1200 species of vertebrates have been identified that eat the fruits of *Ficus* species. Some of the *Ficus* species in India and nearby countries are used as hosts in the cultivation of *Laccifer lacca* insects, the source of shellac and certain natural dyes. A number of the *Ficus* and several species of other related genera cause contact dermatitis, especially when persons come in contact with the latex.

Other important members of the Moraceae include *Artocarpus altilis*, an important food crop in the humid tropics; it occurs in two forms. Breadfruit produces abundant 1–2-kg starchy fruits eaten like potatoes. This large (to 30 m) tree produces no seeds but reproduces aggressively by root suckers. Breadnut (the seeded form) is grown for its large edible seeds. Although once used by Pacific Islanders for canoes and surf boards, the wood is little used today. A related species is the jackfruit, *A. heterophyllus*. It produces large (up to 20 kg) cauliflorous syncarps with sweet pulp eaten raw or cooked and large seeds that are roasted or boiled. The wood finds minor local uses for furniture and the extraction of a yellow dye. Another important genus is the mulberry (*Morus*) with important representatives white mulberry (*M. alba*), black mulberry (*M. nigra*), and American mulberry (*M. rubra*). All produce delicious fruits of minor importance and are used to some extent as ornamentals. White mulberry is the principal fodder grown for silkworms (*Bombyx mori*). American mulberry wood is used for fence posts, furniture, and caskets. *Morus serrata*, native of the Himalayan area, produces valuable wood used for furniture and carvings. Osage-orange (*Maclura pomifera*), a temperate representative of the family, has been used extensively for fence posts, cattle shade, windbreaks, and conservation plantings in North America. Its neotropical relative, *M. tinctoria*, is a timber tree producing wood used for flooring, and other uses requiring toughness, and is the source of a yellow-brown dye. Two African species, *Milicia excelsa* and *M. regia*, produce valuable timber often substituted for teak.

Some members of the genus *Brosimum* produce valuable wood used locally and traded internationally. The leaves and fruits are important food for domestic and wild animals during times of drought. The seeds are edible when cooked and the sap of some of the species is drunk as a tonic. The bark of *Broussonetia papyrifera*, native or planted through Southeast Asia and the Pacific, is used to make a high-quality bark cloth for clothes, mats, wall hangings, and funerary rites. *Antiaris toxicaria* of Africa through Australia is used in the same way to make cloth, and the sap is used as an arrow poison and to treat several medical conditions. *Castilla elastica* produces a copious latex that was once tapped to make natural rubber but is of low quality and has fallen into disuse. *Bagassa guianensis* and several species of the genera *Clarisia*, *Pseudolmedia*, and *Trophis* are harvested for timber. Finally, many lesser known members of the family are used in herbal medicine.

Mangroves

M Spalding, UNEP World Conservation Monitoring Centre, Cambridge, UK

Introduction

The term mangrove is used to define both a group of plants and also a community or habitat type in the coastal zone. Mangrove plants are trees or shrubs that normally live in the intertidal zone. Mangrove communities are those in which these plants predominate. Other terms for these communities include coastal woodland, intertidal forest, tidal forest, mangrove forest, mangrove swamp, and mangal. The word mangrove can be traced to the Portuguese word 'mangue' and the Spanish word 'mangle,' both of which are actually used in the description of the habitats, rather than the plants themselves, but still have been joined to the English word 'grove' to give the word mangrove. It has been suggested that the original Portuguese word has been adapted from a similar word used locally by the people of Senegal.

Mangrove Species

Mangrove plants are not a simple taxonomic group, but are largely defined by the ecological niche where they live. The simplest definition describes: 'a shrub or tree which normally grows in the intertidal zone and which has developed special adaptations in order to survive in this environment.' Using such a definition a broad range of species can be identified, coming from a number of different families. Although there is no consensus as to which species are, or are not, true mangroves, a core group of some 30–40 species is agreed by most authors. These 'core' species are the most important, both numerically and structurally, in almost all mangrove communities. **Table 1** provides a more complete list of mangrove species (of tree, shrub, fern, and palm), highlighting the core species.

All of these plants have adapted to a harsh environment, with regular inundation of the soil and highly varied salinities, often approaching hypersaline conditions. Soils may be shallow, but even where they are deep they are usually anaerobic within a few millimeters of the soil surface. Many mangrove species show one or more of a range of physiological, morphological, or life history adaptations in order to cope with these conditions.

Coping with Salt

All mangroves are able to exclude most of the salt in sea water from their xylem. It would appear that most species operate an ultrafiltration process at the endodermis of the roots. *Bruguiera, Lumnitzera, Rhizophora*, and *Sonneratia* species are highly efficient in this initial salt exclusion. Others, including *Aegialitis, Aegiceras*, and *Avicennia*, are less efficient and hence also actively secrete salt from their leaves. This is done metabolically, using special salt glands. Evaporation leaves salt crystals on the leaf surface which are often clearly visible (**Figure 1a**).

Anaerobic Soils

The morphological feature for which mangroves are best known is the development of aerial roots. These have developed in most mangrove species in order to cope with the need for atmospheric oxygen at the absorbing surfaces and the impossibility of obtaining such oxygen in an anaerobic and regularly inundated environment. Various types of roots are illustrated in **Figure 1**.

The stilt root, exemplified by *Rhizophora* (**Figure 1b**) consists of long branching structures that arch out away from the tree and may loop down to the soil and up again. Such stilt roots also occur in *Bruguiera* and *Ceriops* although in older specimens they fuse to the trunk as buttresses. They also occur sporadically in other species, including *Avicennia*.

A number of unrelated groups have developed structures known as pneumatophores which are simple upward extensions from the horizontal root into the air above. These are best developed in *Avicennia* and *Sonneratia* (**Figure 1c**), the former typically with narrow, pencil-like pneumatophores, the latter with secondary thickening so that they can become quite tall and conical.

Root knees are more rounded knobs which, like pneumatophores, extend upwards from the roots. In *Xylocarpus mekongensis* these are the result of localized secondary cambial growth, but in *Bruguiera* (**Figure 1d**) and *Ceriops* they are the result of a primary looping growth. In these species branching may also occur on these root knees.

Table 1 List of mangrove species

Family	*Species*[a]
Pteridaceae	*Acrostichum aureum*
	Acrostichum danaeifolium
	Acrostichum speciosum
Plumbaginaceae	*Aegialitis annulata*
	Aegialitis rotundifolia
Pellicieraceae	***Pelliciera rhizophorae***
Bombacaceae	*Camptostemon philippensis*
	Camptostemon schultzii
Sterculiaceae	*Heritiera fomes*
	Heritiera globosa
	Heritiera littoralis
Ebenaceae	*Diospyros ferrea*
Myrsinaceae	*Aegiceras corniculatum*
	Aegiceras floridum
Caesalpiniaceae	*Cynometra iripa*
	Mora oleifera
Combretaceae	***Conocarpus erectus***
	Laguncularia racemosa
	Lumnitzera littorea

[a] Species in bold typeface are those that are considered 'core' species.

Buttress roots are a common adaptation of many tropical trees, but in *Xylocarpus granatum* (**Figure 1e**) and to some degree in *Heritiera* such flangelike extensions of the trunk continue into plank roots which are vertically extended roots with a sinuous planklike form extending above the soil.

The surfaces of the aerial roots are amply covered with porous lenticels to enable gaseous exchange, while the internal structure of the roots is highly adapted, with large internal gas spaces, making up around 40% of the total root volume in some species. It is further widely accepted that there must be some form of ventilatory mechanism to aid gaseous exchange. A system of tidal suction is the probable mechanism in most species: during high tides, oxygen is used by the plant, while carbon dioxide is readily absorbed in the seawater, leading to reduced pressure within the roots. As the tide recedes and the lenticels open air is then sucked into the roots.

Seeds and Seedlings

Establishment of new mangrove plants in the unstable substrates and regular tidal washing of the mangrove environment presents a particular evolutionary challenge. All mangroves are dispersed by water and particular structures in the seed or the fruit are adapted to support flotation. In a number of groups a degree of vivipary is observed which is unusual in most plants other than mangrove species. The Rhizophoraceae have developed this to its fullest extent and here the embryo grows out of the seed coat and then out of the fruit while still attached to the parent plant, so that the propagule that is eventually released is actually a seedling rather than a seed (**Figure 1f**). In a number of other groups, including *Aegiceras, Avicennia, Nypa*, and *Pelliciera*, cryptovivipary exists in which the embryo emerges from the seed coat, but not the fruit, prior to abcission.

Figure 1 Mangrove adaptations. (a) Salt crystals secreted onto the surface of a leaf of *Avicennia*; (b) stilt roots of *Rhizophora*; (c) pneumatophores in *Sonneratia*; (d) root knees in *Bruguiera*; (e) plank roots in *Xylocarpus*; (f) *Rhizophora* propagule.

Longevity of seedlings is clearly important for many species. Most species are able to survive (float and remain viable) for over a month, while some *Avicennia* propagules have been shown to remain viable for over a year while in salt water.

Mangrove Productivity

Although mangroves often form quite low forests, under ideal conditions species have been recorded growing to heights of 50 or 60 m. Unlike most other forest types there are no characteristic understory species, with the forest floor dominated by aerial roots and mangrove saplings. The biomass is dominated by the mangrove species, but there is a considerable associated productivity arising both from epiphytes and from marine algae and bacteria in the intertidal areas and in the subtidal waterways. The associated food webs link directly with both marine and terrestrial ecosystems, including an important diversity of mollusks and crustaceans, but also terrestrial insects, birds, and some mammals.

Efforts to quantify biomass and productivity have been somewhat limited. Earlier estimates have suggested typical levels of net primary production of 18–34 $kg\,C\,ha^{-1}\,day^{-1}$, but more recent studies have shown that such figures may be considerable underestimates. Productivity in a 22-year-old *Rhizophora* stand in Malaysia was measured at 155 $kg\,C\,ha^{-1}\,day^{-1}$. Even the lower productivity figures show that mangroves are highly productive, considerably more so than adjacent marine ecosystems. It has been suggested that 40% of this net primary production is surplus to ecosystem requirements. About one-third of this surplus is exported into the adjacent marine ecosystems where it plays a critical role in supporting nearshore and offshore fisheries. The carbon storage by the world's mangrove forests is also considerable, both in the living biomass and in the accumulated sediments. This is increasingly being seen as an important carbon store in calculations of global carbon budgets.

Distribution and Biogeography

As a result of their restriction to intertidal areas, mangroves are limited in global extent (**Figure 2**), and are one of the most globally restricted of all forest types. **Figure 2** clearly shows the absolute limits to mangrove distribution. Mangroves are largely confined to the regions between 30° north and south of the equator, with notable extensions beyond this to the north in Bermuda (32°20′ N) and Japan (31°22′ N), and to the south in Australia (38°45′ S), New Zealand (38°03′ S), and South Africa (32°59′ S). Within these confines they are widely distributed, although their latitudinal development is restricted along the western coasts of the Americas and Africa. In the Pacific Ocean natural mangrove communities are limited to western areas, and they are absent from many Pacific islands.

In all, an estimated 114 countries and territories have mangroves. However, for many nations the total area is very small indeed, and the total global area of these forests is only 181 000 km^2. **Table 2**

Table 2 Total mangrove area by region

Region	*Area (km^2)*	*Proportion of global total*
South and Southeast Asia	75 173	41.5%
Australasia	18 789	10.4%
The Americas	49 096	27.1%
West Africa	27 995	15.5%
East Africa and the Middle East	10 024	5.5%
Total area	**181 077**	

Data calculated from best available national sources in Spalding MD, Blasco F, and Field CD (eds) (1997) *World Mangrove Atlas*. Okinawa, Japan: International Society for Mangrove Ecosystems.

Figure 2 The global distribution of mangrove forests. Data kindly provided by the UNEP World Conservation Monitoring Centre.

provides a summary of total mangrove areas by region.

Although these statistics suggest a relatively wide distribution, the distribution of individual species within these areas is clearly far more restricted, and **Figure 3** provides a plot of mangrove biodiversity patterns. A number of points of particular interest are clearly illustrated.

1. There is a distinct region of very high mangrove diversity, sometimes referred to as the 'diversity anomaly,' centered over Southeast Asia.
2. Away from this high diversity region mangroves generally show relatively even levels of low diversity, although there is smaller peak of diversity around southern Central America.
3. There is a wide area of the central and western Pacific Ocean from 120 to 160° W where mangroves do not occur.
4. Even in the area of highest mangrove diversity there is a very rapid latitudinal decline in species numbers away from the tropics.

One further observation, which is not fully illustrated in the figures, concerns the division of the global mangrove flora into two highly distinct subregions. An eastern group (sometimes known as the Indo-West Pacific) forms one vast and contiguous block stretching from the Red Sea and East Africa to the central Pacific. This group has a totally different species composition from the western group (the Atlantic East Pacific or Atlantic–Caribbean–East Pacific), which includes both Pacific and Atlantic shores of the Americas, the Caribbean, and the shores of West Africa.

A number of these patterns are explored more fully below.

Latitudinal Patterns

Mangroves limits are closely correlated with minimum temperature requirements. There is only one genus (*Avicennia*) that survives in environments where frosts may occur, but many species appear to have their latitudinal limits set by less extreme cold temperatures: air temperatures of 5°C appear inimical to most mangrove species. Sea surface temperatures may be more important than air temperatures for some species. The 24°C mean annual isotherm appears to be the minimum water temperature tolerated by mangroves in most areas, although this minimum is closer to 27°C on the north Atlantic coasts of America and Africa, and may be much lower in areas such as southern Japan. The relatively low-latitude limits to mangroves in Peru and Angola are probably related to the cold water currents which affect these coastlines.

Eastern and Western Floras

The division of mangroves into two distinct floras is almost complete at the species level: of the species listed in **Table 1**, three genera are shared between the two regions, but only one species. In addition to having distinctive floras, the overall niche-space occupied by the two floras differs, with western mangroves restricted to higher intertidal and downstream estuarine locations than those of the eastern group.

None of these differences can be related to contemporary ecology, and they are clearly of historical origin. Mangroves have a considerable known history, with the oldest of the modern taxa, *Nypa*, being recorded from the Cretaceous (69 million years BP) and *Pellicera* and *Rhizophora* dating back to the Eocene (30 million years BP). Information on the centers of origin and subsequent distribution patterns of mangroves is still unclear, and it is likely, given their disparate taxonomic origins, that mangroves evolved independently in a number of localities. Despite this, a number of authors have suggested that the majority of mangrove species have an eastern Tethys Sea origin with dispersal north and

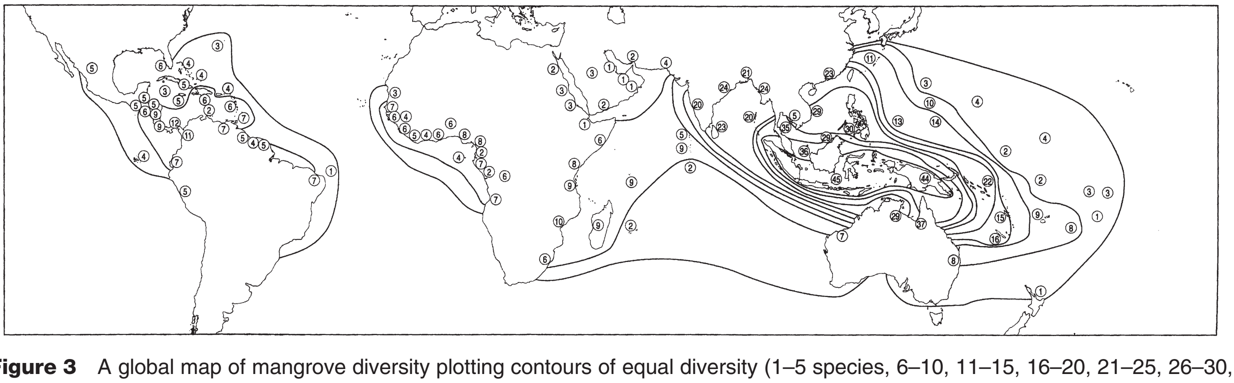

Figure 3 A global map of mangrove diversity plotting contours of equal diversity (1–5 species, 6–10, 11–15, 16–20, 21–25, 26–30, 31–35, 36–40, and 41–45). Reproduced with permission from Spalding MD (1998).

westwards (through a proto-Mediterranean) into the Atlantic and then via the Panama gap into the eastern Pacific. Whatever mechanisms may have operated, climatic conditions that were once suitable for a pan-Tethyan flora changed, and with the cooling and closure of the Mediterranean from the Tethys Sea the mangrove floras were separated. Divergence of the two communities then occurred through one or more of a number of mechanisms, including natural process of genetic drift and separation, possible extinction, and radiation. It is clear that the Atlantic Ocean and the isthmus of Panama now represent insurmountable barriers to mangrove dispersal; however, the closeness of the floras on either side of these barriers reflects the relatively short geological time since these barriers were put into place.

The Diversity Anomaly

Apart from having quite distinctive faunas, the eastern mangroves have a much greater diversity than the western group. Of the species listed in **Table 1**, only 13 are found in the western group, while 59 are found in the eastern group. This 'diversity anomaly' is reflected not only in regional maps, but also at local scales, with individual sites in the west typically having lower species counts than equivalent sites in the east. A number of theories have been propounded to explain this. It has been suggested, for example, that if most mangroves had originated in the eastern Tethys Sea the western flora may be depauperate simply as a result of being an immigrant flora. Alternatively the harsh environmental conditions during the Pleistocene, with significant temperature and sea level fluctuation, may have driven the extinction of a number of western mangroves. By contrast the Indo-West Pacific with its long and complex coastline is known to have had at least pockets of benign climatic conditions over geological timescales. These refugia may have allowed for further allopatric speciation events during periods of isolation from other areas, followed by periods of recombination with other areas as conditions ameliorated.

The relatively rapid tailing off of diversity westwards from Southeast Asia has been related to the relatively harsh climatic conditions which still prevail over much of this area, and the very large distances between more suitable localities for mangroves preventing recolonization. Similarly the gap of mangroves from the central and eastern Pacific is related to the very long distances between areas of suitable habitat. There is some evidence that mangroves may once have been more widespread in the Pacific, but if this is the case their disappearance from certain islands is probably explained by the climatic and eustatic changes of the Pleistocene.

Given the good dispersal ability of many mangrove species, distances must be very large indeed to prevent colonization, but it has also been suggested, given the relatively short time since the beginning of the last interglacial, that mangrove communities may currently be in a state of expansion.

Biodiversity Patterns at Finer Resolutions: Zonation and Succession

Numerous localized ecological factors influence the occurrence and growth patterns of mangroves. In addition to factors that affect the majority of plant species, such as water, nutrients, drainage, and soil type, significant further influence is produced by salinity and tidal influence. Considerable efforts have been made to define patterns of zonation in mangrove communities, and while such patterns do occur in many communities, the enormous variation in local conditions makes the preparation of simple summaries of 'typical' zonation patterns very difficult.

In many tidal areas the regular drying out of the soil, often coupled with patterns of restricted water circulation, or high rates of evaporation, serves to increase salinities to considerably higher levels than the surrounding seawater. This is particularly the case in areas of back mangrove where tidal flushing is less frequent and water circulation may be more restricted. It is further exacerbated in arid regions. In many areas this leads to the development of wide areas of stunted mangroves, or even bare salt pans where mangroves cannot grow. This situation is diminished or even reversed in areas where the freshwater input is more considerable, either from high rainfall or terrestrial runoff, or in some estuarine environments.

The tides also exert influences in other ways, most notably through inundation, but also through their influence on soils. Different mangrove species show quite different tolerances to inundation. Species such as *Avicennia* and *Rhizophora*, which are relatively tolerant of frequent and quite high tidal waters, typically form the most seaward zone of the mangrove system. Tides influence the soil through the delivery or removal of nutrients, and also the re-sorting of sediments. Typically finer sediments are found at higher locations in the tidal frame, while coarser sediments tend to be deposited or redistributed lower down. Once again, the complexity of interactions is highly varied between localities.

In many cases it is believed that mangrove communities may follow a succession and this has been linked to the process of terrestrial advancement (coastal progradation). It is suggested that the zonation patterns provide a model of such a succession, starting with the species more tolerant inundation and high salt levels. These are able to bind nutrients and sediments, gradually raising their position in the tidal frame such that they are then replaced by those species requiring slightly less saline and inundated conditions, and then by mangrove associates, and finally by nonmangrove species. Such a succession undoubtedly occurs in many areas, for example in parts of Southeast Asia where there is a high input of allochthonous material and where rates of coastal advancement have been recorded at 120–200 m $year^{-1}$. In other areas, however, the notion of mangroves 'creating land' is clearly not valid and mangroves show a range of responses to differing impacts of waves, climate, and sediments. In the Florida Everglades there is considerable evidence for the movement of mangrove communities both landwards and seawards, depending on sea level changes, and it may be more accurate to regard mangroves in many areas as opportunistic followers of changes in sedimentation and substrate or elevation.

Humans and Mangroves

Humans have lived in close contact with mangrove communities for millennia and in many cases have made considerable use of this association. Archaeological sites have been located that demonstrate human presence in mangrove areas in Venezuela dating back 5000–6000 years, and there is an Egyptian inscription dating back to the time of King Assa (3580–3536 BC) which mentions mangroves. Countries of the Middle East began a vigorous trade in mangrove timber from about the ninth century AD, largely for boat-building, exporting from outposts along the shores of East Africa. The European nations became involved in the utilization of mangrove bark as a source of tannins, particularly from the Americas from the sixteenth century.

The earliest record of mangrove protection dates to an edict from the King of Portugal in 1760 who restricted the cutting of mangroves for timber in Brazil unless their bark was also used for tannins. Despite such early concerns, the overexploitation of mangroves began in earnest towards the middle of the twentieth century and is continuing, and in many areas accelerating at the present time.

In many areas mangroves are highly productive and their location on the coastline places them in a zone where many other human activities have, until recently, been somewhat restricted. At the same time they often exist in close proximity to centers of human population, and can be relatively easily approached by sea or land. This makes their utilization inevitable in many areas, although the degree of sustainability of such use is highly variable.

Utilization of Mangroves

Timber and Wood Products

One of the commonest uses of mangroves is as a source of wood. Mangrove wood is often used for fuel, either directly or after conversion into charcoal. The former is widespread among artisanal communities worldwide, the latter is often for commercial purposes. Mangrove wood is also used for timber; the relatively small size of mangrove trees in many areas has meant that the primary usage of timber is the preparation of timber poles for fencing, housing construction, making of fish-traps, and other activities. Larger trees can be utilized for preparation of planking, and indeed some species have a very high value associated with their dense wood and resistance to rot, which is important for construction of houses and boats (both for local and industrial use). Further industrial use of mangrove wood is in the production of wood pulp for the paper industry, and chipboard. Large-scale commercial timber extraction or charcoal production has led to clearance of wide areas of mangroves worldwide, but there have also been some highly successful efforts to promote sustainable silvicultural practices. The Matang Mangrove Forest Reserve in Malaysia was established in 1906. With a 30-year rotation cycle this forest produces average yields of 17 tonnes ha^{-1} $year^{-1}$ of timber and fuelwood.

Fisheries

Mangroves and the associated channels that run between them are highly valuable areas of fish productivity. Numerous species inhabit mangrove areas and form the basis of artisanal and commercial fisheries, including crab, prawn, and mollusk fisheries. Mangrove areas are also widely used by a number of offshore fish species of commercial importance. These species, which include some highly profitable shrimp species, use mangrove areas for spawning or as a nursery ground, and loss of mangrove areas has severe negative impacts on fishery productivity. Cage-based fisheries have been established in many of the wider channels, and mangrove areas are widely used for the capture of juvenile prawns for transfer to aquaculture ponds. In recent years, wide areas of mangrove forest have been cut down in the development of intertidal aquaculture ponds, particularly in Southeast Asia.

Although this is a highly profitable industry, poor planning has led to the rapid and virtually irrevocable degradation of many of these ponds after only a few years. Rehabilitation of these lands is rarely undertaken, with the result that local communities lose a source of valuable natural resources, and the shrimp ponds move on to new areas.

Coastal Protection

The important role that mangroves play in the stabilization of coastal sediments and the reduction of coastal erosion has already been mentioned. This role is frequently overlooked until such time as the mangroves are removed and major storm events hit coastlines. The massive and devastating cyclones that regularly impact the coastline of the Bay of Bengal have drawn particular attention to these issues and in a number of localities around the globe there are now efforts to establish mangrove plantations precisely to stabilize sediments and reduce the impact of storm surges.

Alongside these three key areas of human importance, mangroves are regularly utilized for other purposes, a number of which are outlined in **Table 3**. It is highly difficult to place values on many of these uses and functions of mangroves. Apart from direct utilization of wood products, the link between particular products or functions and the mangrove communities which provide them is rarely made. Furthermore, for numerous communities the value in economic terms is greatly enhanced by the social value, providing a source of employment, protein, and protection for some of the world's poorest communities.

Overexploitation and Loss

Mention has already been made of the widespread loss of mangrove communities worldwide. Apart from conversion into aquaculture ponds, much of this is related to land reclamation activities for agriculture and for urban and industrial development, and large areas have also been severely degraded or removed by commercial timber companies or through overexploitation by local communities. Some further degradation or loss has been related to human-induced changes to the water regime (including upstream dams leading to reductions in sedimentation at river mouths), pollution (mangroves are particularly sensitive to oil spills), and conversion into salt pans for industrial salt production. Accurate figures for the global extent of mangrove loss are unavailable, but it is generally agreed that between 30% and 50% of the world's original mangrove cover has already gone. Reliable statistics are available for a number of countries. In Southeast Asia, for example, the loss figures for four countries are:

- Malaysia: 12% from 1980 to 1990
- The Philippines: a 60% loss from 4000 km^2 originally to 1600 km^2 by the 1990s
- Thailand: a 55% loss from 3679 km^2 in 1961 to 1676 km^2 in 1996
- Vietnam: a 37% loss from 4000 km^2 originally to 2525 km^2 by the 1990s.

These figures alone suggest a total loss of some 4% of the current global total. The four countries concerned have certainly suffered significant loss of mangrove, but they are not alone.

Sea level rise associated with global climate change must also be considered as a significant threat to mangrove ecosystems. It is important to note that the impacts of proposed changes (most models predict rises in sea level of 30–100 cm by 2100) are relatively insignificant in some areas where high levels of sediment movement and deposition will counter such rises, or where other eustatic changes, such as those associated with tectonic movements, will remove or further enhance changing sea level effects. Furthermore, mangrove species and communities are highly

Table 3 Minor or regionally restricted uses of mangroves

Honey production	An important economic activity in some countries
Fodder	For cattle, camels, and goats, notably in India and Pakistan
Recreation	Walkways, boat-based tours, and other visiting facilities have been established for tourists and local communities in some areas, notably Australia, Bangladesh, and Trinidad
Thatch and matting	Primarily from the leaves of the mangrove palm *Nypa fruticans* in Southeast Asia and from introduced populations in West Africa
Tannin extraction	Formerly widespread, this activity has become less significant as synthetic products have become available
Traditional medicine	A wide array of secondary metabolites has been recorded from mangrove plants. Products are widely used in many traditional communities, and studies are showing important anti-viral properties as well as potential uses for insect control and protection from ultraviolet light
Food	*Nypa fruticans* is widely used for the production of sugar, alcohol, and vinegar. Fruits of *Avicennia, Kandelia*, and *Bruguiera* are used as a source of food in some countries

opportunistic and will colonize new areas with some rapidity. Sea level rise remains a problem, however, as mangrove communities in many areas may become squeezed out as sea level rise forces mangrove communities landwards, but human use prevents landward migration.

Protection and Plantation

Despite the massive losses that mangrove communities have gone through in the past decades there have also been concerted efforts to protect them in some areas, and the growing realization of their value has led to widespread efforts to utilize mangroves in a more sustainable manner, and in some places large areas of mangrove plantations have now been established.

Worldwide, there are currently over 1100 protected areas with mangroves managed for conservation purposes spread between 99 countries. These cover some 10% of the global total. Although this is a far higher proportion than for many other forest types, active protection is absent from many of these areas, and the remaining unprotected sites are probably more threatened than many other forest types because of their vulnerability to human exploitation.

Increasing recognition of the various values of mangrove forests is leading to the establishment of mangrove plantation or restoration projects in many countries: for coastal defense, as a source of fuel or timber products, for fisheries enhancement, or often for a combination of these benefits. Plantation and restoration has been most widespread in Asian countries, with over 2300 km^2 in Bangladesh, Pakistan, and Vietnam.

Although the total area of such plantations remains insignificant when compared to global mangrove losses, they represent an important new development. Active management for direct economic benefits in these and other mangrove areas is growing. The Matang Mangrove Reserve in Malaysia has been managed for 100 years. Studies have shown combined benefits arising from timber and fuelwood products (notably charcoal), but also from the large nearshore fishery (directly or indirectly providing employment for over 4000 people), from aquaculture on the mud flats below the mangroves, and from tourism.

It is rare that such holistic studies have been carried out. Often the human benefits provided by mangrove fall between several sectors of the economy – fisheries, forestry, tourism, and coastal protection – and their combined benefits are not realized. Improved assessment of these benefits will undoubtedly lead to much wider-scale protection and sustainable management for mangroves globally.

Southern Hemisphere Conifers

J C G Banks, Australian National University, Canberra, Australia

Introduction

The southern hemisphere is home to almost half of the world's conifers including a small number of tropical species that occur in both hemispheres

Table 1 World conifers, by hemispheres, families, genera and species

Taxon	World	Hemisphere

[a] Southern hemisphere genera: *Araucaria*, *Agathis*, *Wollemia*.
[b] Southern hemisphere genera: *Diselma*, *Fitzroya*, *Austrocedrus*.
[c] This family is represented by a single species, *Pinus merkusii*, in the southern hemisphere.
[d] Southern hemisphere genera: *Podocarpus sensu lato*, *Dacrydium*, *Phyllocladus*, *Lagostrobus*, *Saxegothaea*.
[e] The only genus of this family in the southern hemisphere is *Athrotaxis*.

(**Table 1**). All five conifer families are represented in both hemispheres with 40% of the genera south of the equator. The Cupressaceae is the most cosmopolitan of the families with 10 genera in each hemisphere, but with most species in the north. The Podocarpaceae occurs in all southern continents with significant numbers of species extending north of the equator in Africa, Southeast Asia, Central America, and the Caribbean. The Araucariaceae has a more restricted distribution found in Australasia, and north through the island chain to Malaysia, with one genus in South America. The Pinaceae and Taxodiaceae are centered in the northern hemisphere with only one and three species respectively found south of the equator. Further details on the ecology of the southern conifers is found in the reference texts. Many northern hemisphere conifers are today grown in the southern continents in plantations and/or as ornamental trees and shrubs in city parks and gardens. The major plantation species is *Pinus radiata* originating from California which supports major timber and paper industries, while other species include *P. elliottii*, *P. caribaea*, *P. patula*, and *P. pinaster*. Ecologically, these are pioneer species and when freed from their natural pests and diseases they are fast growing. Numerous ornamental cultivars, mostly from the Cupressaceae, are important components of the urban forests where they are planted for their decorative features by civic and private landholders.

Taxonomy

The focus here is on the three dominant southern families, Araucariaceae, Cupressaceae, and Podocarpaceae, with minor reference to Pinaceae and Taxodiaceae that are comprehensively covered in the article on the conifers of the northern hemisphere (*see* **Temperate and Mediterranean Forests**: Northern Coniferous Forests). The structure of the female cone can be used to recognize the southern families. In the Araucariaceae the female cone scales are spirally arranged with only one relatively large seed per cone scale to which it is fused in the genera *Araucaria* and *Agathis*, but free in *Wollemia*. In all three genera the cone disintegrates at maturity to release the seed. In Cupressaceae all the southern genera belong to the subfamily Callitroideae which has only one monospecific genus, *Tetraclinis articulata*, north of the equator. The cones in this subfamily are distinct possessing valvate scales in pairs or whorls of three; at maturity these open to release relatively small-winged seeds. In contrast the seed bearing cones in Podocarpaceae are variously reduced and in the extreme may consist of a single seed atop a fleshy, plumlike receptacle comprising the fused remnants of the cone, or with one or two seeds attached to the central axis of the 'cone.' This origin of this reduced cone was initially misidentified with the family allocated to the Taxaceae, the yews.

Araucariaceae: The Araucarias and Kauri and Wollemi Pines

The Araucariaceae consists of three distinct genera, *Araucaria*, *Agathis*, and *Wollemia*, found in an island arc from Malaysia to New Zealand and including eastern Australia with *Araucaria* extending to South America (**Figure 1**). Species occur in tropical to warm temperate rainforests in coastal to montane environments. Rainforest species are regarded as postcyclone pioneers possessing rapid growth and apical dominance. They overtop the broadleaf rainforest as emergents with the tallest species *Araucaria klinkii*, klinki pine (**Figure 2**), reaching 70 m at maturity. It is found in tropical hill rainforests in New Guinea.

Araucaria: The Araucarias

The genus *Araucaria* consists of about 19 species, two in South America and two in eastern Australia with the remainder in Oceania along the island arc from Norfolk Island to New Caledonia where several

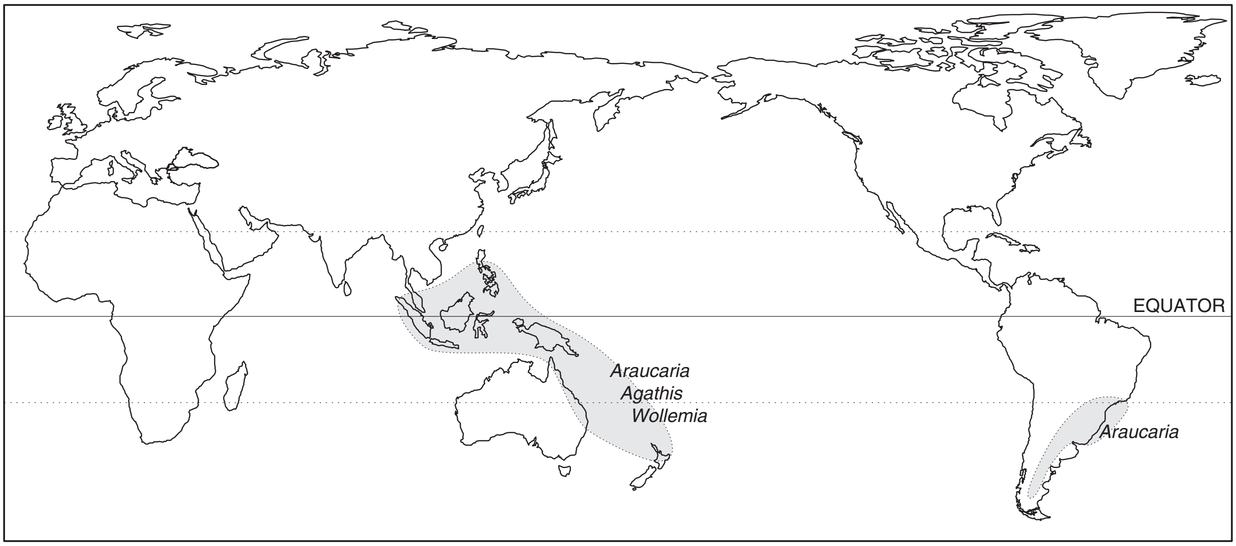

Figure 1 World distribution of Araucariaceae.

Figure 2 Klinki pine, *Araucaria klinkii*, rainforest emergents 70 m tall near Bulolo, Papua New Guinea.

species coexist on the Isle of Pines. The majority of species are maritime often occurring in pure coastline forest stands exposed to onshore salt-laden winds. To survive this hostile maritime environment the leaves are covered in a thick surface wax coat which protects them against salt damage. The significance of this feature was clearly illustrated when in the 1970s *Araucaria heterophylla*, the Norfolk Island pine, long established as a backdrop to Sydney's famous Bondi Beach, went into rapid decline. The primary cause was a new nonbiodegradable detergent that was polluting onshore winds, stripping the wax coat off the foliage and allowing salt to attack the exposed leaves.

A distinctive feature of the araucarias is that species can be readily recognized by their distinctive crown silhouettes. For example the Pacific island species *A. columnaris*, Cook's pine, has the peculiar habit of shedding its lower branches and then regenerating the lower crown from adventitious buds resulting in a dense narrow columnar crown which widens out towards the apex. Another is *A. heterophylla*, which maintains almost perfect crown symmetry with a simple two-order branching system (**Figure 3**). Similarly, the South American *A. angustifolia*, candelabra pine, and *A. araucana*, Chile pine, which both occur in pure forest stands, possess characteristic sillouettes. *Araucaria bidwillii*, the bunya bunya from eastern Australia, has the distinction of having large football-sized cones weighing 4–5 kg at maturity. *Araucaria cunninghamii*, hoop pine, is the most important araucaria plantation species providing a major softwood resource in southeast Queensland. This species exhibits some genetic variability both within and between geographic occurrences that extend from northern New South Wales to New Guinea. Tree breeding programs that began last century have significantly improved today's breeding stock for plantation use.

Figure 3 Norfolk Island pine, *Araucaria heterophylla*, showing its symmetrical crown trees at Twofold Bay, New South Wales.

Agathis: The Kauri Pines

The kauri pines are majestic trees with examples planted in urban parks in both hemispheres. The genus contains about 19 species that resemble angiosperms by having a wide-spreading crown atop massive primary branches arising from a distinct crown break. The bark is deciduous, a unique feature in the conifers with the exception of *Pinus bungeana*, the lace-bark pine from China. The bole attains massive proportions in old trees and exhibits little or no taper.

The most extensive and greatest kauri forests were in New Zealand where *Agathis australis*, known simply as kauri pine, dominated much of the temperate rainforests in the northern half of North Island. These were first seen by Capt. Cook in 1770 and noted as a potential source of spars with the first trial shipment in 1794. By 1820 timber was being exported from Whangaroa harbor. Exploitation of these forests in Northland and the Coramandel Peninsula was in full swing by the 1860s reaching its zenith by the turn of the century. Kauri timber is unsurpassed in the conifers. The wood is off-white to red and brown, resinous, straight grained, of great strength and durability and it was available in large sizes. On occasions timber was cut from buried logs, remnants of earlier forests destroyed in past volcanic eruptions. Some of these fossil logs have been dated to 30 000 years old, attesting to the timber's durability. Today only small stands remain, protected in reserves including one in Waipoura which has conserved the stand containing one of the world's largest living conifers, the Tane Mahuta or 'Lord of the Forest,' a 52-m tall tree estimated to be over 2000 years old. In eastern Australia, the three species of kauri pines are minor rainforest trees. Harvesting started in the nineteenth century and followed a similar cycle with the last cutting in the 1960s in the Ingham hinterland. Some kauri timber is still cut in small quantities in Malesia. As a plantation species in Queensland, *A. robusta*, the South Queensland kauri, was unsuccessful as it suffered severe insect defoliation when planted in pure stands.

An unusual commercial product from the kauri forests is the kauri gum, a resin that freely exudes from wounds accumulating on branches and in quantity over time beneath trees more than 1000 years old. Both fossil and fresh resin, called copal or dammar, were harvested in large quantities in New Zealand and Malesia around the end of the nineteenth century. Its principal uses were in varnishes and linoleum. Today small amounts, especially pieces with entrapped insects, are made into jewellery.

Wollemia: The Wollemi Pine

The discovery of this new monospecific genus in 1994 surprised the botanical world, as it had long been assumed that all of the world's conifers had been discovered and the major interest to conifer taxonomists was the ever-increasing number of ornamental cultivars entering horticulture. Its discovery, less than 200 km from Sydney, is described in Woodford's book devoted to the species. The scientific name given to this new taxon is *Wollemia nobilis* (**Figure 4**). The genus name is that of the national park in which it was found while the specific name alludes to its majestic form. Wollemi pine trees were found in the bottom of a deep sandstone canyon, one of many in this national park. Following intensive searching, only three stands have been located, consisting of fewer than 50 trees in total growing in small remnant stands of warm temperate rainforest that includes *Ceratopetalum apetalum*, coachwood. The pollen record shows the species to have been once widespread in southern Australia with occurrences in Antarctica and South America. Trees exceed 30 m in height and age estimates calculated from annual growth rings on a fallen tree indicates mature trees to be around 400 years old. One very distinctive feature of this new conifer is that it readily regenerates vegetatively from adventitious and basal buds. Only two widely distant conifers exhibit similar features: *Pinus canariensis*, Canary Island pine, and *Sequoia sempervirems*, Californian redwood.

Cupressaceae: The Cypress Pine Family

Most species of the southern Cupressaceae are components of the cool temperate rainforests in South America, New Zealand, and Tasmania with several extending to tropical rainforests in Malesia (**Figure 5**). Species from four genera have adapted to semi-arid environments comparable to several northern cypresses and junipers, such as *Cupressus arizonica*, the Arizonia cypress, and *Juniperus monosperma*, the one-seed juniper from North America's southwest. Compared with their counterparts in the northern hemisphere very few species of the cypress pines are sources of commercial timber and then in only limited quantities, and none has attracted horticultural interest as in *Chamaecyparis, Cupressus*, or *Thuja*. Several are monospecific genera representing relic tree genera persisting under present-day environments. One is *Diselma archeri*, known only from a few isolated mountaintops in western and central Tasmania. On Mount Dundas trees of this species reach 11 m in height and 2.0 m in girth with ages in excess of 500 years. Long-lived trees can be used to provide dated tree ring chronologies from which climate signatures can be

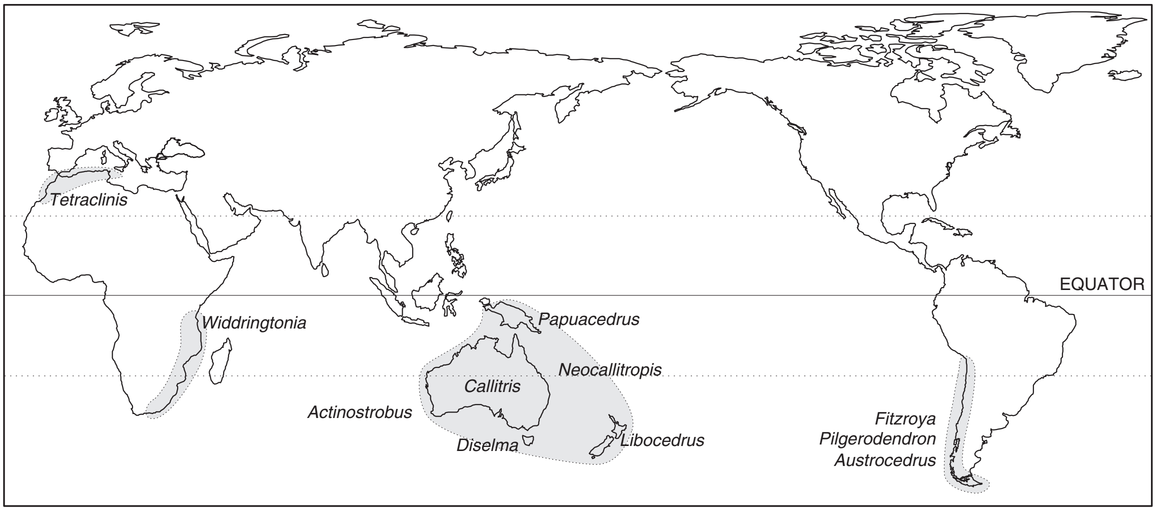

Figure 5 World distribution of Cupressaceae.

extracted for developing past climates. Pines and oaks have been used for this purpose in the northern hemisphere. In the south several Cupressaceae trees, and some from the Podocarpaceae, have proved useful for climate reconstruction. Chronologies of 1500 years have been extracted from *Fitzroya cupressiodes*, the Chilean alerce, trees that can be 50 m tall with a girth of 10 m, and similarly from *Austrocedrus chilensis*, Chilean cedar, a long-lived tree found in pure stands of xeric woodlands near the ecotone with the Patagonian steppe.

Callitris: The Australian Cypress Pines

Callitris and *Actinostrobus* in Australia and *Widdringtonia* in Africa have adapted to dry semi-arid woodlands. The most successful genus, *Callitris*, the Australian cypress pines, has three species in New Caledonia and about 12 in Australia. *Callitris intratropica*, the tropical cypress pine (**Figure 6**), is a slender tree up to 8 m tall, occasionally found in small isolated stands in the eucalypt woodlands across the summer rainfall zone of northern Australia. In contrast *C. glaucophylla*, the white cypress pine, is widely dispersed across southern Australia with major occurrences in the southeast where forests lie on the western slopes of New South Wales. It is a small to medium sized tree up to 18 m tall with a conical crown clothed in a variable but usually glaucous foliage. Interestingly, when first discovered, these forests were open woodlands of scattered white cypress pine and eucalypts from the ironbark, box, and red gum groups including *Eucalyptus crebra, E. microcarpa*, and *E. dealbata*. Following severe droughts in the late nineteenth century graziers abandoned extensive areas of these woodlands. Dense cypress regrowth then established which is the origin of today's forest stands in the Barrbine and Narrabri and Cobar districts (**Figure 7**). These are managed for their durable timber, providing about 5% of the State's total timber production.

Figure 7 Regrowth forest of white cypress pine, *Callitris glaucophylla*, Pilligra State Forest, Coonabarabran, New South Wales, Australia.

Podocarpaceae: Podocarps, Plum Pines, and Yellow Woods

The Podocarpaceae comprises seven tree and two shrub genera with *Podocarpus* as the largest genus. It is divided into eight sections; these are elevated to generic status by some botanists. All genera are represented in the Australasian–Oceanic region suggesting that the family originated in this area (**Figure 8**). In total about 130 species are recognized with the majority (70%) in southeast Asia and Australasia, 20% in Central and South America, and 10% in Africa. Almost all are rainforest trees, slow growing and fire-sensitive with tree species producing strong, even-grained, easy-to-work highly valued timbers. The implications of this are that once the slow-growing virgin trees are cut out there will be no secondary timber sources; moreover it is important to conserve areas as examples of the original forest.

Podocarpus

African species of *Podocarpus* belong to the section *Afrocarpus*, most of which are called 'yellow woods' on account of the color of the timber. These include *Podocarpus latifolius*, real yellow wood, a tree growing to 30 m in height and 2 m in girth which is widely distributed in southern Africa especially in the southeast. Others are *P. falcatus* called yellow wood, also from southern Africa, and *P. dawie*, a large timber tree up to 30 m tall, from the tropical rainforests in Central Africa. In the Australasian–Oceanic region *Podocarpus* is the most widely distributed genus, with species extending to Asia including the eastern Himalayas and the southern Japanese islands. *Podocarpus nagi*, one of the most widespread species found from Burma to Fiji, is a slender tree up to 20 m in height that was much sought after as a spar tree in the days of sails. In New Caledonia *P. sylvestris*, the false kauri, has been a valued source of high-quality timber, while *Podocarpus ustus* (a smaller tree) was recognized as late as 1957 to be parasitic on another conifer *Dacrydium taxoides*. This is the only known example of parasitism in the conifers.

In tropical New Guinea the podocarps *Podocarpus archboldii* and *P. papuanus* are found in the cooler tropical environments in high-altitude primary forests between 2000 and 3000 m above sea level. In South America two species, *P. curvifolius* and *P. nubigenus*, are found in the southern Andes. Australian tree species are all rainforest trees and never very common; *P. amarus* and *P. elatus*, the black and brown pines, are large trees up to 30 m tall in lowland rainforests. In New Zealand the podocarps have in the past been important timber trees. *Podocarpus dacrydioides*, the kahitatea, is a buttressed 30 m tree of wet swamp forests, and *P. spicatus*, the matai, of the hill forests at altitudes up to 600 m above sea level. Today temperate rainforests containing residual stands of these conifers are in conservation reserves. Several species have adapted to environments outside the rainforest where they occur as small trees or shrubs. In Australia *P. spinulus* occurs in coastal sand dune woodlands in the southeast, *P. drouynianus* is a shrub in the jarrah forest in the southwest growing on poor laterite soil dominated by *Eucalyptus marginata*, and *P. lawrencei* is a small tree

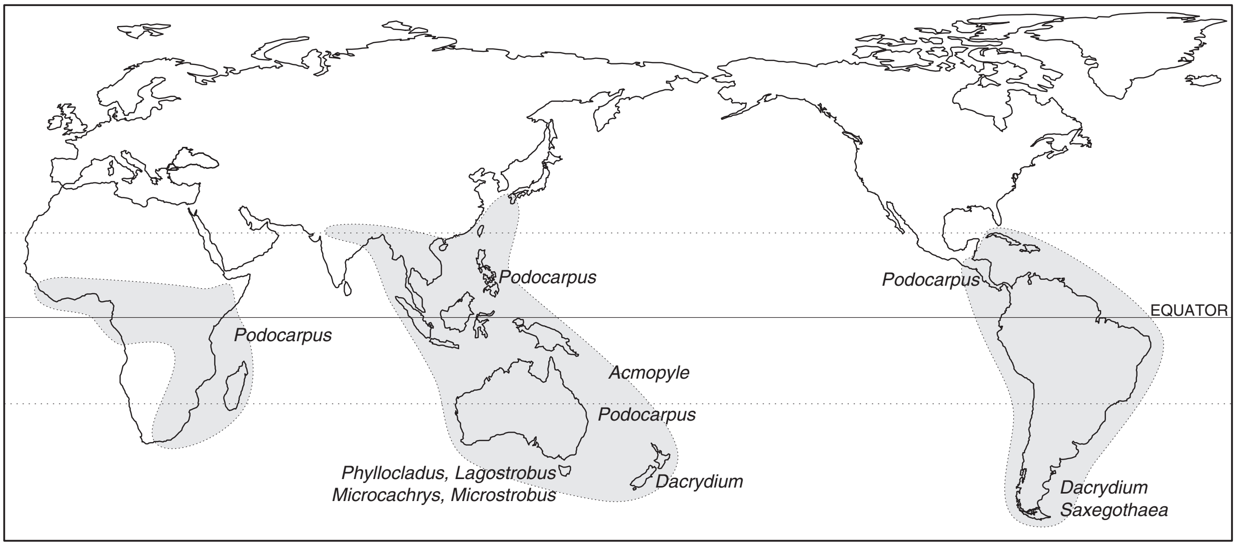

Figure 8 World distribution of Podocarpaceae.

in the subalpine forest and as scramblers in the alpine zone.

Dacrydium, Phyllocladus and *Lagostrobus*

Dacrydium, allied to *Podocarpus*, contains 20 species of which five occur in New Zealand, four in New Caledonia, and an equal number in the Indonesian island arc extending as far as Thailand. Two species are also found in New Guinea. The New Zealand species have been important elements in the virgin temperate rainforests with *Dacrydium cupressinum*, the rimu, a major timber species. It has scale leaves similar to those found in the cypress family but differing by being spirally arranged. One small species, *D. fonkii*, is found in Patagonia adding another link to the southern temperate rainforests.

The five species of *Phyllocladus* have one unique feature for the conifers: flattened branchlets, or cladodes, that take over the function of the leaves which are reduced to nonfunctional scales. *Phyllocladus asplenifolius*, the celery top pine, is a long-lived slender tree typically found in the tall wet sclerophyll forests in Tasmania. The cool temperate rainforest species *Lagostrobus franklinii*, the Huon pine, is a very slow growing long-lived species found in valley floors along stream lines and on Mt Read in the north-west. It challenges *Pinus longaeva*, the bristle cone pine, for being the oldest living conifer. The resin rich timber of Huon pine is highly prized for boatbuilding as it works easily and is durable in salt water.

Saxegothaea

This is a monospecific genus native to southern Patagonia in South America where it occurs in dense cool temperate rainforest. *Saxegothaea conspicua*, the Albert yew, is a small tree 10–12 m tall, and is regarded as a living link between *Araucaria* and *Podocarpus* having foliage resembling the former and wingless pollen and cones of the latter. It was discovered by the plant hunter William Lobb and introduced into cultivation in 1846.

Pinaceae and Taxodiaceae

Only one of the 250+ species in the family Pinaceae extends into the southern hemisphere. This is *Pinus merkusii*, the Tenasserim pine, which has natural occurrences in Burma, Cambodia, Vietnam, the Philippines, and Indonesia extending to the island of Sumatra where it is found in montane forests between 1000 and 1500 m above sea level in the Barsian Range just south of the equator. It grows in small groups of trees in the broadleaf forest and owes its survival to occasional dry-season spot fires to provide suitable regeneration gaps in the forest.

The genus *Athrotaxis* is an extreme geographic outlier of the redwood family, Taxodiaceae, reminding us that in past times this family was once widespread. Today three species are restricted to the cool montane temperate forests of Tasmania. *Athrotaxis selaginoides*, King William pine, is found in the Western Ranges and around Lake St Claire. It is a slow-growing tree, up to 30 m tall, typically occurring in small isolated stands. It is long-lived, persisting on sites that are rarely burnt by natural wildfires. At higher altitudes the smaller *A. selaginoides* is a component of the treeline forests. The third species, *A. laxifolia*, has intermediate morphology and ecologically lies between the other two species.

S E Ward, Mahogany for the Future, Puerto Rico

Introduction

The *Swietenia* genus ('true' or American mahoganies) consists of three closely related species (*S. humilis*, *S. mahagoni*, and *S. macrophylla*) whose largely allopatric natural distributions are concentrated in the seasonally dry, lowland neotropics. The latter two species have also been widely planted elsewhere, particularly in tropical Asia and Oceania. The long-established, sustained demand for mahogany timber is largely due to its high stability, durability, easy workability, and beauty. It is used principally in the manufacture of high-quality furniture, flooring, doors, window frames, and decorative veneers. *Swietenia macrophylla*, the only species still with commercially exploitable natural populations, is a massively buttressed, light-demanding canopy-emergent, reaching heights of up to 70 m and diameter at breast height (dbh) of 3.5 m. It occurs principally at low densities of 0.1–3.0 merchantable trees ha^{-1}, although higher densities may occur as a result of catastrophic disturbance, e.g., hurricanes, fires, and floods. The natural ranges of *S. humilis* and *S. mahagoni* are largely deforested; the ecology of these species in natural forest is little known, but is probably similar to that of *S. macrophylla*. All three species are subject to restrictions on international trade under Appendix II of the Convention on International Trade in Endangered Species (CITES), a consequence both of general deforestation and the unsustainable exploitation to which they have been subjected. Sustained production of *S. macrophylla* in natural forests is thought to be feasible. However, due to the species' requirement for high light and relatively low competition in its early years – conditions unlikely to be met under selective logging – it will require intensive methods. The establishment of *Swietenia* plantations has been inhibited by the attacks of mahogany shoot borers (*Hypsipyla* spp.). However, accumulated experience and growing experimental knowledge indicate that, with appropriate pest management methods, mahogany can be successfully grown in plantations.

Taxonomy and Genetics

American or true mahoganies (*Swietenia* spp.) are the most valuable species of the Meliaceae, a pantropical family which includes other high-quality timber trees such as Spanish cedar (*Cedrela odorata*), andiroba (*Carapa guinanensis*), the African mahoganies (*Lovoa*, *Entandrophragma*, *Khaya*), and the Asia-Pacific red cedars (*Toona* spp.) (all of the Swietenioideae subfamily), as well as less closely related species of value, e.g., neem (*Azadirachta indica*) and pride of India (*Melia azedarach*). The genus, named after the Austrian botanist Gerard von Swieten, consists of three largely allopatric species: *S. humilis* (dry-zone, Pacific, Pacific Coast, or Mexican mahogany), *S. macrophylla* (big-leaf, Brazilian or Honduras mahogany), and *S. mahagoni* (Cuban, Dominican, West Indian, or small-leaf mahogany) (**Figure 1**). The latter, restricted naturally to the Bahamas, Cuba, Jamaica, Hispaniola, and southern Florida, is the type species. The first to enter into international trade, its rapid depletion led quickly to commercial displacement by *S. macrophylla*. This has the largest natural distribution of the three, ranging from southern Mexico (23° N) to the southern Amazon of Bolivia and Brazil (18° S). *Swietenia humilis*, the least-known species, is restricted principally to the dry Pacific watersheds of Mesoamerica from the Mexican states of Durango and Sinaloa to northern Costa Rica; although sometimes referred to as Pacific Coast mahogany, it also occurs well inland. Within and outside their natural ranges, the species are generally known as caoba (in Spanish-speaking states except Bolivia, where the name mara is used), mahogany (English-speaking states), and mogno (Brazil), i.e., without the epithets found in the technical literature. Many other names are used locally by indigenous peoples.

Biologically, the three species are rather poorly defined; the current taxonomy is maintained essentially on the basis of the largely allopatric distribution described above, coupled with general morphological differences. The species are not easily distinguished on the basis of leaf and flower morphology, and appear to hybridize readily when in proximity (e.g., *S. humilis* and *S. macrophylla* where their ranges overlap in northeastern Costa Rica; *S. macrophylla* and *S. mahagoni* as exotics in Puerto Rico). Although both common-garden experiments and preliminary studies with DNA markers confirm that the species represent distinct genetic entities, it may be that *S. humilis* and *S. macrophylla*, at least, are no more genetically distinct than regional variants of other species that range over similarly diverse conditions, e.g., Pacific and Atlantic

Figure 1 (a) Mature *Swietenia humilis* tree, Comayagua, Honduras (courtesy of JP Cornelius); (b) *S. macrophylla* saplings in 3-year-old plantations, Quintana Roo, Mexico (courtesy of KE Wightman); (c) foliage of *S. mahagoni*, Puerto Rico. Courtesy of JP Cornelius.

Central American ecotypes of *Cedrela odorata* and *Cordia alliodora* (Boraginaceae). The taxonomic significance of observed interspecific variation in chromosome number is questionable because wide intraspecific variation in chromosome number has also been reported.

The little provenance work that has been carried out (*S. macrophylla* and *S. humilis* only) suggests substantial genetic variation between widely separated provenances, but little differentiation between populations at a more local scale (e.g., within the Yucatan peninsula of Mexico). Joint consideration of randomly amplified polymorphic DNA (RAPD) studies in Mesoamerica and allozyme work in Bolivia suggests that neutral genetic variation shows a similar trend. Quantitative and molecular (allozymes, RAPDs, microsatellites) data indicate abundant genetic variation at the within-population level, as is common in tropical trees. Long-distance pollination has been demonstrated in *S. humilis*, and probably occurs in all three species, contributing to the maintenance of genetic variation even in apparently isolated populations. Sporadic tree improvement activities have been implemented, e.g., clonal seed orchards in Mexico and Fiji (*S. macrophylla*), and seedling seed orchards and progeny tests in Costa Rica, Mexico (*S. macrophylla*), and Honduras (*S. humilis*). The absence of large, sustained planting programs explains the lack of more intensive breeding activities.

Swietenia macrophylla and, to a lesser extent, *S. mahagoni*, have been widely planted outside their native ranges, particularly in Southeast Asia and Oceania; plantations established in Fiji, Indonesia, Philippines, Solomon Islands, and Sri Lanka total more than 190 000 ha. There are also increasing areas of *S. macrophylla* plantations within the natural range, particularly in southern Mexico and

Guatemala. Worldwide, however, mahogany remains a minor plantation species, with total area less than one-twentieth that of teak. In large measure, this can reasonably be attributed to the problem – real or perceived – of mahogany shoot-borer attack.

Ecology

Swietenia macrophylla

Typically, *Swietenia* are species of relatively low-altitude (≤ 1400 m), seasonally dry forests, and are largely absent from or rare in perhumid regions within their natural ranges. These factors are responsible for an interruption in the natural range of *S. macrophylla*, formed by the coast-to-coast humid and/or high-altitude belt that runs diagonally from northeastern Costa Rica to north-Pacific Panama. Similarly, *S. macrophylla*'s arc-shaped range in South America traces the seasonal tropical forests along the northern, western, and southern rims of the Amazon basin.

Big-leaf mahogany is one of the giants of the tropical forest, reaching heights of up to 70 m and diameter (above often massive buttresses) of 3.5 m. Trees of such dimensions are probably more than 400 years old and are now rarely found; across its range, the average merchantable big-leaf mahogany tree is likely to be 20–30 m tall with dbh of 60–120 cm. Young trees have narrow, shallow crowns and may remain unbranched for 6–8 m. The mature crown, composed of a few, large primary branches, tends to be irregular or umbrella-shaped. The thick bark of older trees is deeply furrowed and sometimes nearly black. The pinnately compound leaves are deciduous; trees tend to be leafless for weeks rather than months. The small, unisexual flowers emerge with the leaves, and appear to be pollinated by small bees and moths. In natural forest, trees of 14 cm dbh may flower, but only trees >30 cm with exposed crowns are likely to do so consistently. The species is monoecious and tends to be fully outcrossing, at least in relatively undisturbed conditions. It is unknown whether this is due to genetic self-incompatibility, abortion, selection against inbred zygotes, or dichogamy. Mahogany fruits are woody capsules, each containing 25–60 wind-dispersed, samaroid seeds (**Figure 2**). These measure 1–2 cm (up to 13 cm including the wing) and generally land within 50 m of the mother tree. Maximum seed production occurs in large but vigorous trees of 90–130 cm dbh, which can produce up to 800 fruit capsules in a single year. Germination of mahogany seed is maximal under shaded, closed-canopy conditions, where seedlings show remarkable persistence. Nevertheless, they will not grow vigorously without higher light levels.

Figure 2 Opened capsule and seeds of *Swietenia macrophylla*. Courtesy of KE Wightman.

Two particular patterns of frequency and abundance of big-leaf mahogany have been widely noted. First, and more rarely and locally, mahogany may form relatively dense aggregations of up to 40–50 mature trees ha^{-1}. These formations, reported particularly from the Yucatan peninsula, seem to derive from the resistance of mature mahogany trees to hurricanes and fires, both relatively common in the Caribbean region. Such catastrophic disturbances favor the species by opening the canopy and destroying seed trees and advance regeneration of other species. The copious seed rain of surviving mature mahogany trees can then lead to seedling densities of up to 1000 ha^{-1}. The annual height growth of young seedlings, which may exceed 2 m during the first 5 years, is sufficiently rapid to permit high adult stocking. The second, more common pattern is of low densities of 0.1–3.0 merchantable trees ha^{-1}, found in small aggregations. It occurs in much of Quintana Roo, Mexico, the Chimanes region of lowland Bolivia, seasonally flooded forest in the Peruvian Amazon, nonriverine, upland or terra firma landscapes in western Amazonia, and southeast Pará, Brazil, and seems to reflect absence of (recent) catastrophic disturbance. Studies demonstrate that, under spatially smaller and/or lower-intensity disturbance (resulting, for example, from flooding or tree-fall of mahogany and other large trees such as *Hura* and *Manilkara*), advance or postdisturbance regeneration of mahogany will almost always die due to lateral canopy closure or competitive effects of exploitative gap-invaders. This seems to explain the low density of mahogany in such forest: that is, conditions dictate that, of the lifetime seed fecundity of individual trees, only a small proportion – on the order perhaps of 1 in 0.25 million dispersed seeds – survives to adulthood. The survival of even this proportion is presumably facilitated by the ability of seed to germinate in closed-canopy conditions and the relative robustness and shade tolerance of mahogany seedlings.

Although mahogany is tolerant of a wide range of soil types (derived from alluvial, volcanic, metamorphic, and calcareous material) and conditions (deep, shallow, acid, alkaline, well drained, and gleyed), edaphic or hydrologic factors certainly also partly determine distribution patterns. However, the relative roles of disturbance and such factors are unknown. Physiographic associations at the population level remain poorly described and understood across the natural range. Big-leaf mahogany was first observed in riparian situations in coastal Belize. Similarly, descriptions from South America emphasize the species' association with river floodplains in the upper reaches of the western Amazon basin. From Bolivia, Brazil, Ecuador, and Peru many observers have noted highest densities on drier, firmer, and infrequently flooded soils slightly above seasonally inundated floodplains. Nonriverine associations have also been described, e.g., in interfluvial and upland ecosystems in Belize, where mahogany will even invade stands of *Pinus caribaea* on drier sites with high understory light levels.

Swietenia humilis and *S. mahagoni*

As little natural forest remains within the generally highly (human-) populated natural ranges of *S. humilis* and *S. mahagoni*, their ecology in natural conditions is to some extent a matter of conjecture. However, the close similarity between all three species suggests a similar ecological role and regeneration ecology to that of *S. macrophylla*. *Swietenia humilis* is found in farmers' fields, fence lines, riparian strips, and in some of the few remaining areas of relatively intact natural forest. *Swietenia mahagoni* is found principally in remnant stands on inaccessible terrain. Large individuals of either are rare. For *S. mahagoni*, this may be due to past exploitation (in Jamaica, a harvested specimen reached 3.7 m in diameter, and 200-year-old avenue trees in the US Virgin Islands have attained 2.0 m). Consistent with its epithet, no such *S. humilis* individuals seem to have been recorded. Common-garden provenance and species trials suggest that both *S. mahagoni* and *S. humilis* are adapted to drier conditions than *S. macrophylla*, as their respective distributions would suggest.

Conservation Status

None of the species is in imminent danger of biological extinction. Nevertheless, there is justified concern about the current conservation status of all three. *Swietenia humilis* and *S. mahagoni* are both commercially exhausted, as illustrated by current imports of *S. macrophylla* to the Dominican Republic, formerly a producer of *S. mahagoni*. They were listed in CITES Appendix II in 1975 (*S. humilis*: all parts and derivatives except seed, pollen, seedlings, or tissue cultures) and 1992 (*S. mahagoni*: logs, sawnwood, veneer, and plywood). As pioneers – considered potentially invasive in exotic locations – both species are well equipped to survive in the highly disturbed conditions where they now generally occur. However, their continued persistence is likely to depend on the nurturing of regeneration by farmers.

In parts of Central America, e.g., northern Costa Rica and adjoining parts of Nicaragua, *S. macrophylla* also is increasingly rare. In South America, particularly in Brazil and Peru, substantial stocks remain. However, intensive logging in recent decades has led to virtual local extinction over large areas of the natural range in both these countries and Bolivia. Growing concern over the impact of logging – on the species itself, on associated forest types, and on forest-dwelling indigenous peoples – led in the 1990s to a sometimes acrimonious debate, centered around successive proposals to include *S. macrophylla* in CITES Appendix II. The third such proposal was approved in November 2002, and applies to mahogany logs, sawn timber, and veneer.

Silviculture

Natural Stand Management

To date, with the exception of relatively small areas of forest certified by the Forest Stewardship Council in Mesoamerica, mahogany has been 'mined' rather than managed; with exhaustion of merchantable stems in one area, loggers have moved on to new 'deposits' in other regions or countries. Selective logging for mahogany tends to cause relatively little canopy disturbance. As discussed above, in natural, unlogged forest, rare recruitment to adulthood in tree-fall gaps may be adequate to maintain low-density populations. However, the probability of replacement arising from a specific canopy opening (e.g., one logging event) is vanishingly small, even supposing that, contrary to frequent practice, trees are not felled before seed dispersal. Consequently, sustained production of mahogany in selectively logged forests is likely to require intensive management and more complete ecological information. Recently initiated experimental management in Acre, Brazil reflects these requirements, emphasizing knowledge of local distribution patterns and population structures; retention of hollow adult trees and highly fecund individuals for seed production and maintenance of genetic structures; acceleration of diameter increment of retained trees through vine cutting and crown liberation thinnings; and artificial regeneration in treated (cleaned, burned) logging gaps with regular postharvest cleaning. Such management has the potential to increase mahogany densities substantially in 'natural' forest. In the longer term, this could permit the use of classic shelterwood regeneration systems, as has been proposed for some mahogany plantations.

Mean periodic annual diameter increments reported in the literature range from 0.36 to 0.91 cm year^{-1} in Belize over an 8-year period; an estimated 0.38–1.09 cm year^{-1} in Mexico's Yucatan peninsula, with highest increment growth by 15–30-year-old trees; 0.26–0.9 cm year^{-1} in Bolivia over a 2-year period, with fastest rates by trees 20–80 cm dbh; and 0.19–0.59 cm year^{-1} in southeast Pará, Brazil over 3 years, with increment rates declining with increasing diameter and maximum increment rates of individual trees approaching 2 cm year^{-1}. Mean rotation lengths required to grow merchantable trees from seed range from an estimated 85 years in Pará (50 cm dbh) to 122 years in Mexico (55 cm dbh), with fastest-growing trees reaching merchantable size in 50–55 years.

Plantations

The choice of species is the first decision to be faced by the potential mahogany planter. In relatively moist sites with short (2–4 months) dry seasons, *S. macrophylla* is the species of choice. Research carried out in Puerto Rico and the US Virgin Islands suggests that *S. mahagoni* or, if available, the F_1 hybrid, should be preferred to *S. macrophylla* in dry forest. Within its native range, *S. humilis* is probably the safest choice. However, consideration should be given to *S. macrophylla* in moist or irrigated sites within the range of *S. humilis*. Whatever species is used, seed should be derived from a local (or locally tested) source. *Swietenia macrophylla*, particularly, occupies an ecologically variable range, and long-distance seed transfers should be avoided. Germination capacity of fresh seed is 80–95%, although drying of seed on ventilated screens in partial sunlight for 2–3 days is recommended to reduce rot. Unopened capsules can also be dried in the sun to encourage opening. Mahogany seed is orthodox and may be stored for long periods at 4–5% moisture content and -20°C, with little or no loss of viability. If necessary, seed may also be stored in ambient conditions for 7–8 months (approximately 50% decline in viability). Seed is usually dewinged to facilitate planting, although such seed may have lower viability after storage. It should be planted flat or with the winged end pointed down. No pretreatment is necessary. Germination is hypogeal, beginning in moist soil after 2 weeks and finishing 4 weeks later. Seedlings develop a strong taproot. Planting stock can also be produced vegetatively, e.g., in nonmist propagators.

Common substrates for poly-bag production include mixtures of forest soil with sand and a variety of composted organic materials. However, results vary greatly depending on nutrient concentrations and proportions in local materials. In container nurseries, common mixtures include 50% sphagnum moss, 25% vermiculite, and 25% perlite mixed with a slow-release fertilizer. Substrates should be kept partially shaded and moist during the first weeks of germination. Seedlings are ready to plant when the base of the stem has lignified and reached a minimum diameter of 8 mm. Seedlings from 20 to 80 cm, produced after 3–6 months in the nursery, may be planted successfully. The use of bare-root stock and striplings is inadvisable because subsequent field growth may be retarded. Direct seeding in the field is a viable option, but requires high soil moisture, early competition control, and the use of abundant seed.

Plantations can be successfully established on cultivated fields (e.g., in taungya) or recently cleared areas. Weed competition must be controlled carefully but can also be managed to provide lateral shade (**Figure 1b**). This encourages height growth, reduces soil exposure, promotes biodiversity (species richness), and may reduce and/or mitigate *Hypsipyla* attack. Close spacing (2×2 m or 3×3 m) allows greater flexibility in selection of final crop trees – an important consideration when *Hypsipyla* is present – and quicker canopy closure. Wider spacing, or deployment in mixed plantations or agroforestry systems, permits biological and product diversification, intermediate income generation and may form part of the integrated management of *Hypsipyla*. Mahogany has also been successfully used in line (enrichment) planting, although this approach requires careful management of the overstory. Fertilization during the first two to four growing seasons (increasing to 200 g per plant of a complete granular fertilizer) can be effective. Well-tended plantations of any of the species on well-drained, fertile sites can easily reach average heights of 6 m in 3 years. Maximum mean annual increments for well-managed, conventionally spaced (i.e., 1111–2500 trees ha^{-1} at establishment) plantations reach 25 m^3 ha^{-1} year^{-1}. First thinning should usually take place after 5–10 years. Commercial sizes (>50 cm dbh) can be reached in 20–30 years.

Abundant regeneration has been observed in *S. macrophylla* and *S. mahagoni* plantations, suggesting that planting may be unnecessary for establishment of second and subsequent rotations. Suggested silvicultural systems include the uniform shelterwood and group selection systems. Under the latter, trees are removed in groups in order to open canopy gaps sufficiently large for continued development of new and advance regeneration. In the former, a regeneration felling is carried out 4–6 years before final felling. The resulting advance regeneration is released by the final felling of the seed trees. In either system, intensive tending would be necessary, as in natural forest.

Mahogany's relatively fast growth, ease of nursery production, and high value suit it to plantation production. However, these advantages must be weighed against the serious pest problem of the mahogany shoot-borer (**Figure 3**). The larvae of the pyralid moths *Hypsipyla grandella* (neotropics) and *H. robusta* (old tropics) feed on the pith of mahogany shoots, principally while succulent or semisucculent. *Hypsipyla* attack approaches 100% in many plantations. Unless pruned, affected trees often develop into multiple-stemmed individuals of little commercial value. Attack may also reduce growth rate because of stalling for a variable period before dormant axillary buds respond. The problem has led to widespread avoidance of mahogany and related species both by tree planters and development projects. Nevertheless, there is no doubt that mahogany can be successfully cultivated in plantations. Tree mortality due to *Hypsipyla* is very unusual, and deformations caused by *Hypsipyla* up to at least 3 m height can be relatively easily corrected by biannual or annual pruning. The length of clean stem laid down between attacks, which depends both on growth rate and speed of post-attack lateral bud break, can be increased by both genetic selection and environmental manipulation (including appropriate site selection). There is evidence that lateral shading can both reduce *Hypsipyla* oviposition and stimulate vertical growth. Finally, selective thinnings in higher density plantations can be employed to favor the best-formed trees. A combination of all these control tactics should form the basis of an integrated pest management system.

In the neotropics, mahogany plantations can also be severely attacked by leaf-cutting ants, leading to growth reduction and, in young seedlings, death or forking. Leaf-cutters may be efficiently controlled using specific insecticides. Where these are unavailable or prohibitively priced, attack may be minimized by providing alternative browsing sources (interplanted or in neighboring areas) and avoiding clean-weeding. Other pest problems, such as Ambrosia beetle (*Crossotarsus externedentatus* and *Platypus gerstaeckeri*) and termite attack in Fijian plantations, have also been noted.

Utilization

Mahogany has been one of the world's most traded timbers for the last four centuries. Currently, it is used principally in furniture manufacture, flooring, doors, window frames, and decorative veneers. Free-on-board sawnwood prices in the early 2000s have been around US\$1000 m^{-3}. At the same time, retail prices in the USA were around US\$5–6 board $foot^{-1}$, equivalent to more than US\$2000 m^{-3}. The sustained demand for mahogany is largely a result of its excellent properties: extraordinary dimensional stability, high strength (particularly for its relative lightness), workability and exquisite, subtle beauty. These qualities, combined with centuries of use, have also

Figure 3 (a) *Hypsipyla*-attacked *Swietenia macrophylla* shoot in Turrialba, Costa Rica; (b) attacked *S. macrophylla* sapling, Guanacaste, Costa Rica; note multiple leaders due to lack of post-attack pruning. Courtesy of JP Cornelius.

given rise to an associated cachet – reflected in the many different woods commercially sold as mahogany, including not only other Meliaceae, but also Dipterocarpaceae (*Shorea* spp.) and various eucalyptus – that in itself sustains demand.

Wood quality, particularly density, appears to be related to environmental conditions, particularly as they affect growth rate; faster growth appears to be related to lower density. This factor, rather than inherent genetic characteristics, may also explain an apparent tendency of both *S. humilis* and *S. mahagoni* to have higher-density wood than *S. macrophylla*. The drier conditions in the natural ranges of *S. humilis* and *S. mahagoni* are probably less conducive to fast growth than those of typical *S. macrophylla*.

Exploitation and trade have shown three distinct phases: early exploitation of *S. mahagoni* in the Caribbean; cutting and substantial commercial exhaustion of *S. macrophylla* in Mexico and Central America; exploitation from the mid twentieth century of South American sources, particularly in Bolivia, Brazil, and Peru. The exploitation history of *S. humilis* is little known. It may be that mahogany exploitation is now entering a fourth phase, as international and domestic pressures lead producing states to adopt increasingly stringent management and trade regulations.

Teak and other Verbenaceae

P J Wood, Commonwealth Forestry Association, Oxford, UK

Introduction

The family Verbenaceae contains over 3000 species of trees, shrubs, herbs, and lianes in some 86 genera, virtually all of which are tropical or subtropical and a number of which are economically important tree species. It contains what is probably the most prized and famous of all timbers, teak (*Tectona grandis*). Other important tree genera include *Clerodendrum* and *Vitex* (Viticöideae) and *Gmelina*, *Lantana*, and *Lippia* (Verbenöideae).

Teak

Teak is arguably the most famous timber in the world (**Figure 1**). The combination of the wood's strength, durability, and stability, as well as its availability in long lengths gave it a key role not only in shipbuilding for the European empires in south and southeast Asia since the seventeenth century, but much further back in trade to Mesopotamia in the third millenium BC. In its natural habitats in India, Myanmar, Thailand, and Laos teak occurs mixed with many other species, but since the sixteenth century the species has been heavily exploited, as well as encouraged and replanted, so that today simplified monocultures of teak are the rule rather than the exception. Teak is thought to have been introduced in the fourteenth century from India to Indonesia by Hindu monks. The large-scale plundering of teak forests in the colonial era gave rise to early concerns for its regeneration and protection among some colonial administrators, so that sustained management of teak in India, Myanmar, and Indonesia probably has the longest history of any tropical tree species.

Teak occurs naturally as a component of many forest types ranging from moist to dry, though in all cases in a monsoonal climate. Like many other members of the Verbenaceae it is insect pollinated. Major phenotypic and genotypic differences have been identified in different parts of the natural distribution which have been used in tree breeding programs across the tropics, especially in south and southeast Asia.

Global areas of teak forest in 1998 were approaching 28 million ha, of which some 25 million ha were reported as natural forest (**Table 1**).

Figure 1 *Tectona grandis*.

Other Species of *Tectona*

In addition to *Tectona grandis* four other species of the genus have been identified: *T. australis*, *T. hamiltoniana*, *T. philippinensis*, and *T. ternifolia*. These are, however, of low social or commercial importance, though they form important components of different natural ecosystems.

Other Important Genera

The genus *Gmelina* is represented by over 57 species that occur mostly in the Indo-Malaysian and Australasian regions. The most commercially important species is *Gmelina arborea*, widely planted in many parts of the humid and subhumid tropics for general-purpose timber and the subject of important breeding and conservation programs. The pantropical genus *Vitex* contains several hundred species, some of which are of commercial importance.

Table 1 World teak area statistics

Country/zone	*Teak area reported, 1998 (ha × 10^3)*	*Plantations as % of teak area reported*	*Country/zone area as % of world area*
Myanmar	14 225	1.6	51
India	10 000	10	36
Thailand	2 100	4.8	7.8
Laos	22	11	<1
Indonesia	1 100	100	3.5
Other Asia	159	100	4.5
Africa	124	100	<1
Latin America	47	100	<1
Total	27 777		

Note: these figures should be regarded as a general guide only.
Source: Derived from Behagel I (1999) State of teak plantations in the world. *Bois et Forêts des Tropiques* 264(4).

The genera *Lantana*, *Lippia*, and *Clerodendron* are also pan-tropical, contain several hundred species, and are important components of many forest ecosystems. They comprise trees, shrubs and lianes. Species of *Lantana* are important weeds and *Lippia* species are important sources of medicine.

Tropical Pine Ecosystems and Genetic Resources

J Burley and R D Barnes, University of Oxford, Oxford, UK

Introduction

The genus *Pinus* (family Pinaceae) is one of the most widely distributed genera of trees in the northern hemisphere (**Figure 1**). The species often dominate the natural vegetation types in which they occur and provide some of the most important timber trees in the world. *Pinus* comprises approximately 100 species, of which about half occur naturally within the northern tropics. The tropical pines consist of two categories: first, those that occur naturally in the tropics, e.g., *P. oocarpa* (**Figure 2**) and, second, nontropical pines that are planted for wood production or shelter in the tropics, e.g., *P. elliottii* and *P. taeda* (**Figure 3** and **Table 1**). This definition is taken from the account of the tropical pines given in *Tree Crop Ecosystems* (Barnes *et al*., 2001; see Further Reading) and on which this contribution is based.

There are virtually no natural pine forests in the southern hemisphere (**Figure 1**). It is not surprising, therefore, that the tropical pines have been used most extensively as exotics in the southern tropics, where some 6 million ha of plantations have been established to produce structural lumber and long-fibered pulp for particleboard, kraft paper, and newsprint manufacture (**Figure 3**). Unlike other crops, it is not usually economic to modify the plantation environment artificially through fertilization or irrigation. However, the extensive gene pool of tropical pine species has made it possible to establish plantations that are many times more productive than the natural forests over a great range of environmental conditions.

Taxonomy and Variation in Natural Populations of Tropical Pines

The pines are evergreen, resin-yielding, small to very large trees, usually with a single stem and strong apical dominance. If open-grown, most branches are retained and the bole tends to be conical but, under forest conditions, lower branches are shed and clean cylindrical boles are produced. Bark varies from rough and furrowed (**Figure 4**) to smooth and scaly (**Figure 2**). All pines have mature needles in fascicles (bundles) of from one to six, enclosed in a deciduous or persistent basal sheath. The fascicles are dwarf short shoots and are important in their identification. The needles contain resin canals running along their length which vary in number and position and which are also important for species identification. Needles may possess one or two vascular bundles, upon which the two major divisions of the genus are based, viz., Haploxylon and Diploxylon. Stomata (pores for gas exchange) are borne in lines on all surfaces, varying in number between species and within subspecies and ecotypes of single species.

All pines are monoecious with male and female strobili borne on the same individual tree. The female strobilus is usually terminal or subterminal and is composed of two series of spirally arranged scales, a very small bract scale and a much larger ovuliferous scale. The latter bears two pendulous ovules on its upper surface. The mature cone shows considerable variation in size, degree of woodiness, shape and size of the individual scales, and position of the apophysis and umbo (the exposed part of the scale when the cone is closed). In the Haploxylon group of

Figure 1 World distribution of the genus *Pinus*. Reproduced with permission from Critchfield WB and Little EL (1966) *Geographic Distribution of the Pines of the World*. USDA Miscellaneous Publications.

pines (**Table 1**) the apophysis is terminal, whereas in the Diploxylon it is dorsal. The female strobilus is very important for species identification and without it an exact determination cannot usually be made. Female cone development takes from 1 year (e.g., *P. merkusii*) to 3 years (e.g., *P. leiophylla*). Pine seed is either winged or wingless (some pinyon pines).

Although the genus *Pinus* is a homogenous and natural group, its division into infrageneric and sectional groups has been the source of argument and confusion; many different schemes have been proposed. The classification adopted in **Table 1** is modified from that published by Elbert Little and William Critchfield which is based on the work of Jack Duffield who segregated groups but did not give them formal names.

Information on natural hybridization among tropical pines is scattered, incomplete, and mostly unconvincing. Many species occur sympatrically and are apparently isolated by complete or almost complete genetic barriers. There are very few published examples of natural species hybrids that have subsequently been verified by later controlled pollinations. Those that have are:

- *P. flexilis* × *P. strobiformis*
- *P. leiophylla* × *P. chihuahuana*
- *P. yunnanensis* × *P. tabulaeformis*
- *P. yunnanensis* × *P. kesiya*
- *P. pseudostrobus* × *P. montezumae*
- *P. montezumae* × *P. hartwegii*
- *P. palustris* × *P. taeda*
- *P. caribaea* × *P. oocarpa*
- *P. patula* × *P. oocarpa*

Ecology of Natural Stands of Tropical Pines

Natural Distribution

Geographic range Tropical pines occupy two disjunct areas in the western and eastern hemispheres (**Figure 1**). The smaller Latin American area has the larger number of species, and no taxon is common to both. Some species, e.g., *P. kesiya* and *P. merkusii*,

Figure 2 A natural stand of *Pinus oocarpa* at 1000 m in Honduras.

occupy enormous geographical areas in Southeast Asia. *Pinus* is almost unknown in the southern hemisphere except for *P. merkusii*, and it is absent from Africa south of the Sahara (**Figure 1**).

The folded mountain ranges and varied topography of Latin America provide an abundance of habitats and, although pines (36–40 species) are considered to have migrated south from the west and east of North America in the Tertiary period, Mexico is now recognized as a center of considerable species diversity and a secondary center of endemism. No pine has ever been recorded south of latitude 12° N in Central America and the total lack of fossil records indicates that no species of pine has ever existed in South America. In Southeast Asia, tropical pines occur in southern China,

Figure 3 Exotic pine plantations of *Pinus elliottii*, *P. patula*, and *P. taeda* at 1000–1500 m altitude in the eastern districts of Zimbabwe.

chiefly in the states of Yunnan and neighboring Szechwan, the island of Formosa (Taiwan), the whole of the former Indochina peninsular, Myanmar (Burma) and Thailand, together with the north-eastern states of India.

Altitude and climate In both geographical areas, pines commonly grow under conditions that are far from tropical. Almost all are montane, some with altitudinal ranges between 700 and 4000 m. *Pinus caribaea*, in Central America and the Caribbean, rarely grows at elevations greater than 700 m, whilst *P. merkusii* in Southeast Asia and *P. strobus* var. *chiapensis* in southern Mexico and Guatemala may be found up to 1000 m or slightly higher. These three species are the most 'tropical' of all pines and are unable to tolerate severe frost.

All the other species are submontane or montane, although one or two survive at the timberline, sometimes in permanent snow. Most seem to be adapted to a fairly narrow altitudinal range and inhabit distinct zones. Temperature appears to be the main factor controlling the altitudinal range of a species. In Latin America, however, *P. oocarpa* extends from *c*. 700 m in Central America (**Figure 2**) to 2500 m in Mexico. The lower altitude ecotypes are always frostfree, whereas the higher populations are frequently subjected to periods of severe frost. Some of the more upland pines have equally large ranges, e.g., *P. patula* and *P. tecunumanii* from 900 to 2800 m and *P. pseudostrobus* from 2000 to 3000 m. *Pinus hartwegii* is found at the highest altitude, between 2000 and 4000 m (**Figure 4**).

In Southeast Asia most of the species appear to have a greater range of altitudinal tolerance, several occurring from sea-level to 2500 m. Populations of *P. armandii* are found from sea level to *c*. 3800 m. The majority, e.g., *P. roxburghii*, are found between 1500 and 3500 m, whilst *P. densata* grows at the highest altitudes (to 4000 m).

The temperature range, therefore, over which tropical pines grow varies enormously from an annual mean of about 26°C (e.g., *P. merkusii* in Sumatra and *P. caribaea* in Nicaragua) down to treeline conditions with mean annual temperatures of 10°C (*P. hartwegii*). Mean annual rainfall also varies greatly over the areas occupied by tropical pines from as much as 10 000 mm (*P. kesiya* in the Khasi Hills, India) down to less than 600 mm (*P. caribaea* in Honduras). Almost invariably, the climate where tropical pines occur is characterized by an annual seasonal fluctuation in rainfall or temperature.

Soils Pines are able to thrive on a great variety of soils, particularly infertile, well-drained acidic soils. On richer soils, competition from broadleaved species is greater and their success in regeneration is poorer. In Central America, *P. oocarpa* tends to avoid the more alkaline soils overlying basic rocks, as does *P. caribaea* var. *hondurensis*. *Pinus caribaea* var. *bahamensis*, however, thrives on almost pure coral limestone (**Figure 5**).

Table 1 The tropical species of the genus *Pinus* classified according to Little EB and Critchfield WB (1969) (*Subdivisions of the Genus* Pinus (*Pines*). USDA Miscellaneous Publications.) and modified by BT Styles and A Farjon (Oxford Forestry Institute)

Authorities' names are given for precise identification. All the species listed occur in the tropics except for those followed by [a] which occur naturally only north of the tropic of Cancer but have been used operationally within the tropics.

Natural Ecosystems

Plant communities Natural pine forest ecosystems are relatively simple; species diversity is low and the number of associated taxa limited. *Pinus oocarpa* in Honduras probably forms the main forest cover over most of the country (**Figure 2**) whilst *P. caribaea* var. *hondurensis* is dominant in the savanna and lowlands of Belize, Honduras, and eastern Nicaragua. *Pinus densata* and *P. armandii* form dense forest masses in the mountains of southern China. As many as six different pines may grow together, e.g., in some forests in the state of Chiapas, southern Mexico. In both geographical areas *Quercus* species (oaks) are the broadleaved trees most commonly associated with pine, although other hardwoods can play the same role.

In Mexico and Central America at least, most pine communities are secondary fire climaxes. Irregular burning by anthropogenic fires or through lightning strikes prevents invasion by the broadleaved competitors that suppress pine growth. Fire also eliminates the build-up of seed- and seedling-eating animals, especially in the Central American *P. oocarpa* forests. The shade cast by dense pine growth suppresses the development of a significant ground flora. At the higher altitudes where rainfall is higher, temperatures lower, and fires less frequent, the pine

Figure 4 *Pinus hartwegii* in natural mixed pine forest at 2300 m in Honduras.

forest may be transitory and no longer part of a climax community and it merges with, and is finally replaced by, upper montane rainforest (**Figure 6**). A mixture of both types of forest is common in Mexico and Central America at altitudes of 2800 m and above. There is a similar transition at lower altitudes where high rainfall and fertile soils also make fire less frequent.

Mycorrhizae All pines form ectotrophic mycorrhizae with ascomycetous or basidiomycetous fungi. Fungi frequently encountered belong to genera of the Agaricales (*Amanita*, *Boletellus*, and *Suillus*); Russulales (*Lactarius*, *Russula*); Aphyllophorales (*Cantharellus*, *Thelephora*); Hymenogastrales (*Rhizopogon*); and Sclerodermatales (*Astraeus*, *Pisolithus*, *Scleroderma*). Ectotrophic associations are rare in tropical

Figure 5 Fire-maintained forest of *Pinus caribaea* var. *bahamensis* on impoverished soils over limestone rock in Bahamas.

regions, forming only in response to certain edaphic and climatic factors. Information concerning mycorrhizal fungi in these forests is very scanty (**Table 2**), mainly because the fruiting structures of the organisms are ephemeral in hot climates and because their taxonomic affinities are uncertain and difficult to ascertain.

Diseases Little is known about the pathology of most tropical pines in their native habitats. Natural forests generally contain trees of widely different ages, often consist of more than one pine species, and frequently contain a substantial component of nonconiferous shrubs and trees. In such areas, selection pressures are likely to operate against pathogens that give rise to severe epidemic diseases and in favor of pathogens that cause chronic low-level disease. This appears to be the case in the pine forests of Central America and the Caribbean islands where the trees are debilitated by mistletoes (e.g., *Arceuthobium* spp. and *Psittacanthus calyculatus*), heart rots caused by various basidiomycetous fungi, and cone rust (*Cronartium conigenum*). Other pathogens that have the potential to cause severe disease epidemics, such as the fungi *Mycosphaerella dearnessii*, *M. gibsoni*, and *M. pini*, also exist at low levels in some Central American pine forests. However, they appear to be restricted by the lack of susceptible host tissues available for infection; the very susceptible individuals and species have long since been eliminated from the forests. Similarly, heteroecious leaf and stem rust diseases also occur on the pines and alternate host plants but rarely cause severe epidemics.

Predators Six orders of insects contain significant pine pests – Coleoptera, Hemiptera, Isoptera, Lepidoptera, Orthoptera, and Thysanoptera. These pests bore into the bark, wood, shoots, cones, and seed, suck sap from stem shoot or needles, and defoliate the trees. In the undisturbed natural forest they are endemic and rarely become conspicuous. However, when the forest ecology is disturbed by climate or humans, populations can build up to epidemic levels and devastation can result. For example, in 1928 the first attacks by pine bark beetles (*Dendroctonus* spp.) were noticed in remnant trees weakened by lopping in cleared sheep pastures in highland Guatemala. Damage can also be severe at high stand density, even where this does occur naturally.

Of the larger animals, humans and their domestic or feral beasts have the most profound influence on the ecology of the natural pine forests wherever they exist. Exploitation, grazing, and clearing for agriculture all involve management or mismanagement of the natural ecosystems that leads to the progressive decline of the forest.

Ecology of Artificially Created Plantations of Tropical Pines

Exotic Distribution

Species used in plantations Of the species listed in **Table 1**, four that occur in the tropics (*P. caribaea*, *P. kesiya*, *P. oocarpa*, and *P. patula*) are widely planted as exotics for industrial plantations. Another two (*P. massoniana* and *P. merkusii*) are extensively planted in the regions where they are indigenous and a further four (*P. greggii*, *P. maximinoi*, *P. pseudostrobus*, and one 'soft' pine, *P. strobus* var. *chiapensis*) are being used commercially on special sites. Of the eight extratropical pines that have been planted as exotics in the tropics, *P. elliottii* and *P. taeda* are the most important. Exotic pines have been widely planted in environments where the biotic, climatic, and edaphic factors are frequently unlike those in their indigenous habitats. The ecology of plantations, therefore, is in marked contrast to the ecology of the natural forest.

In 1980 it was estimated that about 3 million ha of softwood plantations had been established in

Figure 6 A natural stand of *Pinus tecunumanii*, probably established after a rare fierce fire, being replaced by hardwood species at 2000 m altitude in Honduras.

76 tropical countries of Africa, America, and Asia and this had increased to 4 million by the end of the twentieth century. About 80–90% of this area were tropical pines. In 1980, *P. elliottii* was still the largest single contributor, mainly in Brazil (*c*. 30%), but by 2000 it was equaled if not surpassed by *P. caribaea* followed by *P. patula*, *P. oocarpa*, *P. kesiya*, and *P. merkusii*; all the remaining species will contribute less than 10%.

Climatic factors The most successful plantation schemes have been those where species have been used in monoculture homoclimally, i.e., in climates similar to those in which they occur naturally. Absence

of natural pests and diseases contributes to this success and to productivity unseen in the natural stands. There has, however, been a tendency to move species that have demonstrated excellent silvicultural characteristics in the exotic homoclime to lower and hotter areas. The physiological stress and ecological changes that occur may not be immediately apparent but, as the plantation matures, disease and pest problems develop and the natural vegetation soon destroys the pine stand structure. Less frequently, species have been moved to higher altitudes and lower temperatures than those that occur in their natural range. Although there are significant reductions in growth rate, the ecological consequences are not as striking as when species are moved to warmer climates.

Tropical pines vary in their drought-hardiness but most species will grow with mean annual precipitation as low as 800 mm. However, species cannot be moved from winter rainfall to summer rainfall areas without severe problems; for example, *P. canariensis, P. halepensis, P. muricata*, and *P. radiata* were planted operationally in the tropics but have been abandoned.

Edaphic factors With appropriate temperature and dry season, exotic tropical pines are able to exploit the full potential of the soil and become dominant even on the very best sites. Where the climate is wrong, however, fertile soils contribute to the rapid demise of exotic tropical pine forest. In such conditions, the indigenous vegetation is not a fire climax type and there are many aggressive pioneering woody species that will take advantage of the physiologically weak pines and start recolonizing the site as the first step in reestablishing wet tropical forest ecology.

The tropical pines as exotics vary in their tolerance of soils with low nutrient status (e.g., *P. kesiya* can grow on degraded sites but *P. chiapensis* requires fertile sites) and particularly in their ability to grow on poorly drained soils (e.g., *P. kesiya* is very intolerant and *P. elliottii* very tolerant). Great depths of sandy soil can have amelioratoring effects on climatic influence where rainfall is low. The most serious problems with nutrient deficiencies have been with phosphorus (e.g., *P. caribaea* in Queensland), potassium (e.g., *P. kesiya* in Madagascar), and boron (e.g., *P. caribaea* in Papua New Guinea and *P. kesiya* in Zambia).

Ecology in the Exotic Environment

Plant communities The most important biotic influences are human beings and the silvicultural practices they use to establish and maintain the pines as exotics. Initially at least, the species is nursed into its new surroundings by careful sowing, planting, and weeding techniques. On poorer soils, the pines are able to compete favorably with grass and shrubby growth but generally not with woody regrowth. On more fertile sites, it is necessary to keep woody regrowth, shrubs, and creepers cut back until the pine crop forms a canopy.

Almost invariably, when crops are harvested the area is artificially regenerated by planting. Where soil fertility is high, the second crop is often faster-growing than the first because the forest floor by that time is almost devoid of ground vegetation. On poorer sites, however, nutrient deficiencies may result in reduced production. In both cases, there are changes in the associated macro- and microflora but the long-term prognosis in this respect cannot yet be predicted. Woody weeds, both indigenous and exotic, have become conspicuous problems in pine plantations (e.g., *Acacia ataxacantha*, *Lantana camara*, and *Rubus pinnatus* in Africa).

Notwithstanding the careful cultural procedures that are used to establish exotic plantations of tropical pines, many species regenerate naturally in their new environment once they are established and some have become serious invaders of indigenous grassland and woodland, particularly where frequent fires have been preventing the local succession to climax forest communities. A good example of this is *P. patula* in the fire climax grassland and *Brachystegia* woodlands of the eastern mountainous region of Zimbabwe (**Figure** 7).

Mycorrhizae Pine plantations are usually planted on old forest or grassland sites where indigenous ectotrophic trees are absent or sparse and indigenous fungi rarely form a significant source of mycorrhizal

Figure 7 *Pinus patula* colonizing a hillside at 1800 m in Zimbabwe. Seed has been blown in from a nearby planted stand and many trees have already survived fires.

inoculum for introduced pines in areas remote from natural *Pinus* spp.

Exotic ectomycorrhizal fungi were probably introduced along with their native hosts by early settlers long before the importance of mycorrhizae was realized. However, when attempts were made to grow pines in new areas from importations of tree seeds, mycorrhizal deficiency problems were often encountered; uninfected seedlings would usually remain stunted and chlorotic in appearance and they would usually die in the nursery. Later, these problems were overcome by the introduction of fresh pine soil or the use of 'mother seedlings' in nursery beds.

The type of inoculum, its origin, the method of transportation, the method of inoculation, and possibly the identity of the recipient *Pinus* species. have had considerable influence on which fungi were successfully introduced to any given area. Usually only a few of the 23 commonly encountered fungi (**Table 3**) are observed at any one site; the range of species observed is affected by the age of the trees, the host species, and site factors, such as altitude, climate, and rotation.

Diseases Exotic pine plantations in the tropics and the southern hemisphere have mostly been established in areas that were naturally free from any specialized pine disease organisms. Thus the majority of disease outbreaks reported in pine plantations from these areas were, until recently, caused by nonspecialized pathogens with a wide host range able to spread from indigenous host species to exotic pines.

These pathogens usually affect the roots or heartwood of the pines. The most notable of these diseases is *Armillaria* root disease. Following felling of infected trees the roots and stumps become extensively colonized by the fungus, which then spreads to healthy trees. Most *Pinus* species are susceptible but *P. elliottii* appears to be exceptionally so. Several other nonspecialized pathogens also give rise to similar diseases in various parts of the tropics; these can lead to serious economic losses but they can usually be minimized. Since 1950 there has, however, been a gradual influx of specialized pine pathogens from the north into exotic plantations in the tropics and the southern hemisphere where some have already proved to be a serious threat to certain *Pinus* species. Dothistroma blight, caused by the fungus *Mycosphaerella pini*, is probably the most important of the pine diseases in the tropics to be caused by an exotic specialized pine pathogen. This fungus was identified as the cause of a severe needle blight of *P. radiata* in Tanzania in 1957 and has since been reported from many other countries in the tropics. Plantations of pines are obviously more prone to epidemic disease than natural forest; however, they also provide more scope for the avoidance or control of disease in addition to being vastly more productive than most natural forest areas.

Predators The first crops of exotic pines have been characteristically devoid of associated animal life but there is an increasing number of birds, insects, and mammals becoming associated with and adapted to the forests. Even-aged stands of trees provide ideal media for population explosions, particularly of insects, both native and introduced. There have now been epidemics of insect pests from all the main orders, e.g., bark beetles and aphids in southern Africa, termites in Malaysia, shoot moths in the Philippines, defoliating moths in Zimbabwe, grasshoppers in Malawi, and thrips in Kenya. The worst damage is frequently associated with mis-siting of the host species when environmental stress is thought to bring about high nutrient levels in the tree through remobilization of reserves; this makes it attractive to the pest and at the same time impairs the tree's defensive mechanisms. Epidemics may eventually be brought under control by local predators or diseases, e.g., coccinelids on aphids and various viruses on lepidopterous larvae.

Birds and mammals use pine plantations for shelter, particularly before they are pruned and thinned, but, surprisingly, a number of mammals find a source of food in pines and can become destructive. Elephants strip pine species in Africa and eat the inner bark; they find it convenient to work down the plantation rows. Eland antelope have similar habits in Zimbabwe and are very destructive in *P. patula* plantations. Pigs, wild or feral, in all parts of the world feed highly selectively on the roots of young *P. oocarpa*; it has been suggested that this is due to a specific mycorrhizal association, possibly *Rhizopogon* spp., that have edible subterranean fruit bodies. Opossums feed on the young bark of *P. taeda* in Queensland, porcupines debark *P. leiophylla* by gnawing at the base in Zimbabwe, and baboons eat the bark of several pine species in southern Africa.

Genetic Resources and Adaptation

Evidence from many national and internationally coordinated comparative trials of species, varieties, populations (provenances), and progeny in many of the large number of tropical pine species have demonstrated that significant genetic variation occurs in clinal, ecotypic, and random patterns of distribution. This stresses the importance for the forester to choose the correct original natural population for exotic plantations and to monitor the change in genetic population structure under exotic conditions.

Development of landraces The possibility of genetic differences developing between the local exotic population and the original introduced sample is dependent upon the extent of heterozygosity, the genotypes of the founder members of the exotic population, the expression of the genetic variation in the new environment, and the selection pressures encountered under local conditions.

It appears that both a reduction in genotypic variation and a changed environment may, through their effect on phenotypic expression, contribute towards the rapid changes that can take place in local exotic populations. The changes may not be possible where the species is indigenous even when it is grown under plantation conditions. Such factors as endemic disease, competition with other indigenous species, and different climatic or edaphic conditions may prohibit the expression of genes that might otherwise improve commercially important characteristics.

Despite frequently small numbers of founder individuals, there is little evidence to suggest that introduced exotic tree populations are inferior to, or much less variable than, the indigenous parent populations. In fact, adaptation can take place over surprisingly few generations and the exotic population often exhibits superiority over material that is reintroduced from indigenous stands.

Development of genetically distinct exotic populations is occurring very much more rapidly now that selection and breeding in tropical pines have started. Achievements initially have been in improvements in wood yield and in stem and branch form (**Figure 8**). These have brought a correlated response in improved physiological adaptation to the environment and, as the environments are quite different from one country to another, a large amount of variation in

Figure 8 Seventeen-year-old plantation of *Pinus patula* from first generation of bred seed in Zimbabwe.

adaptability can be preserved in the global development of a species.

Implications for Management

Plantation silviculture aims to increase uniformity in the forest and to simplify the ecology; variation increases the complexity of management. Uniformity invites biotic, climatic, and edaphic disasters. Uniformity can aggravate damage from drought and cyclone, lead to soil impoverishment and erosion, and provide ideal conditions for population explosions of plant competitors, diseases, and pests. These in turn cause wild swings in the ecology and these swings themselves can sometimes prove to be beyond control through management. In the exotic environments, it is impossible to predict or even conceive of the events that may occur and to know their consequences. Introduction of diversity in the forest through mixed ages, mixed species, rotation of species, silvicultural treatment, and genetic variation may make ecology and management more complex but it will render the crop ecosystem much more stable, robust, and self-perpetuating and provide buffers against disasters. The forester must treat crop protection as part of silvicultural planning.

TROPICAL FORESTS

Contents

Bombacaceae

S Harris, University of Oxford, Oxford, UK

Introduction

The family Bombacaceae contains trees with some of the most enigmatic of all traits, whether it is the lightness of South American balsa wood (*Ochroma pyrimidale*), the fabled odor of Southeast Asian durian fruit (*Durio zibethinus*), or the unusual architecture of African baobabs (*Adansonia digitata*). Traditionally, the Bombacaceae have been separated as a family, distinct from the Sterculiaceae (cocoas), Malvaceae (cottons), and Tiliaceae (limes). However, detailed analyses of molecular and morphological data have concluded that a single monophyletic Malvaceae should be recognized that encompasses all of the other families. The Bombacaceae cannot be maintained as a separate family since it appears to be paraphyletic with respect to the traditional circumscription of the Malvaceae and, furthermore, the genus *Durio* and its allies are more closely related to the traditional circumscription of the Sterculiaceae.

The traditional Bombacaceae comprises some 25 genera and 250 species of tropical (primarily neotropical) trees (**Table 1**), although some generic limits are controversial. For example, the important timber species *Bombacopsis quinata* is often separated from the genus *Pachira*, whilst the widely planted ornamental genus *Chorisia* may be recognized as distinct from *Ceiba*. The majority of species are found in lowland rainforest, although some genera (e.g., *Adansonia*, *Ceiba*, *Cavanillesia*) show water-storage adaptations for survival in dry, open habitats, for example, small crowns and thick, bottle-shaped trunks.

Table 1 Distribution of genera in the family Bombacaceae

Genus	*Approx. species number*	*Distribution*
Adansonia	15	Africa, Madagascar, Australia
Aguiaria	1	Brazil
Bernoullia	2	Tropical America
Bombax	20	Old-world tropics
Camptostemon	2	Central Malesia, Australia
Catostemma	11	Northern South America
Cavanillesia	3	Tropical America
Ceiba	11	Tropical America and Africa
Coelostegia	5	West Malesia
Durio	28	Myanmar to West Malesia
Eriotheca	19	Tropical America
Gyranthera	2	Panama, Venezuela
Huberodendron	5	Tropical America
Kostermansia	1	Malaysia
Matisia	25	Tropical South America
Neesia	8	West Malesia
Neobuchia	1	Hispaniola
Ochroma	1	Tropical America
Pachira	20	Tropical America
Patinoa	4	Tropical South America
Phragmotheca	5	Tropical South America
Pseudobombax	20	Tropical America
Quararibea	35	Tropical America
Scleronema	5	Tropical South America
Septotheca	1	Peru

The hermaphrodite flowers of Bombacaceae are generally large and showy, being produced during drier periods when the trees lose their leaves. The flowers attract insects (e.g., ants in *Adansonia*), birds and mammals (particularly bats), and are generally highly outcrossed, with pollen moving large distances between trees. The fruits of Bombacaceae are often dehiscent capsules containing wind-dispersed seeds that are surrounded by cotton-like fibers, e.g., *Bombax* and *Ceiba*. *Adansonia* has an indehiscent capsule containing a sour, dry flesh that is dispersed by large mammals, whilst *Durio* seeds are surrounded by a fleshy aril, the odor of which attracts large mammals, e.g., elephants and monkeys, which may also act as dispersal agents. In the neotropics, parrots readily damage fruit capsules to retrieve the oily seeds, and this can be a problem if Bombacaceae species are being grown for their seeds.

Economically, the most important species is *Ochroma pyramidale*, which is the source of commercial balsa wood. However, other genera (e.g., *Bombax*) may also be used where light, low-quality timbers are needed. *A. digitata* is an important multipurpose African species, with a complex mythology surrounding it. Uses of *Adansonia* include fruit pulp as a drink, young leaves as a vegetable, seeds as fruits and sources of oil and tartaric acid and bark for rope and cloth. *Pachira fendleri* (synonym: *Bombacopsis quinata*) is used as a living fence in Central America and *Ceiba pentandra* is the commercial source of kapok. *Durio zibethinus* is an important fruit tree in Southeast Asia, where the fruit is said to 'smell like hell but taste of heaven.'

Combretaceae

S Harris, University of Oxford, Oxford, UK

The Combretaceae, based on morphological and molecular data, is a monophyletic family comprising 19 genera (approximately 510 species) of subtropical and tropical trees (to 50 m), shrubs, or lianas (**Table 1**). In general, forests have a predominance of trees and lianas whilst in grasslands shrubby species are more common. Shrubby species may be suffructices, the aerial shoots of which are frequently grazed or burned, making the plants appear annual. The two most important genera are *Terminalia* and *Combretum*. *Terminalia* species are important constituents of primary and secondary forests; for example, in Malaysia the genus is common in evergreen and semideciduous rainforest, and swamp and riverine forests, whilst *T. catappa* (native to tropical Asia and Pacific region) is a common constituent of littoral forests, sandy beaches, and eroding rocky shores, often as street or garden trees rather than for commercial forestry. *Combretum* species are commonly lianas, often found in riverine habitats and on the margins of primary and secondary forests. The species of the two closely related genera (*Laguncularia*, *Lumnitzera*) are mangrove species, whilst species of the more distantly related genus *Conocarpus* are mangrove associates. For example, the adaptations of *Laguncularia racemosa* to salt-water flooding include salt glands, vivipary, and pneumatophores.

Table 1 Distribution of genera in the family Combretaceae

Genus	*Approx. species number*	*Distribution*
Subfamily Strephonematoideae		
Strephonema	6	West tropical Africa
Subfamily Combretoideae		
Anogeissus	8	Tropical Africa and Asia
Buchenavia	20	West Indies, tropical America
Bucida	8	Tropical and subtropical America, West Indies
Calopyxis	23	Madagascar
Combretum	250	Tropics and subtropics (excluding Australia)
Conocarpus	2	Tropical America and Africa, Arabia
Dansiea		Australia
Getonia	1	Indo-Malaysia
Guiera	1	North Tropical Africa
Laguncularia	2	Tropical America, West Africa
Lumnitzera	2	East tropical Africa to Pacific
Macropteranthes	3	Australia
Meiostemon	3	South-east and tropical Africa, Madagascar
Pteleopsis	9	Tropical Africa
Quisqualis	16	Old-world tropics
Terminalia	150	Tropics worldwide
Terminaliopsis	2	Madagascar
Thiloa	3	North South America

The Combretaceae are part of the Myrtales (together with Vochysiaceae, Myrtaceae, Melastomataceae, Memecylaceae, Lythraceae, and Onagraceae), a monophyletic order, of uncertain position within the Rosids, based on morphology, embryology, anatomy, and DNA sequence data. The family Combretaceae is distinguished from the other families in the Myrtales by the occurrence of characteristic hairs, unilocular, inferior ovaries with apical placentation and flattened, ribbed, or winged drupes with large fibrous seeds. However, the relationships of the Combretaceae within the Myrtales are uncertain. Traditionally, the occurrence of combretaceous hairs in some Myrtaceae has suggested a close relationship of the Combretaceae to this family, although the Combretaceae may be closely related to the Lythraceae or Onagraceae.

The flowers of Combretaceae are often clustered in globular or spicate inflorescences, and typically produce nectar to attract insects, birds, and small mammals. For example, the long tubes of *Quisqualis* flowers presumably make pollination possible only by long-tongued insects. In the majority of species, flowers are hermaphrodite and outcrossing is promoted by protogyny. However, other mating systems are found in the family; for example, *Conocarpus erectus* is dioecious, *Laguncularia racemosa* has populations of male and hermaphrodite individuals and *Terminalia* species have male and hermaphrodite flowers on the same individual.

Combretaceae fruits of savanna and grassland species are often winged and adapted for wind dispersal, whilst forest species often have wingless fruits which are either fleshy and animal-dispersed or spongy and water-dispersed. Mangrove species (e.g., *Laguncularia*) have viviparous fruits that germinate on the parent plant. Combretaceae fruits can be important for species identification in some genera (e.g., *Terminalia*), whilst in others, flowers are important (e.g., *Combretum*).

The majority of Combretaceae produce poor-quality timber, although *T. ivorensis* and *T. superba* are internationally important timbers and have been grown in West African plantations; others (e.g., *Lumnitzera* in Malaysia and *T. arjuna* in India) have important local timber uses. The family produces important ornamentals (e.g., *Quisqualis indica*, *Combretum grandiflorum*) and widely planted pantropical street trees (e.g., *T. catappa*). The fruits of some *Terminalia* species (known as myrobalans) are important in tanning, whilst other combretaceous species are important as local foods, dyes, and medicines.

Lauraceae

S Harris, University of Oxford, Oxford, UK

Introduction

The Lauraceae is a family (about 50 genera and about 3000 species) (**Table 1**) of mainly subtropical and tropical trees (except the genus *Cassytha* which is an herbaceous parasite), and is most diverse in the American and Asian tropics, although many species occur in Australia and Madagascar. Some genera range into the temperate region, e.g., *Sassafras* in North America, *Lindera* in Japan, and *Beilschmiedia* in New Zealand. The family is primarily found in lowland and montane rainforest, and can occupy a wide range of elevations from sea level to páramos in South America. In some habitats the Lauraceae is one of the most common trees families, for example, in the foothills and at mid-elevations in the Andes and as dominants in the relict laurel forests of the Canary Islands and Madeira.

Classification

Morphological and molecular data indicate that the Lauraceae is a monophyletic family, although classification with the family is less clear. Despite its ecological importance in tropical ecosystems, the Lauraceae is poorly known, since material is difficult to collect, the flowers are inconspicuous, and fruits and flowers are needed for accurate identification of most species. This creates problems for the delimitation of both genera and species, and thus absolute statements about generic distribution are difficult to make, particularly for genera that have widely disjunct distributions (e.g., *Apollonias* between India and the Canary Islands).

Traditional Lauraceae classifications have placed the parasitic genus *Cassytha* in its own subfamily (Cassythoideae), and treated the remaining genera as a second subfamily (Lauroideae). Within the Lauroideae, morphological characters (e.g., flower and wood anatomy) have been used to define three tribes: (1) Laureae (e.g., *Laurus*); (2) Perseeae (e.g., *Persea*); and (3) Cryptocaryeae (e.g., *Beilschmiedia*). However, molecular analysis of the family suggests that *Cassytha* should be placed with either *Hypodaphnis* or *Neocinnamomum*, and that the Lauroideae tribes, as currently defined, are not monophyletic.

Reproduction

Lauraceae flowers are insect-pollinated, usually with modified stamens that secrete either odor or nectar, and individual trees are hermaphrodite, monoecious, or dioecious. In addition to dioecy, there are mechanisms to promote outcrossing, including the occurrence of two flower types with different daily patterns of stigma receptivity and pollen presentation, as found in *Persea americana*. The Lauraceae

Table 1 Distribution of genera in the family Lauraceae

Genus	*Approximate number of species*	*Distribution*
Actinodaphne	100	Asia

Umbellularia	1	North America
Urbanodendron	3	Southeast Brazil
Williamodendron	3	Central and South America

usually have a unilocular ovary that produces a single-seeded drupe. The fruit may be free of the fruit stalk or partially or entirely enclosed by the receptacle.

Lauraceae fruits are primarily dispersed by specialist frugivorous birds, particularly bell birds, fruit pigeons, quetzals, and toucans, with approximately 80% of the diet of some species comprising lauraceous fruits. In the majority of cases the whole fruit is swallowed and the seed then regurgitated a short distance from the parent tree. Nonspecialist birds are important dispersers in temperate regions, whilst mammals (e.g., squirrels and monkeys) and fish may also be important dispersers.

Economic Uses

Historically, the Lauraceae is a very important economic family, especially the genus *Cinnamomum*, as a source of spices, e.g., cinnamon (*C. verum*), cassia bark (*C. cassia*) and laurel (*Laurus nobilis*), perfume oils, e.g., rosewood oil (*Aniba roseodora*) and sassafras oil (*Ocotea odorifera*), and pharmaceuticals, e.g., camphor (*C. camphora*). However, the most internationally important product produced today is the avocado fruit (*Persea americana*). Lauraceae wood is widely used locally, although a few are internationally important as high-quality timbers for furniture making or for resistance to salt water, e.g., greenheart (*Chlorocardium rodiaei*), Borneo ironwood (*Eusideroxylon zwageri*), and Queensland walnut (*Endiandra palmerstonii*). Some species (e.g., *Ocotea bullata*), once internationally important, are now protected because of past over-exploitation.

Lecythidaceae

S A Mori, New York Botanical Garden, New York, USA

Introduction

The Lecythidaceae is a pantropical family of trees found in the tropics of Central and South America, southeast Asia, and Africa, including Madagascar (**Table 1**). The family is divided into five subfamilies: (1) the Planchonioideae, with six genera, the best known of which is *Barringtonia*, and 59 species in tropical Asia, Malaysia, northern Australia, the Pacific Islands, and Madagascar; (2) the Foetidioideae, with a single genus, *Foetidia*, and 17 species in Madagascar, Mauritius, and East Africa; (3) the Napoleonaeoideae, with two genera, *Crateranthus* and *Naopoleonaea*, and 11 species in West Africa; (4) the Scytopetaloideae, with a single species, *Asteranthos brasiliensis*, in the Negro and Orinoco river basins of Brazil and Venezuela and six genera and as many as 21 species in Africa; and (5) the Lecythidoideae of the western hemisphere. This article focuses on the New World species of Lecythidaceae.

New World Lecythidaceae range from Veracruz, Mexico (*Eschweilera mexicana*) to Paraguay (*Cariniana estrellensis*). The Caribbean harbors only *Grias cauliflora*, a species found in Jamaica, Central America, and northwestern South America. Several species of *Eschweilera* occur on Trinidad and Tobago, but these islands are South American, both geologically and in their floristic affinities.

Neotropical Lecythidaceae are best known for the Brazil nut of commerce (*Bertholletia excelsa*); for the cannon-ball tree (*Couroupita guianensis*), which is planted as a botanical curiosity in tropical and subtropical botanical gardens; and because species of the family are often ecological dominants in Amazonian forests.

Taxonomy and Genetics

In tropical America, there are 10 genera and 202 known species of Lecythidoideae and a single species, *Asteranthos brasiliensis*, of the African centered Syctopetaloideae. The largest genus is *Eschweilera* with 85 species followed by *Gustavia* (41), *Lecythis* (26), *Couratari* (19), *Cariniana* (15), *Grias* (7), *Corythophora* (4), and *Couroupita* (3). *Allantoma lineata*, *Asteranthos brasiliensis*, and *Bertholletia excelsa* belong to monotypic genera.

Molecular studies have demonstrated that the Lecythidaceae are monophyletic if members of the

Table 1 Subfamilies and genera of Lecythidaceae according to Morton *et al.* (1998)

Subfamily	*Region*	*Genera*	*Number of species*

		Scytopetalum	3

Scytopetalaceae are included. The relationship of *Asteranthos brasiliensis* with the Scytopetalaceae is supported by similarities in embryology, the presence in both of ruminate endosperm, and molecular affinities.

Ongoing molecular studies of neotropical Lecythidaceae indicate that not all of the genera are monophyletic. *Cariniana*, *Eschweilera*, and *Lecythis*, for example, include several clades that may have to be segregated as separate genera. Other genera, for example *Corythophora, Couratari*, *Couroupita*, *Grias*, and *Gustavia*, form natural groups as they are currently defined.

Ecology

New World Lecythidaceae are often dominant in lowland forests on well-drained soils between 19° N and 25° S latitudes. They rank as the first or second most important family of trees in frequency, density, and dominance in the vicinity of Belém, Brazil; the third most important at La Fumée Mountain, French Guiana; and one of the most important in central Amazonian Brazil.

A 100-ha plot established for the study of Lecythidaceae as part of the Biological Dynamics of Forest Fragments Project in central Amazonian Brazil about 80 km north of Manaus illustrates the ecological importance of Lecythidaceae in Amazonian forests. In this plot, there are 7791 trees of Lecythidaceae equal to or greater than 10 cm in diameter at 1.37 m (dbh, diameter at breast height). Among these trees are 38 different species, or nearly 19% of all of the species of Lecythidaceae known from the Neotropics. In each hectare, there are 45 to 149 individuals and 11 to 24 species. In this forest, where there are about 285 species of trees in all families in this size class per hectare, the Brazil nut family accounts for 12% of the individuals and 6% of the species of trees.

Species of the Brazil nut family diminish in importance at elevations above 1000 m, in periodically flooded forests, and in extremely dry habitats such as the *llanos* of Colombia and Venezuela and the *caatinga* of northeastern Brazil.

Nearly all neotropical Lecythidaceae are trees of either the understory, canopy, or emergent layers. The tallest, for example the forest-dwelling *Cariniana micrantha* and *Couratari stellata*, may reach 55–60 m in height. These genera, both dispersed by the wind, possess species of smaller stature when they are found in more open habitats; for example, *Couratari pyramidata* of the *cerrado* of central Brazil. The smallest is *Eschweilera nana*, a species that often possesses an underground trunk adapting it to survive the frequent fires of the *cerrado*. Individuals of *E. nana* may only reach several meters in height.

Trees of *Bertholletia excelsa* in the 140–150 cm dbh size class have been estimated by radiocarbon dating to be only 270 years old. One of the oldest known trees from the Neotropics is an individual of *Cariniana micrantha* radiocarbon dated at 1400 years old.

Species of Lecythidaceae are not common in secondary vegetation because they are extremely vulnerable to fire. If a forest is cut down and not subjected to fire, many Lecythidaceae will sprout from the cut stumps and flower and set fruit from the new branches. However, if fire follows cutting most Lecythidaceae are killed; hence old slash-and-burn fields throughout the Neotropics harbor few species and individuals of Lecythidaceae. Species of Lecythidaceae are generally indicators of undisturbed habitats.

Pollination Biology

The Brazil nut family provides examples of plant–animal coevolution. The flowers, fruits, and seeds are morphologically and anatomically adapted to the animals that pollinate their flowers and the animals, wind, and water that disperse their seeds.

Adaptation of Lecythidaceae for pollination has taken place, for the most part, in the male part of the flower. There are two types of flowers, radially and bilaterally symmetrical and three different rewards offered to pollinators – fertile pollen, sterile pollen, and nectar (**Figure 1**). Radially symmetrical flowers, such as those of *Gustavia superba* (**Figure 2**), offer only fertile pollen as a reward; consequently the pollinator reward and the pollen that effects

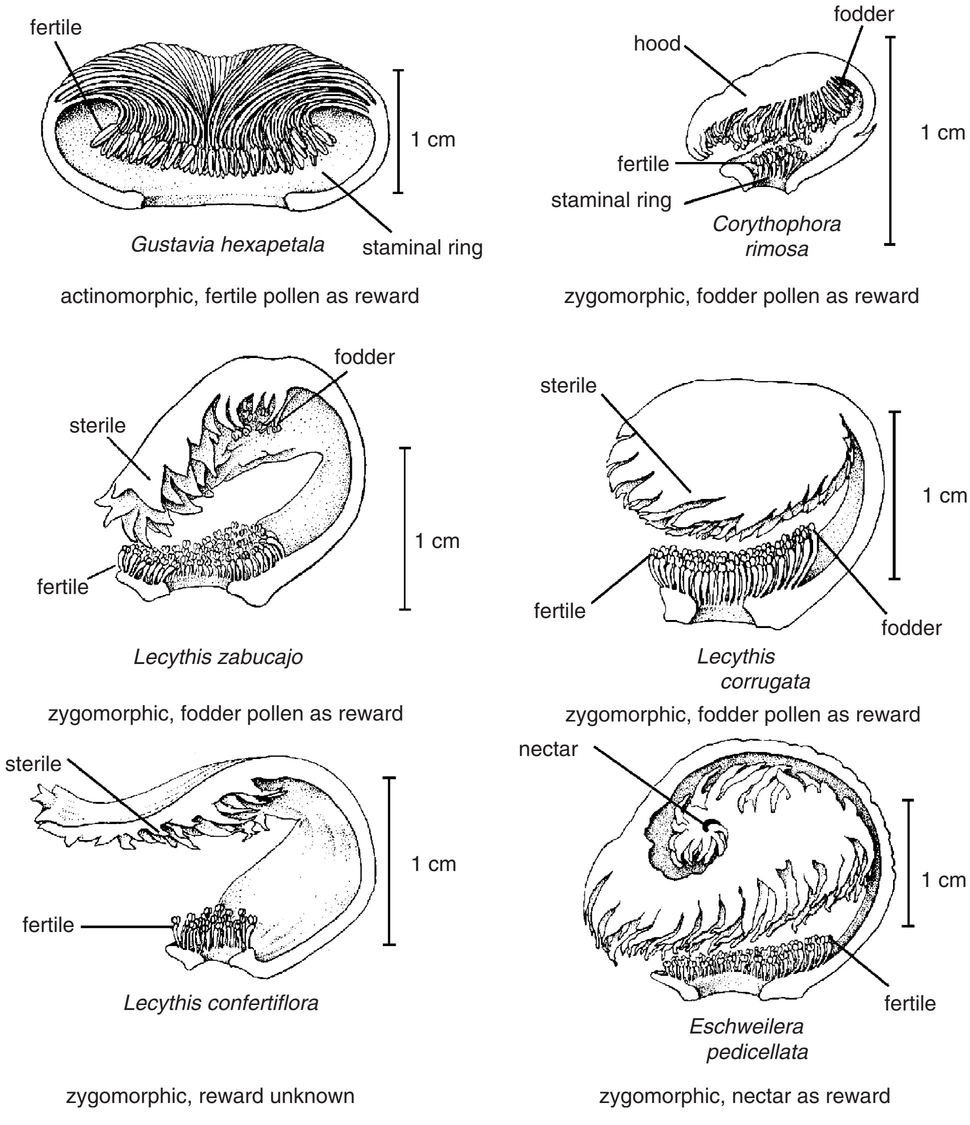

Figure 1 Examples of flower symmetry and pollinator rewards of Neotropical Lecythidaceae. Adapted with permission from Mori SA (1989) Diversity of Lecythidaceae in the Guianas. fertilization are morphologically and physiologically identical. Female bees visit the flower without restriction, collect pollen that is subsequently eaten by their larvae, and pollen is haphazardly deposited on their bodies. When the bees move to a flower of another tree, the pollen is deposited onto the stigma of that flower and eventually effects fertilization.

In contrast, species of Lecythidaceae with bilaterally symmetrical flowers offer two types of rewards, differentiated pollen and nectar. *Lecythis pisonis* (**Figure 3**), the *sapucaia* of the Amazon and the coastal forests of eastern Brazil, is a bilaterally symmetrically flowered species with both sterile and fertile pollen in the same flower. The fertile pollen is located in the staminal ring and sterile pollen is found in the staminal hood. Large, female bees, often of the genus *Xylocopa*, land on the staminal hood to collect sterile pollen from the hood. While collecting this pollen, the bee is dusted on the head and back with fertile pollen from the staminal ring. Experiments have demonstrated that the pollen purposely collected by the bee never germinates while that accidentally deposited onto the head and back always does. It is the latter pollen that is brushed off the head and back of the bees onto the stigmas of subsequent flowers visited that effects fertilization.

Eschweilera pedicellata (**Figure 1**) is a bilaterally symmetrically flowered species that offers nectar as a reward to the pollinators which are usually robust male and female euglossine bees. Both sexes visit flowers of this kind of Lecythidaceae because the nectar reward is utilized as an energy source for adult bees. In this type of flower, the staminal hood usually closes the flower; moreover the hood is internally coiled and nectar is produced at the apex of the coil (**Figure 1**). The nectar is secreted from vestigial stamens that no longer bear anthers.

Although the most important pollinators of Lecythidaceae are bees, at least two species (*Lecythis barnebyi* and *L. poiteaui*) and perhaps a third (*L. brancoensis*) are pollinated by bats, and some species of *Grias* are suspected to be pollinated by beetles. The bat-pollinated species have nocturnal flowers, display their flowers at the periphery and above the canopy, and emit an aroma dominated by sulfur-bearing compounds that is similar to rotting cabbage, all features of flowers visited by bats. The putative beetle-pollinated species of *Grias* emit aromas dominated by fatty acids similar to those produced by other beetle-pollinated plants.

Dispersal Biology

Neotropical species of the Brazil nut family have fruits that either do not open (indehiscent) or open via a lid at maturity (dehiscent). The seeds of different species are dispersed by animals, the wind, or water.

Several examples will give an idea of the wide variation in dispersal systems found in the New World Lecythidaceae. Species of *Gustavia* and *Grias* possess indehiscent fruits with the seeds often surrounded by a pulp eaten by animals, including humans. For example, *Grias neuberthii* has a fleshy mesocarp surrounding a fibrous endocarp, and, in that regard, is similar in structure, but not shape, to a peach. The fruits are sold in western Amazonian markets for their edible mesocarp. The endocarp, however, facilitates flotation of the fruit once the mesocarp has been eaten by animals, and it appears that this species may be secondarily dispersed by water currents.

In *Couroupita guianensis* (**Figure 4**), the mature fruits fall from trunk and crack open upon impact with the ground to expose a bluish-green, foul-smelling pulp, in which are embedded numerous, small seeds. In the Brazilian Amazon, peccaries have been reported to eat the pulp and swallow the seeds and it is presumed that the seeds pass through the peccaries' digestive tracts and subsequently germinate some distance from the mother trees, thereby effecting seed dispersal. The pulp is often fed to domestic pigs and poultry and seeds have been reported to germinate in the feces of these animals. This is the only genus of Lecythidaceae known to have numerous, long hairs arising from the seed coat. It is hypothesized that these hairs protect the seeds from digestive juices as they pass through the peccaries' digestive tracts.

Bertholletia excelsa, the Brazil nut of commerce, has a very specialized dispersal system. At maturity the fruits drop to the ground with the seeds trapped inside because the size of the fruit opening is smaller in diameter than the size of the seeds (**Figure 5**). Rodents, especially agoutis (*Dasyprocta* spp.) gnaw through the woody fruit walls by enlarging the small opening of the lid, chew through the thick and bony seed coat to consume the embryos of some of the seeds, and cache other seeds for future consumption. Some of the cached seeds are forgotten, and it is these that germinate 12–18 months later to form the next generation of trees. The fruits are so rot resistant that after the seeds have been removed by animals, they accumulate water and serve as breeding sites for an assemblage of anuran and insect species.

The largest fruited species of Lecythidaceae is *Lecythis pisonis* (**Figure 5**). After fertilization by carpenter bees (*Xylocopa* spp.), the fruits reach the size of a human head after nearly a year of development. This species, distributed in the Atlantic forests of eastern Brazil and in eastern Amazonia, opens via a lid that drops when the seeds are mature. The fruit opens while still in the tree crown and the seeds remain attached to the inner fruit wall by a funicle, which, in turn, is surrounded by a fleshy, white outgrowth called an aril. Bats, including *Phyllostomus hastatus*, remove the seeds with the attached aril on the same night that the fruits open. After the aril

Illustration prepared by Bobbi Angell.

is eaten, the bats drop the intact seeds either in flight or under their roosts.

All species of *Cariniana* and *Couratari* (**Figure 5**) are dispersed by the wind. The woody, cylindric fruits open to release seeds that are either winged at one end in *Cariniana* or winged all around the seed in *Couratari*. Species of these genera are either very tall forest trees or smaller trees of open habitats; consequently seeds falling from the fruits are exposed to the wind. The seeds of these genera are very light and possess embryos with leaflike cotyledons that enable the seedlings to begin photosynthesis immediately upon germination of the seeds, thereby compensating for the lack of nutrients in the seeds.

Water dispersal, although relatively uncommon, takes place in two different ways. In some species, the seeds fall from the fruit, float on the water because of the corky seed coats, and are carried away by currents. A common Amazonian tree found in periodically inundated forest, *Eschweilera tenuifolia* (**Figure 6**), is dispersed in this fashion. In *Lecythis rorida*, the entire fruit falls into the water and floats away with the seeds inside. The morphologically most similar species to *L. rorida* is *L. chartacea*, a species that normally grows in nonflooded forest away from the river. *Lecythis chartacea* has fruits that open at maturity to reveal seeds subtended by an aril that is most likely sought after by animals that, in turn, disperse the seeds. The seeds of *L. rorida* lack an aril, which would serve no purpose in water dispersal.

The woody fruits of Lecythidaceae are viewed as a way to protect the seeds from predispersal predation. The thick and woody fruit walls of *Cariniana micrantha*, however, do not deter brown capuchin monkeys (*Cebus* spp.) from opening the lids just before the fruits would naturally open and eating the seeds. The monkeys tear the fruits from the branches, knock them against the larger limbs and trunk, consume seeds, and then drop the fruits with a few remnant seeds to the ground. In one year, 99.5% of the entire seed production of a tree in central Brazilian Amazon was destroyed by brown capuchins.

Silviculture

The methodology for growing Brazil nuts in large plantations has been developed by the Brazilian agricultural research institution, EMBRAPA, in Belém and a great deal of literature exists about starting plantations from seeds and about grafting high-yield clones onto established root stocks. Nevertheless, most of the Brazil nuts reaching the international market are still gathered from wild trees, perhaps because native pollinators are not as abundant in the disturbed habitats of plantations as they are in more mature forests.

Utilization

The Brazil nut is the economically most important species of Lecythidaceae. Brazil nuts are gathered only from *Bertholletia excelsa*, a species of nonflooded forest native to Guyana, Surinam, Amazonian Colombia, Venezuela, Peru, Bolivia, and Brazil. Brazil nut trees are cultivated as a curiosity in tropical botanical gardens and sporadically in experimental plantations outside of the original range of the species. The edible seeds of the Brazil nut, along with the latex of rubber (*Hevea brasiliensis*) are often cited as the most important products of extractive reserves in Amazonia and these products are heralded as a way to conserve tropical diversity while at the same time sustaining human populations.

Brazil nut trees flower during the dry season into the wet season and are only found naturally in regions with a 3–5-month long dry season. Toward the end of the rainy season, the leaves of Brazil nut trees begin to fall. As the dry season approaches, new growth flushes of leaves and inflorescences are produced at the apex of the current growth. The flowers open shortly below daybreak and the petals and attached androecium fall in the afternoon of the day they open. Robust nonsocial or semisocial bees of *Bombus*, *Centris*, *Epicharis*, *Eulaema*, and *Xylocopa* are the pollinators. Both sexes of these bees visit the flowers for nectar. Although the Brazil nut is mostly self-incompatible, a small amount of self-compatibility does occur; therefore, the bee pollinators are usually essential for carrying pollen from one tree to the next as most of the fruit set results from their visits.

Brazil nuts are an economically important crop because the seeds are retained within the fruit when the fruit falls to the ground. The fruits, which weigh from 0.5 to 2.5 kg and contain 10 to 25 seeds, are easily harvested from the ground. A few other species, such as *Lecythis pisonis* (**Figure 5**), produce seeds equally as good to eat and as nutritious as the Brazil nut. However, they appear only sporadically in local markets because the fruits open and the seeds are carried away by bats before they can be harvested. These species are generally harvested by climbing the tree and cutting the entire fruit shortly before the fruit would naturally dehisce, a system that does not lend itself to the easy gathering of massive numbers of seeds by human collectors. Two closely related species, *L. minor* and *L. ollaria*, also yield edible seeds, but the seeds sometimes accumulate selenium, and, if too many of them are eaten, hair and even finger nails may be temporarily lost as the possible result of mild selenium poisoning.

A few species of *Gustavia* and *Grias* are grown in backyard gardens for the pulp surrounding the seeds that can be eaten raw or cooked. The best known are *Gustavia speciosa*, known as *chupa* in Colombia and *chopé* in Peru, and *Grias neuberthii*, the *sacha mangua* of Peru.

For the most part, the Brazil nut family is not known for high-quality timber. However, species of *Cariniana* have long straight boles and excellent timbers. The best known are *albarco* (*C. pyriformis*) of northwestern South America and the *jequitibás* (*C. estrellensis* of eastern Brazil and *C. legalis* of southwestern Amazonia and eastern Brazil). Brazil nut trees also produce high-grade timber, but they are protected by law because of their greater value as producers of edible seeds.

Only minor medicinal properties have been reported for the family. The most significant chemical use of Lecythidaceae is as an arrow poison derived from *Cariniana domestica*. The poison, extracted from the bark, kills small animals by disrupting their blood-clotting mechanisms thereby causing excessive bleeding when the animals are hit by poisoned arrows.

Monsoon Forests (Southern and Southeast Asia)

K K N Nair, Kerala Forest Research Institute, Peechi, Kerala State, India

Introduction

Tropical forests are of two major types – rainforest and monsoon or seasonal forest, close to the equatorial region. Monsoon forests are also known as mixed forests, along the borders or part of tropical rainforests in southern and southeastern parts of Asia. The forest type is characterized by a dry period of 3–5 months, when plant growth is limited by water stress, whereas in typical tropical rainforests this phenomenon does not exist. In general, monsoon forests are more nanic in stature than typical rainforests and many tree species in the forest formation remain leafless during the dry season; this is otherwise known as deciduous species. Because of this, more sunlight reaches the understory, promoting the growth of rich heliophilous ground flora, in addition to several lianas. However, woody epiphytes are comparatively few in number in monsoon forests, compared to rainforests. The monsoon vegetation of South and Southeast Asia is subject to much degradation, especially due to fire in the drought season, as well as shifting cultivation and several other factors. In order to conserve the forest type and its biodiversity, protected areas have been established in almost all countries in the region.

Definition and Terminology

In the early twentieth century, based on climatic and vegetational parameters, monsoon forests were described as more or less deciduous or leafless during the dry season and tropophilous in nature, i.e., alternating in hygrophilous and xerophilous characters, regulated by the monsoon climate. In typical rainforest areas of the Asian continent there is evenly distributed and heavy rainfall throughout the year, whereas in certain countries within the continent (Cambodia, India, Myanmar, Sri Lanka, Thailand and Vietnam), rainfall is seasonal with an annual dry period of about 3–5 months. In those countries, monsoon forests are quite common, apart from the evergreen and semievergreen rainforests. Due to the dry period and consequent deciduous nature of many tree species constituting the upper story of the vegetation, the subcanopy flora is fairly rich with woody climbers, shrubs, and herbaceous ground flora. At the same time, because of the dry climate and the deciduous nature of the forest formation, monsoon forests are poor in biomass content as compared to rainforests. Monsoon forests are also subjected to seasonal fire, promoting the development of savannas or grasslands, containing thorny or unarmed, stunted trees and shrubs. Because of the complex nature of monsoon forests, they are also designated as mixed forests, and vegetation types like moist and dry deciduous forests, savannas, scrubs, and thorn forests all belong to this category. Often, tropical rainforests merge or penetrate into monsoon forest formations, especially along water courses and wet habitats and the continuity of the two forest types is also restricted by repeated fire, resulting in the formation of savannas, which separate the two forest types. Such extensions of rainforests into monsoon forests are called gallery forests. **Figure 1** shows different categories of tropical forests in South

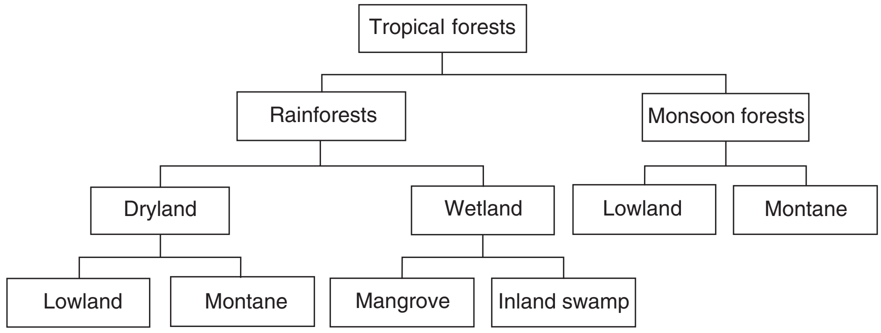

Figure 1 Categories of tropical forests in South and Southeast Asia.

and Southeast Asia. It may be noted that both rainforests and monsoon forests are distributed in lowlands and high mountains, and it is the climate which plays the major role in the development of the two different forest types within the same phytogeographical region.

Based on the duration of the dry period, monsoon forests may be open-canopy deciduous woodlands, closed-canopy thorn forests, scrubs, grasslands, or desert formations. Within the forest type, there are also different localized formations, varying in physiognomy and species composition, depending mainly upon soil, topography, and climate.

Monsoon Forest Environment

In tropical South and Southeast Asia, monsoon forests are mostly developed in rain shadow areas where there is seasonal drought for 3–5 months. During this period, average rainfall seldom exceeds 100 mm and, consequently, dry-weather conditions prevail there. As a result, the vegetation becomes tropophilous in character with deciduous and thorny plants dominating the formation. There are also local variations in monsoon climate. In Myanmar, the forest formation is distributed in areas receiving 400–800 mm rainfall; wherever precipitation exceeds 800 mm, rainforests are more common.

The soil types harboring the monsoon forests differ in different countries of the region. In peninsular India, they are developed in loamy, rocky, and similar uncharacteristic soil types, poor in nutrient content and water retention. However, in the north-eastern part of the country and also Bangladesh, sal *Shorea robusta* – dominated forests are common in alluvial soils along the deltas. In Cambodia, Laos, Myanmar, and Vietnam, both alluvial and dry and rocky soils harbor the vegetation type. In China and Southeast Asian countries (e.g., the Philippines), the forest formation is more common on limestone soils, as in the case of China.

Distribution and Extent of Monsoon Forests

In South and Southeast Asia, monsoon forests are distributed in Bangladesh, Cambodia, China, India, Indonesia, Laos, Myanmar, Philippines, Sri Lanka, Thailand, and Vietnam (**Figure 2**). The estimated area occupied by this forest type in different countries and the percentage of the area of total forest cover are given in **Table 1**. Brunei, Java, Kalimantan, Peninsular Malaysia, Sabah, Sarawak, Singapore, Sumatra, and Taiwan, do not have significant areas of monsoon forests. Among the different countries with monsoon forests, Sri Lanka has the greatest percentage (88%) of total forest area. This is followed by India (70%), China (66%), Cambodia (42%), and Vietnam (34%). Indonesia is predominantly under rainforest with less than 3% of total forest area classified as monsoon

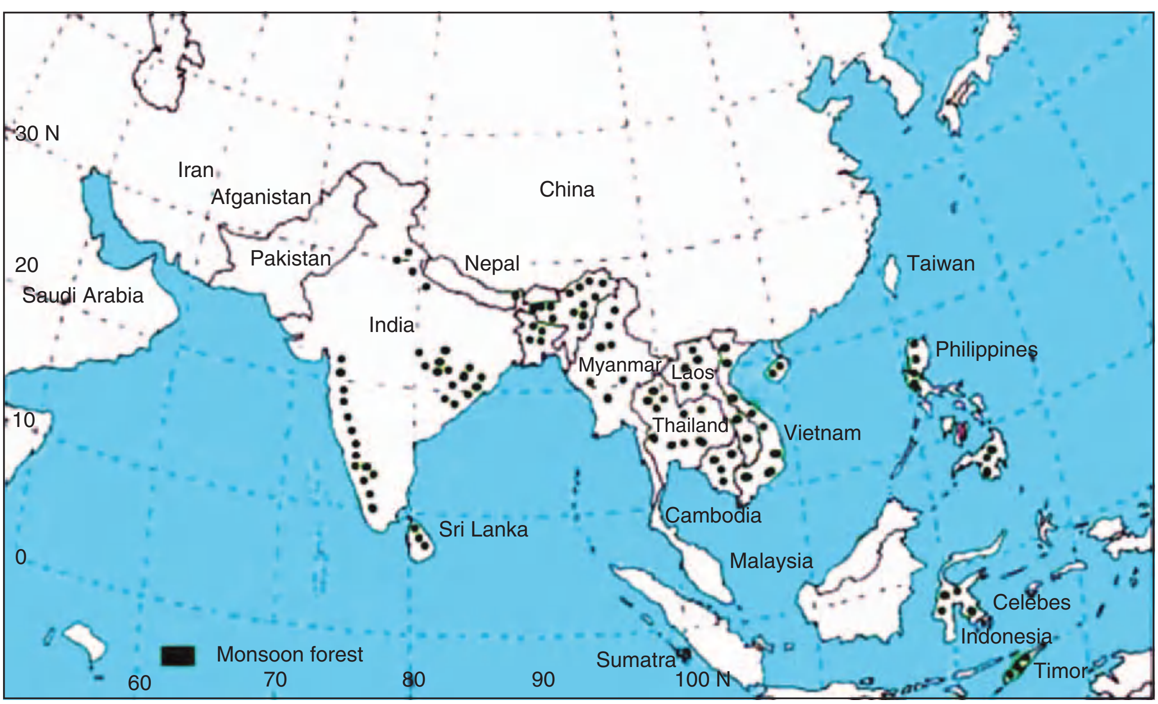

Figure 2 Distribution of monsoon forests in South and Southeast Asia.

Table 1 Total forest area, monsoon forest area and its percentage in different South and Southeast Asian countries

Country	*Total forest area (km²)*	*Monsoon forest area (km²)*	*Percentage*
Bangladesh	14 042	645	4.6
Cambodia	113 250	47 750	42.16
China	24 200	17 050	70.5
India	228 330	158 950	69.6
Western Ghats	38 610	18 410	47.6
NE India	82 490	38 780	47.0
Andaman and Nicobar Islands	6840	3620	52.9
Other parts	100 390	98 140	97.8
Indonesia	1 179 140	30 740	2.8
Lesser Sunda Islands	14 590	13 690	93.8
Sulawesi	11 240	8120	72.2
Moluccas	56 070	8930	15.9
Laos	124 600	25 810	20.7
Myanmar	311 850	88 460	13.4
Philippines	66 020	15 280	23.1
Sri Lanka	12 260	10 820	88.3
Thailand	106 900	31 500	29.5
Vietnam	5680	19 510	34.4

forest. This is because Java, Kalimantan, and Sumatra, are devoid of this forest type, even though about 90% of the total forest area of the Lesser Sunda Islands is covered by monsoon vegetation. With regard to China, even though 70% of the total forest area of the country is occupied by monsoon vegetation, only a very limited part of it is located in South Asia. In the case of Bangladesh, mangrove forests are well represented, with approximately 4.6% of the total forest area occupied by the much-degraded monsoon vegetation. The Pacific island of Papua New Guinea, beyond the limit of Southeast Asia, is also very poor in representation of monsoon forests, with less than 1% of the total forest area of the country belonging to this vegetation type. On the whole, approximately 57% of the total forest area in different countries of South and Southeast Asia comprises monsoon forests.

In Sri Lanka in the Indian Ocean, more than 88% of total forest area is occupied by monsoon forests. Tropical rainforests of the evergreen and semievergreen types, common in neighboring peninsular India, are rather restricted to the southwest corner of the island, where annual rainfall ranges between 4000 and 5000 mm and the altitude exceeds 1000 m above msl. The monsoon vegetation of Sri Lanka is distributed in the northern, northwestern, and eastern rain shadow parts of the country (**Figure 3**). Degraded thorn and scrub forests are common here. Human interventions in the forest area have drastically transformed the original vegetation of the country and the establishment of tea plantations is one of the major reasons for this. Remnants of mangrove forests are also represented in the island (about 10% of the total forest area).

Figure 3 Distribution of monsoon forests in Sri Lanka.

Southern and northeastern parts of India and the Andaman and Nicobar Islands contain monsoon forests, often sharing or merging their borders with the rainforests (**Figure 4**). In peninsular India, monsoon forests are distributed along both the western margins and eastern side of the Western Ghats, where rainfall is very meager or absent for a few

Figure 4 Distribution of monsoon forests in mainland India.

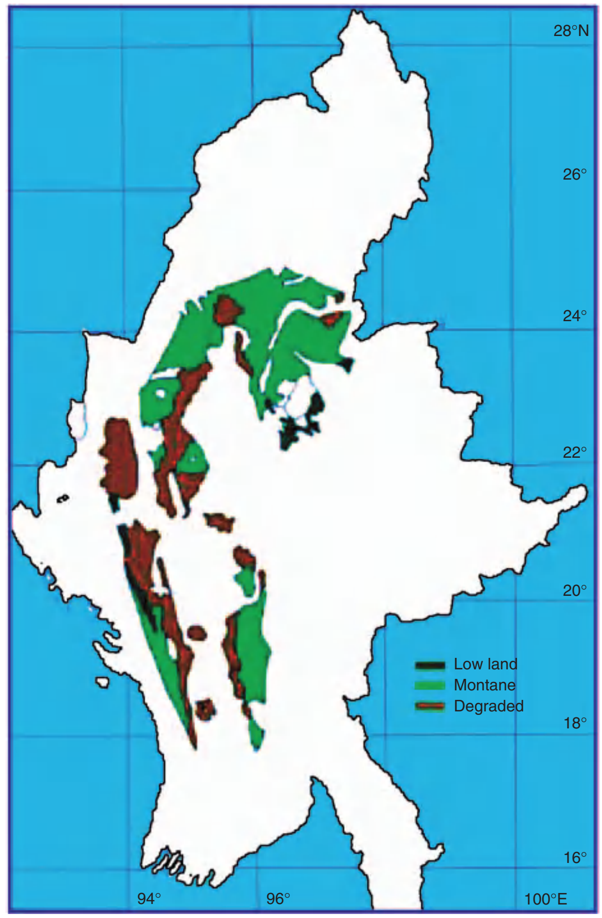

Figure 5 Distribution of monsoon forests in Myanmar.

months. In the northeastern part of the country, bordering Bangladesh and Myanmar, monsoon sal forests are common, often restricted or degraded by the Jhum or shifting cultivation. In the case of the monsoon forests of the southern part of India, degradation is taking place mainly due to encroachments and conversion of forest areas for nonforestry purposes, as well as the unregulated exploitation of timber and nontimber resources, of both plant and animal origin. The monsoon forests of Bangladesh are a continuation of the forest type in northeastern India and are restricted to the inland plains of the country, mainly distributed in the Madhupur tract. Also, relicts of the forest type occur in Dhaka, Mymensingh, and Tarigail forest tracts in the northern part of the country. Sal forests dominated by *Shorea robusta* trees characterize the vegetation type in Bangladesh, which at present is in a highly degraded condition. The major forest type of the country is the Mangals (mangrove forests), distributed along the estuaries and seashores.

Rainforests dominate the vegetation types of Myanmar, distributed along the west-facing slopes of the south–north running mountains, in the western and eastern frontiers of the country, either as evergreen or semievergreen formations. In the rain shadow Irrawadhy plains, on the western side of Myanmar, the characteristic vegetation type is dry deciduous woodlands, dominated by dipterocarp trees, interspersed by thorn forests. Surrounding this zone, monsoon forests are distributed along the eastern flanks of Arakan Yoma and the Chin Hills (**Figure 5**). In the Shan Plateau also, the forest type is distributed towards the east of Salween and towards the south, covering the hills bordering Thailand. Adjoining Myanmar, in the southern part of the mainland of the People's Republic of China, monsoon forests are distributed in areas of limestone substratum, in southern Guangxi. The Island of Taiwan close to the Chinese mainland is devoid of monsoon forests and rainforests are quite prevalent there. However, in the island of Hainan, within the South Asian region, monsoon forests are well represented. Moreover, approximately 70% of the total forest area of China is comprised of monsoon forests; the remaining 30% is composed of lowland and montane rainforests (**Figure 6**). However, most of the monsoon forest areas of mainland China fall in central Asia and not in the southern part of the continent.

In Indochina, along the eastern side of the Mekong river and in the northern part of Tonle Sap, extending to the border of Thailand and the Laos PDR, monsoon forests are distributed in

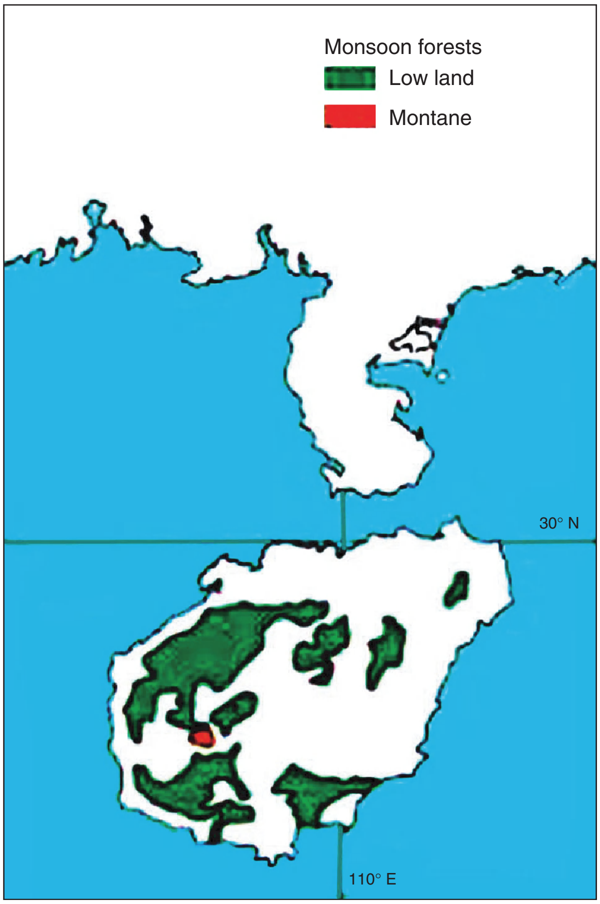

Figure 6 Distribution of monsoon forests in Hainan (PR China).

Cambodia (**Figure 7**). A variety of dense, dry, deciduous and semideciduous woodlands represents the forest formation of the country. The monsoon forests of Cambodia are in a badly devastated and degraded state due to shifting agriculture and fire which transformed the vegetation into open savannas and woodlands. In Laos PDR, monsoon forests are distributed in areas north and west of Mekong and are characterized by the dominance of teak trees of high timber value (**Figure 8**). In the past, more than 50 000 km^2 of the forest area of the country was occupied by monsoon forests, covering the drier parts where 5–6 months of dry weather prevail. However, more than 70% of the natural forests of Laos are constituted by rainforests of both evergreen and semievergreen types which, in many areas, are replaced by monsoon forests due to human and other disturbances, including shifting cultivation. In Vietnam, dipterocarp-dominated lowland evergreen forests are more common in the southern parts of the country, whereas monsoon forests are distributed towards its northern side (**Figure 9**). Almost 45% of the total forest area of Vietnam comprises monsoon forests, where deforestation is a serious problem consequent to migration of people, plantation forestry, and war damage. The rich mangrove wealth of the country, including the *Melaleuca* forests, was also devastated during the much-prolonged Vietnam war and only their remnants remain at present, along the banks of the Red river. Application of the devastating herbicide Agent Orange was highly detrimental to the natural forests of the country, for both mangroves and land vegetation.

Towards the southeastern part of the Asian continent, namely Thailand, monsoon forests are common in the northern parts, bordering Myanmar. However, the adjoining peninsular Malaysian region is predominantly covered by typical rainforests of both evergreen and semievergreen types. At present, the monsoon teak forests of Thailand are in a highly degraded condition (**Figure 10**). Dry deciduous woodlands with species of dipterocarp also occur in the northern and eastern parts of the country. Heath forests, limestone vegetation, freshwater swamps, and beach forests are other vegetation types of Thailand, apart from the complex and very varied montane rainforests, dominated by genera of temperate plants like *Castanopsis, Lithocarpus*, and *Quercus*. The Himalayan species *Betula alnoides* is also common in the rainforests of Thailand.

In the Lesser Sundas, Sulawesi and Malacca near to Irian Jaya, which is the southeastern limit of the Asian continent, about 30 000 km^2 of monsoon forests are distributed. However, in Java, Kalimantan, Sumatra, and also Irian Jaya, the forest type is not very prevalent. In the northeastern part of Java, monsoon forests were seen in the past, in a highly disturbed state. In the Lesser Sunda Islands, monsoon forests and grasslands are restricted to the south-facing sides of the mountain, where sandalwood (*santalum album*) forests are common, similar to that of the dry deciduous forest tracts of southern peninsular India (**Figure 11**). In Sulawesi, the forest type is fairly well represented in the southern part and in Irian Jaya eucalyptus forests and grasslands are more common. Beyond the Southeast Asian limit, in the Pacific Islands of Papua New Guinea, less than 1% of the total forest area is occupied by the monsoon forests; this is the eastern limit of the forest type of the world. In the chain of the Philippine islands, the northernmost Luzon Island contains monsoon forests along the centrally located Mount Data, running in a north–south direction. Also, in Zambales, along the Carapello mountains, towards the western side of the island, disturbed patches of this forest type occur. In southernmost Mindanao also, degraded monsoon forest patches are common towards its western side (**Figure 12**). Both lowland and montane types of forest formations are common

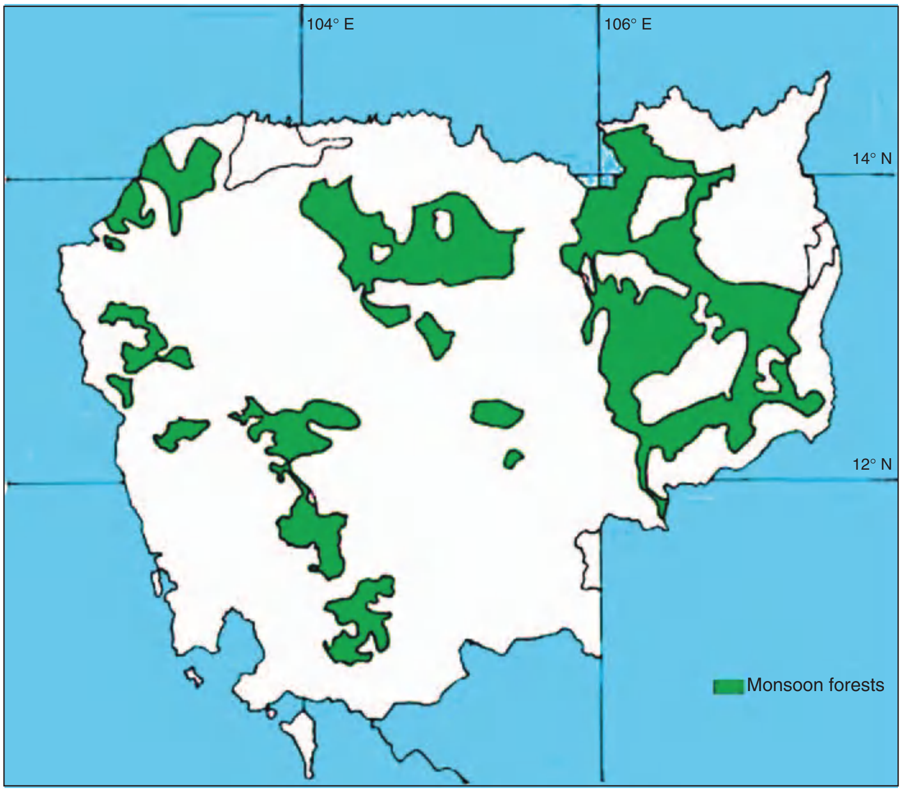

Figure 7 Distribution of monsoon forests in Cambodia.

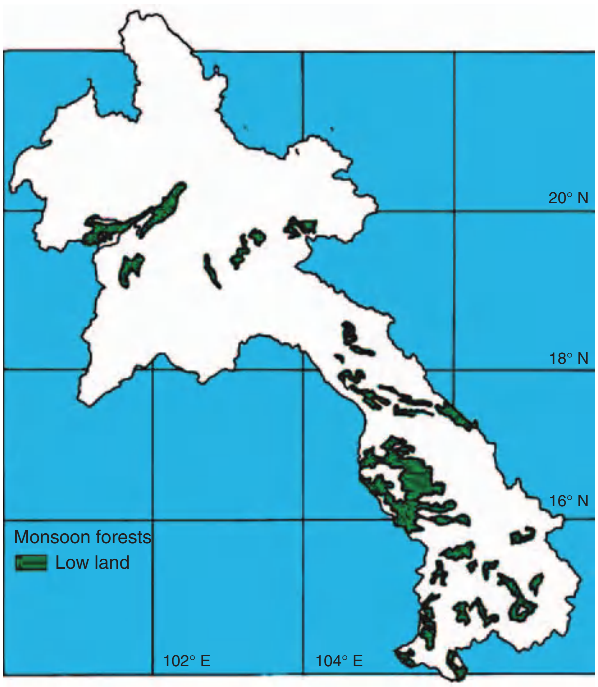

Figure 8 Distribution of monsoon forests in Laos.

in these islands, dominated by two species of pine (*Pinus kesiya* and *P. menkusii*). Forests of Molave are also, in general, monsoon formations, developed in well-drained limestone soil, behind the beach or mangrove formations. The forest type here is characterized by the preponderance of *Vitex* trees belonging to the teak family (Verbenaceae).

Structure and Composition of Monsoon Forests

In South and Southeast Asia, both lowland and montane monsoon forests occur. Also, there are different local formations within the forest type, depending on topography, climate, and soil. The structural and floristic composition of the monsoon forests of South and Southeast Asia differs greatly from the adjoining rainforests of the region. If lofty trees of dipterocarps dominate the rainforests of Southeast Asia, this type of tall tree is less frequent and more stunted in nature in the monsoon forests there. The typical tree species in the monsoon forests of Southeast Asia belong to genera such as *Acacia, Albizia, Borassus, Butea, Caesalpinia, Cassia, Corypha, Dalbergia, Dichrostachys, Feronia, Garuga, Homalium, Lannea, Melia, Schleichera, Stereospermum, Tectona,* and *Tetrameles*. Australian plants, including species of *Banksia, Eucalyptus*, and *Grevillea*, are also common in the monsoon forests of the Lesser Sunda Islands. *Santalum album* and *Melaleuca leucodendron* are other Australian elements found

Figure 9 Distribution of monsoon forests in Vietnam.

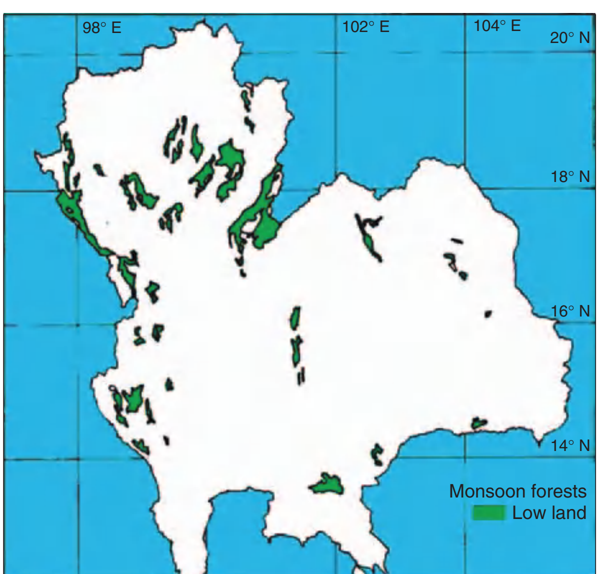

Figure 10 Distribution of monsoon forests in Thailand.

in the monsoon forests of the Lesser Sunda Islands and the former is also common in peninsular India. There are also several endemic species in the monsoon forests, e.g., species of *Semicardium* in Malaysia and *Dalbergia* in peninsular India. However, many plants in the monsoon forests in South and Southeast Asia enjoy wider ranges of distribution from India to Australia or even beyond, as in the case of the tamarind tree (*Tamarindus indica*), distributed in both African and Asian continents. In the monsoon forests of the region, there are also plant species which prefer wet conditions, e.g., fern species belonging to the genera *Dicranopteris* and *Gleichenia,* and the moss flora on the mountains clothed with monsoon forests. However, drought-resistant species dominate the forest type and, apart from the cultivated sugarcane which needs only seasonal dryness, several drought-hardy members of the family Fabaceae are quite prevalent in the forest formation. Due to the highly fragmented nature of monsoon forests, stemming from climatic and degradation factors, many plant groups characteristic of the forest type show regional or national breaks in their total range of distribution, resulting in the phenomenon called disjunctive distribution. For the same reason, many endemic plants are also common in the forest type. Extensions of many species beyond their regional range is mainly due to the fact that the forest type itself was of much greater extent in the past, favoring the distribution of xerophytic plants between countries or regions such as India in South Asia and Indonesia in the southeastern part of the region. Euphorbiaceous plants (e.g., species of *Blackia, Melanolepis*, and *Phyllanthus*) are also common in the seasonal dry parts of Southeast Asia, including Kalimantan. Therefore seasonal drought is one of the major factors that influence the distribution of plants, especially those species characteristic of the monsoon forests.

In South Asia, moist deciduous forests are prevalent in India, especially in the northeastern and peninsular regions. The forest type is also common in Myanmar, western Thailand, and in the central part of the Philippines. The formation has its characteristic teak (*Tectona grandis*) trees in Myanmar and Thailand, in association with species of *Lagerstroemia, Pterocarpus*, and *Terminalia*. In Myanmar, depending on the altitude, upper moist deciduous forests are identified on the flat plains above flood level, composed of species like *Homalium tomentosum, Tectona grandis*, and *Xylia dolabriformis*. The lower-level moist deciduous forests of the country, developed in rich soils, are in a devastated state, mainly due to the cultivation of paddy (rice). Unlike the upper moist deciduous forests, low-level

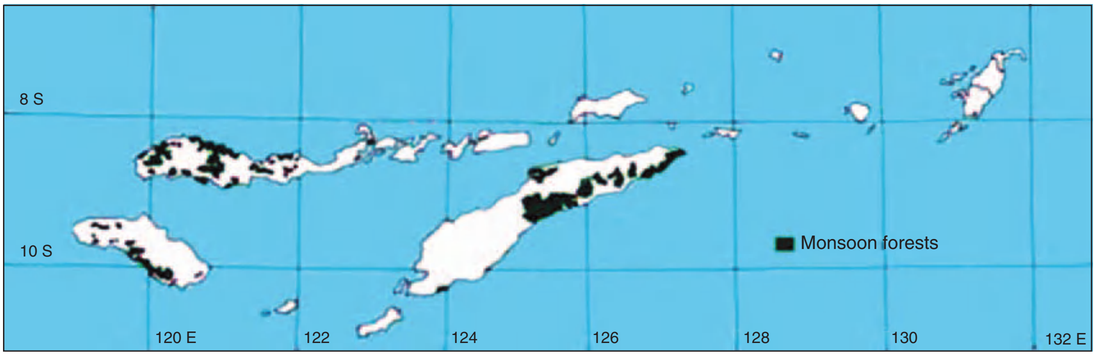

Figure 11 Distribution of monsoon forests in Lesser Sunda Islands and adjacent islands (Indonesia and East Junor).

Figure 12 Distribution of monsoon forests in the Philippines.

Figure 13 Moist deciduous forests of India.

monsoon forests, in general, are devoid of bamboo species, even though the climbing bamboo *Oxytenanthera* is common to both formations. In the southern part of Myanmar, moist deciduous riverine forests and moist clay-soil forests of quite different floristic compositions are distributed. In the Indian subcontinent and Sri Lanka, moist deciduous forests dominate all other monsoon forest types, even though, in Bangladesh, mangrove forests are more widely distributed. Teak forest is a very notable formation of the monsoon forest type, which is very important economically, because of the timber value of the dominant species. Teak forests are also quite prevalent in the central part of India, whereas, towards the peninsular and North-eastern part of the country, the representation of the species is much less (**Figures 13** and **14**). The *Albizia–Xylia–Pterocarpus* association is more common in the south and *Shorea–Schima* trees are quite prevalent in the northeastern parts of the country. In the Andaman Islands, it is the *Pterocarpus–Terminalia–Canarium* association that is characteristic of the monsoon forests. In Sri Lanka, dry-zone evergreen forests are widespread and these are also found in the eastern part of the Deccan peninsula (India), in fragments. In southeastern Indochina, species of *Chloroxylon, Drypetes, Feronia,* and *Manilkara*, dominate the monsoon forests with associated scrub composed of species of *Bauhinia*, *Cassia,* and *Dichrostachys*. *Acacia* thorn scrub is also common there, in heavily disturbed areas. The monsoon forests of Sri Lanka are also characterized by a high degree of endemism and is the major habitat of the Asian elephant. However, more than 75% of the forest type of the island is in a highly degraded state, and a network of protected areas has been established to preserve the forest formation and its biodiversity.

Figure 14 Buttressed trees in monsoon forests.

Biodiversity, Endemism, and Conservation

South and Southeast Asian countries are very rich in biodiversity and endemism. They are also the centers of origin of many cultivated plants and domesticated animals. Forests of the region contain gigantic trees like dipterocarps and terminalias on the one hand and rich and diverse shrub and herbaceous ground flora on the other. Reputed timber trees such as teak, rosewood, and sal, medicinal and other nontimber forest produce plants of arborescent or herbaceous habit, while plants yielding paper and handicraft raw material including bamboos and canes, horticultural plants like orchids and ferns, epiphytic species of both flowering and nonflowering plant groups, creepers, herbaceous and woody climbers form part of the forest type in the region. The Asian elephant, lion, tiger, panther, mountain goat, monkeys, birds, insects, reptiles, and thousands of other terrestrial and arboreal fauna represent the rich and diverse faunal heritage of the monsoon forests of the region. In South and Southeast Asia, India, Indochina, and Malesia are the main biodiversity-rich regions, and specific floristic and faunistic accounts are also available for almost all the countries in the region.

There are no separate estimates available on the biodiversity of the different ecosystems (monsoon forests, rainforests, and savannahs) in the region. **Table 2** gives details of total numbers of plant and animal species in different countries of South and Southeast Asia and also which are threatened with extinction or genetic impoverishment. It may be

Table 2 Total and endangered plant and animal species in different countries of South and Southeast Asia

Country	*Plants*		*Animals*	
	Total	*Endangered*[a]	*Total*	*Endangered*[a]
Bangladesh				
Cambodia	770	0	1334	41
India	15 000	3120	4735	172

Thailand	514 000	70 711	2.5
Vietnam	329 565	9951	1.2

noted here that all the animal and plant groups are not covered in such estimates; angiosperms among plants, and amphibians, birds, fishes, mammals, and reptiles, among animals are the groups on which more exhaustive data are available for most countries in the region. Moreover, such estimates do not reflect the actual species content of the monsoon forests *per se,* and the data given in **Table 2** provide only an overall picture with regard to the biodiversity status of different South and Southeast Asian countries.

Due to various disturbances to the ecosystem and the habitats of species in the region, several plant and animal taxa, and especially those confined to one country, phytogeographical region or ecological niche, are now listed in one of the threatened categories such as rare, endangered, threatened, or vulnerable recognized by various national and international institutions. In **Table 2**, country-wise details on the representation of such taxa in the region are given and many more such species are likely to be added to the list, once their population status is assessed. It may be noted that monsoon forests of the region, rich in timber and nontimber plants and edible and game animals, have suffered the greatest loss in biodiversity, mainly due to the proximity and accessibility of the forest type to human habitations and suitability of the area for agriculture and plantation establishment, as well as from fire and other natural and anthropogenic causes. Also, the food and other habits of people living in the region have influenced the conservation status of the floral and faunal wealth of the region. In order to protect biodiversity, countries in South and Southeast Asia have established conservation areas like wildlife sanctuaries, national parks, biosphere reserves, World Heritage Sites, Ramsar sites, Man and Biosphere sites. Details of the extent of protected areas in relation to the total forest area of different countries in the region are given in **Table 3**. Also, the annual deforestation data given for various countries indicate the pace of loss in biodiversity. Available data point to the fact that deforestation is occurring faster in Laos, Philippines, Thailand, and Vietnam than in Cambodia, Indonesia, and Myanmar, all of which are neighboring countries. Moreover, in the South Asian countries of Bangladesh, India, and Sri Lanka, the deforestation rate will be greater due to various factors, including increases in population and the consequent escalation in demand for land, plant, and animal resources.

The International Union for the Conservation of Nature and Natural Resources (IUCN) has prepared *The Red Data Book* on plant and animal species throughout the world, identifying those belonging to different threatened categories. This is mainly intended to promote a conservation program for such species in order to save them from total extinction. Also, the protected-area network in South and Southeast Asian countries, established in representative ecosystems, including the monsoon forests, can facilitate the preservation of dwindling populations of many such species, in addition to the overall conservation of the ecosystem.

Myristicaceae

J P Janovec, Botanical Research Institute of Texas, Fort Worth, TX, USA
R García, St Louis, MO, USA

Introduction

The Myristicaceae is a pantropical family of trees found in Central and South America, Africa, Madagascar, India, and Asia. The family consists of 20 genera and at least 500 species. Floristic and ecological studies have revealed that the Myristicaceae rank among the top five to ten most common and important tree families throughout the majority of the lowland moist tropical forests of the world, where the family has significant ecological importance. Fruit of the Myristicaceae, particularly the lipid-rich aril surrounding the seed in some species, are important as food for birds and mammals of tropical forests. Numerous species are valued by humans as sources of food, medicine, narcotics, and timber, including *Myristica fragrans*, the source of nutmeg and mace, the spices of commerce.

Throughout the geographical range of Myristicaceae, aromatic leaves, often stellate pubescence, a unique arborescent architecture (**Figure 1**), and sap the color of blood (**Figure 2**) are characteristics that strongly enhance recognition of this family in the field. Species of this family are usually dioecious. Flowers are tiny and found in paniculate inflorescences, with filaments of stamens fused into a column, giving rise to either free or fused anthers (**Figures 3** and **4**). Fruits are one-seeded, dehiscent or indehiscent, and are notable for the typically red arillate covering around the seed.

Taxonomy and Genetics

There are about 500 species of Myristicaceae in 20 genera, restricted to individual continents (**Table 1**). Nutmeg trees first appeared in the earliest botanical works dealing with the East Asian region, and in 1742 Linnaeus established the genus *Myristica*, which remained a broad concept and the only genus in the family until 1856. Warburg produced the first

and last major global treatment and the first phylogenetic tree of the Myristicaceae, and divided the sections of *Myristica* into many of the genera currently accepted. All modern authors include the Myristicaceae within an ancestral lineage of dicotyledonous flowering plants which includes families such as the Magnoliaceae, Canellaceae, Winteraceae, and Annonaceae. Analyses of nucleotide sequences from the chloroplast gene *rbc*L have generated support for this placement. Attempts have been made by Sauquet *et al*. to reconstruct the intergeneric phylogeny within the Myristicaceae. Basic studies of species diversity are needed within each genus to better understand relationships, character evolution, and classification of the family.

Various authors have overviewed the geohistorical setting of Central and South America, so far as it is known. Africa and South America began to separate during the Jurassic approximately 140 million years

before present (BP). By about 90 million years BP, the two continents were completely separated and life on each took its own course. The center of origin for the Myristicaceae may well be South America, or in a geohistorical context, West Gondwanaland of the early Tertiary or late Cretaceous (about 100–70 million years BP). With this in mind, and since the family is present on all Gondwanaland-based continents that currently have tropical forest (South America, Africa, Madagascar, India, Southeast Asia), it can be hypothesized that the Myristicaceae had diversified before the separation of South America and Africa.

From the point of complete separation (about 90 million years BP), the neotropical Myristicaceae evolved on the South American land mass independently from members of the family which currently occur in Africa or elsewhere on the Gondwanan geoplex. It is truly hard to tell what pathways were taken during such a long period of time. However, the genera of the Myristicaceae have evolved in three major regions (Americas, Africa–Madagascar, and India–Asia).

Ecology

Floristic and ecological studies have revealed that the Myristicaceae rank among the ten and often five most common and thus important tree families in lowland moist tropical forests of the world. In the American tropics, the Myristicaceae is one of the eleven families – along with Fabaceae, Lauraceae, Annonaceae, Rubiaceae, Moraceae, Sapotaceae, Meliaceae, Arecaceae, Euphorbiaceae, and Bignoniaceae – that contribute about half of the species richness of any lowland forests and this pattern is present in some samples of Africa and Asia as well.

The center of diversity of the Myristicaceae in the Neotropics is the Amazon basin, represented by *Virola* with a few species reaching Central America. The genus *Otoba* has its center of diversity and endemism in the Chocó region of northwestern South America. *Otoba* has five species in this area and additional species in Panama and another widespread in Amazonia. *Myristica* has its center of diversity in the Malayan peninsula and New Guinea, and *Knema* is dominant in Borneo. In many forests of South America the Myristicaceae are very conspicuous and form an important element of its rich flora. Some pacific tropical forests in Colombia are dominated by *Otoba gracilipes*, *Virola reidii*, and *V. sebifera*. In an inventory of various types of Amazonia terra firme forests in Peru, *Iryanthera juruensis, I. macrophylla, I. paraensis, I. polyneura, I. tricornis, I. ulei, Virola calophylla*, and *V. pavonis* were the most common species. The importance index values in this study showed that the Myristicaceae was largely higher than the other tree families with a preference of well-drained terra firme soils. More recently, Myristicaceae was found to have exceptional numbers of common species in Manu National Park (Peru) and Yasuni National Park (Ecuador).

Although most species of the family in neotropical forests occur on rich soils, some are restricted to higher-stress habitats. For example, *Virola pavonis* is one of the most important species on the nutrient-poor white sand soils around Loreto, Peru. *Virola surinamensis* is common to swampy areas of lowland Amazon forests where it forms associations with the palm *Maurita flexuosa*. Aerial or stilt roots are one of the adaptations to anoxic, inundated soil exhibited by this species (**Figure 5**). *Virola steyermarkii* is reported endemic for the montane tepui forests in Venezuelan Guayana.

The family is poorly represented at higher elevations. In an analysis of the floristic composition and diversity of Amazonia and the Guiana Shield, it was found that Myristicaceae occurs in high density in terra firme forests of western Amazonia. This diminished in Central Amazonia, eastern Amazonia, and the Guiana Shield, suggesting an increase in the abundance and diversity of the family from the Guianas toward Western Amazonia. This difference may be due in part to richer soils present at western Amazonia in comparison to other sites where a different suite of poor-soil-tolerant plants dominate: Chrysobalanaceae, Burseraceae, and Lecythidaceae among others. In a study of several 1-ha forest plots in Amazonia and Central America, the

Figure 5 Aerial or stilt roots of *Virola surinamensis* growing in a *Mauritia flexuosa* palm swamp of the Peruvian Amazon. Courtesy of John Janovec.

late Alwyn Gentry found that Yanamono and Mishana forest preserve areas in northern Amazonia of Peru presented a higher representation in Myristicaceae than Central America. In La Selva (Costa Rica) and Barro Colorado Island (BCI, Panama) forest plots, Myristicaceae is not one of the most diverse tree families.

Many xeromorphic features (thick cuticle, a dense tomentum, sunken stomata) are present in Myristicaceae in spite of its present-day humid tropical forest distribution. This may be indicative of a wider ecological amplitude than the current distribution. The presence and type of pubescence are useful for differentiating the genera in the family; this character has been used since the pioneering studies of this family prior to 1900. It has been hypothesized that the hairs function as protection against herbivory and regulate the physiology of the water in the plant.

Most species of Myristicaceae are trees occupying the middle-story of canopy in the forests. For example, *Virola surinamensis* is a large tree, attaining 30 m in height and 1 m in diameter at breast height (dbh), generally with a straight, cylindrical trunk above the buttressed roots. Other species in the family reaching or exceeding the canopy are: *Virola duckei*, *V. pavonis, Otoba glycicarpa*, and *Osteophloeum platyspermum*. Most *Iryanthera* and *Compsonera* species are treelets or medium-sized trees.

Figure 6 Fruit of *Compsoneura mexicana* from Belize, showing the two-parted dehiscent orange fruit at maturity and the red aril covering a black-mottled seed. Courtesy of John Janovec.

One of the most noteworthy features of the Myristicaceae is its branching architecture corresponding to the Massart model (**Figure 1**). This branching pattern may enable the family to better survive the dynamic conditions of tropical forests. This is especially important during younger stages of growth and establishment for efficient use of forest resources, to allow recovery from traumatic events, and for adjustment to environmental changes in the struggle to reach the canopy.

The small, pale flowers common in the family are presumed to be pollinated by small insects. *Myristica fragans* is pollinated by small nocturnal beetles. Both the male and female flowers are strongly scented and pollen is the only reward. *Compsoneura sprucei* (= *C. mexicana*) has been reported to be pollinated by thrips, based on studies in Costa Rica. In the Asian tropics, *Myristica myrmecophylla* has an association with ants that may play a role in pollination.

The principal dispersers of the family are thought to be birds because of the attractive arillate seeds (**Figure 6**). But this assumption has been challenged in recent studies showing that spider monkeys act as principal dispersers of *Virola calophylla* in the southern Peruvian Amazon. In the Old World, rodents occasionally act as dispersers. Observations in Belize suggest that rodents may act as secondary dispersers, which may account for the camoflauge mottling found on seeds of *Compsoneura mexicana* (**Figure 7**), which are difficult to see in the leaf litter on the forest floor.

Figure 7 Black mottled seeds of *Compsoneura mexicana* from Costa Rica. Courtesy of John Janovec.

Silviculture

As a family primarily of trees, many species of Myristicaceae have been studied in experimental plantations. In Brazil, *Virola surinamensis* has been studied with silvicultural methods. However, few of these studies have been adopted by the industry and an unfortunate consequence is that much of the lumber is coming from the forests. In the Peruvian Amazon it is becoming more common to see timber from *cumala*, the vernacular name for species of Myristicaceae. Some of the more valuable species are: *Otoba glycicarpa*, *Virola pavonis*, *V. duckei*, and *Osteophleum platyspermum*. Seeds remain viable for a limited period of time and germinate in damp, shady environments offered only by tropical old growth forest. Seed germination trials conducted using *Compsoneura* and *Virola* seeds from Central America showed that some seeds can take up to 6 months to germinate in a greenhouse setting.

Utilization

Economically, the most important species, *Myristica fragrans*, is Asiatic and is widely cultivated as the source of nutmeg (the ground seed) and mace (the dried aril). This species is also cultivated in areas of Central America and the Caribbean. Some species are used in the timber industry, such as *Virola surinamensis* in Brazil, and *Otoba gracilipes*, *V. reidii*, and *V. sebifera* in Colombia. In the American tropics, species of the Myristicaceae have been valued as sources of food, medicine, and narcotics. Amazonian Indians utilize the dried sap and ground inner bark of numerous Myristicaceae species (*Osteophloeum platyspermum*, *Virola calophylla*, *V. cuspidata*, *V. duckei*, *V. elongata*, *V. pavonis*, *V. sebifera*, and *V. surinamensis*) to make hallucinogenic snuffs used in spiritual ceremonies and as medicine in the treatment of various ailments. In the Venezuelan Guayana region, the wood of *Iryanthera lancifolia* is used for lumber and the reddish sap of *Virola surinamensis* is used to seal wounds. *Virola surinamensis* is also valued as timber, especially in the plywood industry. Some species yield essential oils and fats that have been used in perfumery and in making candles. It has been suggested that nutmeg produces hallucinations when ingested by humans, but this has been criticized as a myth.

Tropical Dry Forests

S J Van Bloem and P G Murphy, Michigan State University, East Lansing, MI, USA
A E Lugo, US Department of Agriculture Forestry Service, Río Piedras, Puerto Rico, USA

Introduction

Tropical dry forests occur in nearly every tropical country. This forest type provides critical habitat for large mammals and migratory birds, and patches of dry forest can support a high proportion of endemic plant and animal species, as well as being highly valued for agricultural and production forestry uses. Consequently, conservation and understanding of these forests need emphasis, yet conservationists and scientists still frequently overlook this ecosystem.

Distribution and Definition

Dry forests comprise 42% of all tropical forests – the largest proportion of any forest type. They can be found as large continuous tracts, particularly in India, Mexico, eastern South America, northern Australia, and Africa, or in smaller, more local areas. Smaller tracts grow in rainshadows of tropical islands, Central America, and western South America (**Figure 1**). Coastal environments support dry forest when elevation is too low to generate rainfall from orographic uplift of ocean air masses.

Tropical dry forests occur in frost-free areas where annual precipitation is 500–2000 mm, mean annual biotemperature is $>17^{\circ}C$, and potential evapotranspiration exceeds precipitation (**Figure 2**). Rain falls in one or two seasons each year, depending on the latitude of the forest, and forests experience 3–10 dry months (<50 mm rainfall) each year. The most important characteristic is the highly variable length of the dry season, seasonal distribution of rainfall, and amount of rainfall. Perhaps the only real constant from site to site is the occurrence of a dry season. Savannas often grow under the same climatic conditions as dry forests, but sparse tree cover and frequent fire in savannas allow grass to dominate.

Typically, dry forests have a closed canopy, but this may not be the case in the driest parts of their range, or if disturbance is prevalent. Due to their variability in climate and appearance, many names are applied to dry forests. These include: deciduous forest, semideciduous forest, semi-evergreen forest, woodland, and dry seasonal forests. Local names are also used: caatinga in Brazil, miombo in southern Africa, and chaco in parts of South America. Southeast Asia has a specific type of dry forest – deciduous dipterocarp forests – dominated by about six species of Dipterocarpaceae.

As a consequence of prolonged dry seasons, tropical dry forests are less complex than wet or temperate forests (**Table 1**). They have one to three canopy layers and short canopies with relatively low leaf area index (3–7) and leaf biomass (2–7 tonnes ha^{-1}). In mature forest, the stems can still be quite narrow, with common diameters in the range of 3–15 cm, and stem densities can exceed one stem per square meter. Trees are frequently multistemmed. Among dry forests, most structural features vary by two to ten times (**Table 1**), with the upper limits overlapping the lower limits in wetter forests, leading to inconsistencies in the scientific literature when classifying forest types. Climate features such as the amount of rainfall or the length of the rainy season can explain canopy height and biomass, but other structural characteristics,

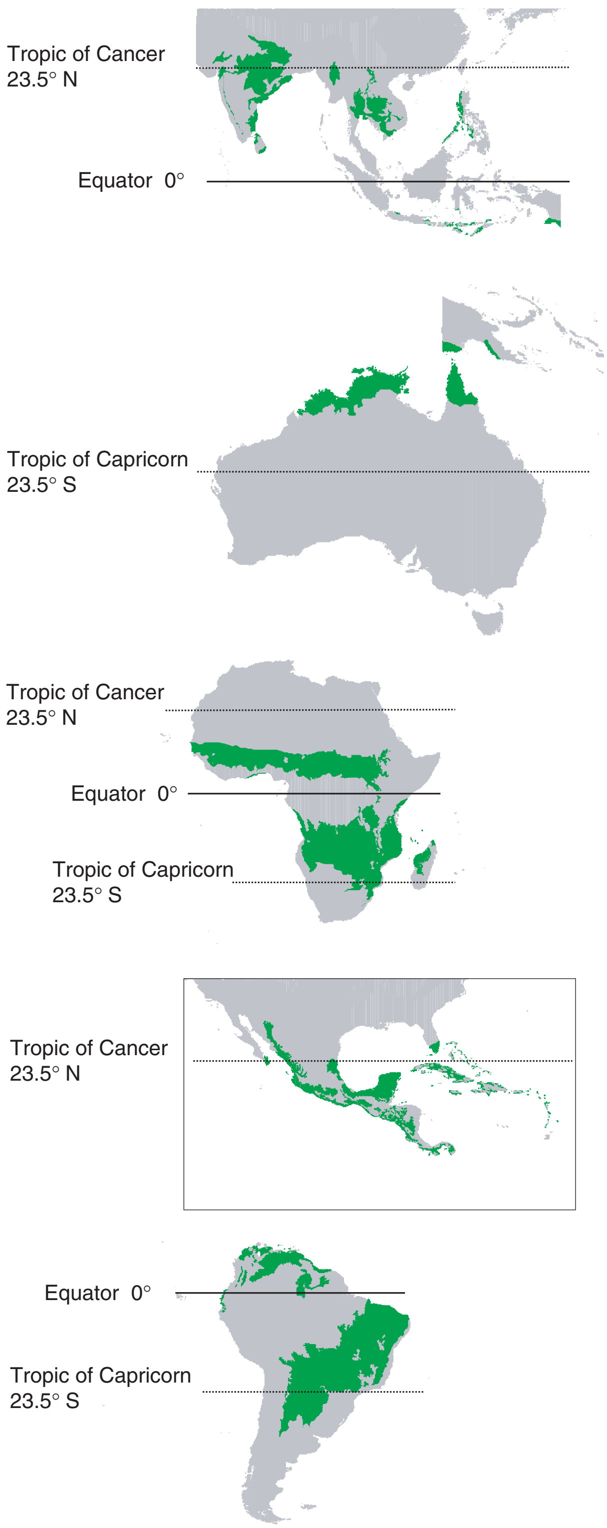

Figure 1 Global potential distribution of tropical dry forests. Highlighted areas are predominantly dry forest, but moist or open forest is interspersed in some areas. Dry forest is also found in many small tropical island nations, including American Samoa, Comoros, Cook Islands, Fiji, French Polynesia, Guam, Kiribati, Marshall Islands, Mauritius, New Caledonia, Palau, Reunion, Solomon Islands, and Vanuatu.

particularly stem density, are often the result of disturbance (see below).

Components of Tropical Dry Forest

Plants

Seasonally dry forest communities worldwide contain a variety of important plant species. Trees valued for lumber include teak (*Tectona*), mahogany (*Swietenia*), sal (*Shorea robusta*), and African mahogany (*Khaya*). Commercially important fruit trees include tamarind (*Tamarindus indica*), mango (*Mangifera indica*), and cashew (*Anacardium occidentale*). Agroforestry projects have planted *Leucaena leucocephala* and *Prosopis juliflora* (mesquite) to improve soils via nitrogen fixation. *Casuarina equisetifolia* (Australian pine) and *Eucalyptus camaldulensis* are native to Australian dry forest and have been introduced in many areas for soil stabilization and wood production. In addition to these species, many others are used for firewood, construction wood, food, and medicinal purposes.

Deciduous trees are usually most common in dry forests, but evergreen species become more important at both the upper and lower limits of the rainfall gradient (**Figure 2**). The frequency of growth forms depends on climate and disturbance. Cacti and euphorbs frequent drier locations while the diversity of lianas and other vines increases with greater rainfall and following disturbances that open canopy gaps. Dry forests have more understory species than tree species but their abundance and biomass is quite low, except in open woodlands.

The high variety of growth forms and numerous physiological adaptations provide tolerance to drought conditions. Dry forest species can maintain metabolism under lower soil and leaf water potentials than temperate or moist tropical species. Dry forests average higher ratios of root to shoot biomass than moist or temperate forests. Though data on root biomass are scarce, 35–49% of root mass is below 10 cm depth as compared to 5–21% in wet forests. In dry forests, maximum root : shoot ratios range from 0.4 to 1.0. In moist forests they rarely exceed 0.25. Cacti and some deciduous tree species store water in succulent stems. The amount of water stored cannot maintain leaves, but supports flower and fruit development prior to the onset of the rainy season.

Water use is influenced by leaf habit (evergreen vs. deciduous), leaf morphology, and wood density. Compared to wetter forests, more dry tropical trees have wood specific gravity greater than 1.0. Dense-wooded and evergreen species have narrow xylem that resists cavitation under dry conditions but

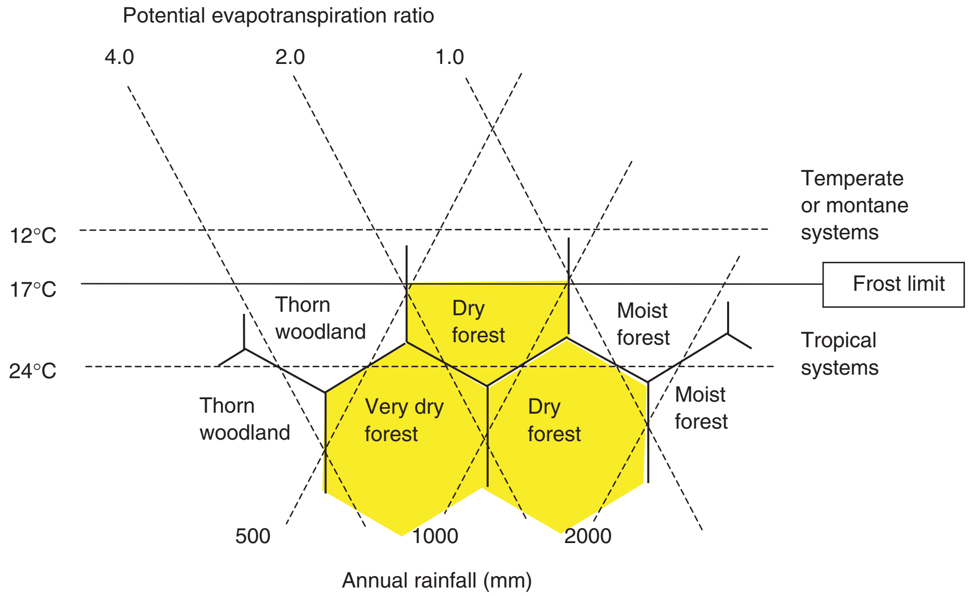

Figure 2 Climate characteristics that define tropical and subtropical dry forest life zones according to the Holdridge life zone classification system. The temperature values represent an adjusted biotemperature. PET ratio is annual potential evapotranspiration divided by annual precipitation.

transports water less efficiently. Light wooded and deciduous species have wider xylem that is more prone to cavitation and greatly reduces water conductance as the dry season progresses, but transports water more efficiently and responds faster to light rains at the onset of the rainy season. Thus, the ability to reduce cavitation during drought is traded for more efficient water conductance. Deciduous species avoid dry season water loss by shedding leaves, usually at the onset of the dry season, while the sclerophyllous leaves of evergreen species have thick cuticles and smaller internal air pockets that resist desiccation. Sclerophylly may increase in plant populations growing under drier conditions, or experiencing nutrient limitation caused by insufficient soil moisture for nutrient uptake and transport. Sclerophyllous trees frequently exhibit high nutrient use efficiency, suggesting nutrient limitation, even when soil nutrient pools are relatively high. Thus, the leaf habit of evergreen species aids in drought tolerance, while deciduousness leads to drought avoidance.

During the rainy season, dry forest trees, regardless of their particular responses to drought, exhibit many physiological similarities. For example, both drought-deciduous and evergreen dry forest species have similar values for carbon assimilation and stomatal conductance. These values equal those found in moist forest trees. When scaled by growing-season days, both dry and wetter forests have similar growth rates, suggesting they all have equally efficient productivity during favorable seasons. This may be expected because trees (with the exceptions of bamboo, arborescent cacti, and some euphorbs) all use C_3 photosynthesis, regardless of their habitat.

Phenology is closely related to the dry season in many cases, but there is a variety of patterns. Most deciduous species lose leaves at the onset of the dry season, but a few are wet-season deciduous (e.g., *Faidherbia albida* and *Jacquinia pungens*). Some species flower and fruit just before the rainy season commences, before leafing out, while others wait until after the rains have begun. Dry forest species generally flower and fruit for shorter periods than moist forest species. Often plants flower for less than 6 weeks – frequently for only the first few days following an isolated rain event or the first significant rain breaking a drought period. As annual rainfall increases on either a regional or local scale, the prevalence of species with wind-dispersed seeds decreases. In general, most species exhibit some pattern of seasonality.

Animals

Larger bodied vertebrates include elephants, large ungulates, and large felines in dry forests of Africa and Asia, jaguar in the neotropics, and monkeys in many mainland areas. In general, reptiles and birds comprise a substantial portion of dry forest fauna. In addition to the many bird species that reside in dry forests year round, dry forests in the neotropics and Africa are essential wintering grounds for many temperate species. For this reason, much of the

international conservation effort in dry forests results from concern for migratory songbirds and raptors. The relatively isolated and compact area of dry forest in western Mexico has had particular emphasis because it is the winter home for the migratory birds from the North American west coast.

Like dry forest plants, animals (both vertebrates and insects) synchronize their activities, such as reproduction, to the seasonality of their habitat. Many species enter a period of decreased activity in the dry season and some change their diets based on seasonal availability or quality of prey. For example, when living in dry forest, the northern tamandua will eat ants in the rainy season, then switch to termites in the dry season, when the termites have a higher moisture content than the ants. Aside from behavioral adaptations to seasonality, many animals have water conserving physiological adaptations as well, such as the production of dry feces.

As in other systems, animals influence plant populations. A wide variety of insects act as pollinators and specialized plant–pollinator systems are common. Vertebrates and termites disperse seed. The former transport seeds stick to their skin or fur, by caching, or in feces. Some species of termites harvest fleshy fruits to provide material for decomposition by symbiotic fungi, which the termites 'farm.' The termites usually throw unused seeds from the fruits out of the nest.

Herbivores include vertebrates and insects, particularly leaf-eating caterpillars, beetles, and leaf-cutting ants. In the neotropics, insects are the main herbivores but this may be an artifact of hunting that has reduced vertebrate populations (e.g., deer). Generally, deciduous dry forests incur greater herbivory than evergreen dry forests. Herbivory tends to be greater in the first half of the rainy season, but not because younger leaves have more nutrients or fewer secondary chemicals. Instead, herbivory decreases as the rainy season progresses, as parasite and predator populations increase, or as larval herbivorous insects mature and stop eating plants. On average, herbivory decreases leaf area from 10% to 17%. Leaf loss due to herbivory appears to decrease fruiting, fecundity, and seed viability in plants but is poorly understood. In addition, about 10% of dry forest plants incur high rates of seed predation, with some species losing nearly 100% of their seeds each year.

Termites play a vital role in dry forest dynamics. Some termite species construct majestic, meters-tall mounds that provide habitat for a suite of other animal species and, in Africa, create locally dry areas with unique tree species composition. Other species of termites live in smaller arboreal or subterranean nests. Many vertebrates and insects exploit termites as an important food source. The ability of termites to collect and process tons of dead plant material every year makes them essential to nutrient cycling in a system where many vectors of decomposition slow or cease in the dry season. Termites hasten decomposition by cutting up litter and move nutrients from place to place in the forest. They also improve soil quality by bringing up leached clay minerals from underground to build their nests.

Soil and Microbes

Dry forest soils vary widely and may be of volcanic, alluvial, or limestone origin – many are lateritic. Soil moisture content falls below field capacity for most of the year. Even during the rainy season, soil moisture drops below field capacity if rains do not occur at frequent intervals. Although leaching is less than in wetter areas, the soils are highly weathered due to their age. Similar to wet forests, the majority of dry forest soils have low nutrient supplies, particularly for phosphorus. Soils from calcareous parent material frequently have high total nutrient concentrations, but an average pH above 7.8 binds phosphorus to calcium and makes it unavailable to plants. Acid soils have high concentrations of iron and aluminum which also bind phosphorus. Conversely, some dry forest soils, particularly younger ones, have high amounts of organic matter and available nutrient pools, leading to high productivity. These soils develop mollic horizons and are found in parts of the neotropics and India. They frequently become converted to agricultural lands. The Brazilian caatinga and some forests on rocky, calcareous soil have a climate favorable for moist forest development, but the soils drain quickly, resulting in edaphically dry habitats.

Shallow or infertile soils tend to support evergreen forests, while deciduous forests generally grow on better soils. Organic matter can build up as humus in such thick litter layers that some soils have been called dryland peats. Soils with lateritic or calcareous crusts provide little habitat for grasses and herbs, supporting greater biomass in trees which can access subsurface moisture reserves.

Research on the soil microbial community of dry forests has lagged behind that in temperate or tropical wet forests, but some patterns have emerged. Like much of the rest of the living community in dry forests, microbial activity decreases greatly in dry seasons. However, termites compensate somewhat for the loss of microbial contribution to decomposition and nutrient cycling in the dry season (see above). As in other ecosystems, symbioses exist between plants and nitrogen-fixing bacteria or mycorrhizae.

Biodiversity

Diversity of dry forest plants and animals tends to be lower than in tropical moist forests, but greater than in temperate forests. Dry forests share a high proportion of their plant families and genera with moist forests, but few species overlap. Little is known about insect diversity. Larger, more mobile animals reside in both habitats, but smaller animals with limited dispersal ability or range tend to be unique to dry forests. Dry forests contain many locally and regionally endemic species of plants and animals, proportionally more than wet forests. Of the 25 hot spots identified by Conservation International as critically important for preserving biodiversity, nine contain tropical dry forest. A general trend of higher diversity in dry forests nearer the subtropics than the equator is well demonstrated in the western hemisphere. Bolivian and western Mexican forests have higher diversities of plants, reptiles, and amphibians than dry forests located at lower latitudes (**Table 2**). Subtropical African dry forests are also more diverse, with the southern region having more species than the northern.

Plant species diversity does not correspond to precipitation in dry forests, but does increase as the ratio of potential evapotranspiration (PET) to precipitation decreases. Low abundance and diversity of epiphytes further distinguish most dry forests from moist forests. Leguminous trees frequently dominate in all regions. Euphorbiaceae, Sapindaceae, and Rubiaceae are commonly found in neotropical dry forests, while Myrtaceae are common in the West Indies, Combretaceae in Africa, and Dipterocarpaceae in some Asian dry forests. The most common lianas belong to Bignoniaceae. Cacti are common in drier neotropical forests, but decrease in abundance as precipitation increases.

Lower animal diversity in dry forests can be explained in part by lower habitat diversity. Dry forests lack niches for frugivorous and semiaquatic species found in moist forests. Dry forests that border wetter forests have greater diversity as some species retreat to adjacent moist areas during the dry season. Seasonal migration of animals between forest types is common in all regions of the world.

Function of Tropical Dry Forest

Functional traits of dry and wet forests differ much less than structural differences. For example, aboveground net primary productivity (ANPP) ranges from 6–16 tonnes $ha^{-1} year^{-1}$ in dry forests and 10–22 tonnes $ha^{-1} year^{-1}$ in wet forests. Only tree growth rates separate distinctly between the two forest types. Diameter growth in dry forests averages

Table 2 Species diversity for tropical dry forests

Species diversity[a]	*Caatinga, Brazil*	*Chamela, Mexico*	*Bolivia*	*Central America*	*West Indies*	*Zambezian Area, southern Africa*	*Thailand and India*
Plants by area		94.3 (0.1 ha)	83 (0.1 ha)	67 (0.1 ha)	52 (0.1 ha)		76 (1.0 ha)
Trees by area	10–47 (0.1 ha)	80 (0.1 ha)	53 (0.1 ha)	51 (0.1 ha)	34–54 (0.1 ha)	95 (0.1 ha)	10–31 (0.2 ha) 42–50 (1.0 ha)
Endemic plants		16%		6%		Up to 35%	
Mammals (endemic species in parentheses)	86 (2)	70 (26)	110 (22)		(29%)[b]		(22%)[b]
Birds (endemic species in parentheses)	<200 (2)	270 (25)	409 (4)		(22%)[b]		(12%)[b]
Reptiles and amphibians (endemic species in parentheses)	47 (1)	173 (74)	80 (low)		(85%)[b]	? (24)	(50%)[b]

Data from Bullock *et al.* (1995); Proctor (1989).

1–2 mm year^{-1} and occurs in one or two pulses per year. In wet forests, diameters increase 2–5 mm year^{-1} and usually grow continuously. The longer, wetter rainy season explains greater growth rates. The overlap in productivity highlights the success of dry forest species in adapting to seasonally xeric conditions.

Characteristics of nutrient cycling in tropical dry forests suggest that many sites are somewhat more fertile than moist forest. N : P ratios in dry forest leaves ($\sim$15 : 1) have lower averages than in moist forest ($\sim$28 : 1), but still exceed plants with well-balanced nutrient supply (10 : 1). Leaf N in dry forests is lower and leaf P similar to moist forests of moderate fertility. Nutrient use efficiency for nitrogen (NUE) and phosphorus (PUE) varies widely among dry forests. Many sites appear to have sufficient nutrient supplies (NUE < 130, PUE < 1600) but other dry forests exhibit phosphorus limitation (**Table 3**).

Dry forests accumulate and store nutrients in surface litter. The residence time can be about 3.5 years for N and over 5 years for P. Microbes alternately immobilize and release these nutrients. Rapid wetting of soils from the first rains burst microbial cells (plasmoptysis), leading to the greatest nutrient release at the onset of the rainy season. This type of release occurs throughout the rainy season because rainfall events are irregularly spaced. Isolated rains after the beginning of the dry season can also cause a nutrient pulse. Where soil microbes immobilize large amounts of nutrients, trees rely on greater amounts of retranslocation before leaf fall to meet nutrient demands.

Dry forest trees associate with either ectomycorrhizae (ECM) or vesicular–arbuscular mycorrhizae (VAM) or both. Mycorrhizae increase water uptake and access forms of phosphorus and nitrogen chemically unavailable to plants. In some forests, such as the dry dipterocarps, ECM species constitute only 10–15% of all plant species, but contribute 30–75% of basal area. The presence of legumes as dominant plants in many dry forests results in the potential for the improvement of soil fertility by N fixation. Limited research suggests that N-fixing trees predominate in areas with low N but can be limited by low available P. ECM are dominant in the driest areas, and both VAM and ECM are common in soils with low P, but patterns in their distribution across soils of varying N concentrations have not been clearly identified.

Disturbance

Disturbance is an important factor in tropical dry forests. Hurricanes bring destructive winds and

floods to some areas, fires affect others, and prolonged or unusually severe droughts threaten all forests. The frequency and intensity of these disturbances can have important effects on dry forest structure and function. High winds from hurricanes result in defoliation and breakage of trees, with long-term consequences for forest structure. Return intervals for hurricanes range from 5 to 100 years. Mature dry forests in the hurricane-prone West Indies tend to have shorter canopies, higher stem densities, and a greater proportion of multiple-stemmed trees than dry forests outside of the hurricane belt.

Fire is a difficult feature to interpret in dry forests. In most locations, even in Africa, fire is not a frequent or severe aspect of the ecosystem. Lightning occasionally starts fires in dry forests, but they are low intensity, small scale, and usually doused by rains. Sparse understory and grass cover limit the intensity of the ground fires that burn leaf litter about every 5–10 years, returning some proportion of nutrients to the soil as ash, while losing others to the atmosphere. Forest floor heterogeneity caused by termite mounds, rock outcrops, and crusty surfaces inhibit the ability of fires to spread. During the last 50 000 years, humans have probably caused the vast majority of fires in dry forest in order to clear land, hunt animals, and burn fallow to encourage new growth for livestock. Frequent burning transforms forests into savanna, shrub, and open woodland – ecosystems more correctly associated with fire. Conversely, humans prevent burning in other forests that naturally would experience ground fires. This alters natural disturbance patterns and can lead to very destructive crown fires sparked by the build-up of litter and underbrush during long fire-free periods.

Dry forests have a particularly long history of human disturbance because they occur in climate regions that are pleasant to live in and favorable for grazing and agriculture. The dry season provides respite from rain and humidity, and reduces populations of agricultural and human pests. Livestock survive well in dry forest areas, and the relatively small trees are easy to clear for agricultural fields. Because of the desirability of dry forest climates, human population densities in these areas exceed 100 km^{-2} globally and are expected to double every 20–25 years.

Human disturbance in dry forests is primarily related to land use change and extractive activities. As in other ecosystems, there are some examples of sustainably managed dry forests, depending on political, economic, and population pressures. Large-scale logging operations affect dry forest primarily in continental locations. Some dry forest species are suitable for plantations but others grow poorly because of infestation by pests (e.g., shoot-boring insects on mahogany in monoculture). Trees are cut for firewood or charcoal production in most regions. Firewood accounts for 80–90% of dry forest harvest. Many trees coppice – an advantage when used for firewood. Unfortunately fuelwood is not regrowing quickly enough to sustain demand in many areas of Africa. The long-term effects of extraction depend on the amount and pattern of biomass removed and the degree of soil disturbance or compaction that accompanies tree harvests.

Conversion of forests to agricultural, industrial, or residential areas completely removes forest cover and disrupts roots and soil structure. Traditionally, shifting agriculture has been practiced in dry forest regions in a sustainable manner, but increasingly short fallow periods prevent re-establishment of the forest. Grazing and agriculture increase nutrient loss from the system by erosion. Grazing reduces forest biomass because cattle reduce understory growth while compacting the soil and accelerating erosion. Approximately 32% of the area that once was dry forest remains, with continuing annual losses of 0.7–1.5%. The highest deforestation rates occur in Africa, even though population densities in dry forests there are only one-fifth of those in Asia. This trend continues in most areas, but in some locations where economies have turned from agriculture to manufacturing, land is reverting back to forest. This is the case in Puerto Rico, Cuba, and the Gambia.

Response to Disturbance

The ability of dry forest to tolerate disturbance, whether natural or anthropogenic, depends on disturbance type, frequency, duration, and severity. The forest that regrows following disturbance may resemble the original, or differ greatly in terms of function and composition. In general, dry forests exhibit a high rate of resilience, defined as the rate at which a forest stand recovers from large, infrequent disturbance. Compared to other forests, succession in dry forests progresses quickly, and in some cases this can lead to expansion into other systems. In Mexico, clearing of large tracts of rainforest resulted in a drier environment that was subsequently recolonized by dry forest.

Dry forests in Puerto Rico have provided a location to compare response to natural and anthropogenic disturbances. The forest recovered similarly from the effects of a recent hurricane and small-scale tree cutting for charcoal production in the past. Both resulted in patchy loss of <25% of trees, while soil systems remained intact. Stem density increased after each disturbance, as broken trees grew from coppice sprouts. After 45 years, cut areas regained an average of 87% of mature forest structure. Post-hurricane forest will probably take about 25 years to fully recover. Neither disturbance changed the species pool. Conversely, forest recovery from abandoned agricultural and residential uses has taken much longer. After 45 years, abandoned agricultural areas had only recovered an average of 71% of mature forest structure, while residential sites were 58% recovered. The disruption of root systems had a large effect – root biomass was half or less that in mature forests and coppice growth was minimal. These areas have shifted from being dominated by native species to the invasive species *Leucaena leucocephala*, although native Puerto Rican species have begun reappearing after 40 years.

Recovery following forest conversion to agriculture or housing illustrates how a disturbance can cause a system to shift toward monodominance by a single, invasive tree species. Conversion of African dry forests to grass-dominated savanna by fire results in both a new species composition, and also dominance by a different growth form. Both of these anthropogenic disturbances have resulted in new ecosystems with different structure, though the *Leucaena* system more closely resembles the original dry forest than does the savanna.

The occurrence of multiple disturbances can have major consequences for dry forests. In the Mexican Yucatan, 10% of trees died following a hurricane, but fires subsequently burned through a portion of the forest resulting in 85% mortality, among the highest mortality rates recorded for a dry forest. On the other hand, when a hurricane hits a forest within a year following the previous hurricane, damage is usually light, as the susceptible trees have already been removed.

Characteristics of dry forests that help confer resilience include a high concentration of nutrients below ground or in litter, high root : shoot ratios, and the ability to coppice. When trees are lost, nutrient pools support regrowth and roots access nutrients and minimize erosion. Mycorrhizae and high nutrient use efficiency of dry forest trees help to keep nutrients from being leached. Dry forest trees have adapted to their natural disturbances, allowing forests to withstand drought and regrow following wind, fire, and insect damage. Dry forests absorb human activities that mimic natural disturbances but when no natural disturbance analog exists, dry forests may shift toward other systems or become susceptible to invasion by exotic species.

Conservation and the Future of Tropical Dry Forests

Loss of forest lands occurs as a function of human population density or energy use. Given the demands of increasing human population size and energy requirements from developing economies, this trend will continue in the dry tropics. On the other hand, some conservation efforts have succeeded. In Puerto Rico and India, plantations have reclaimed degraded agricultural land and fostered the regrowth of dry forest. More countries have committed to increasing forest area in parks and reserves, and about 5% of dry forests worldwide are protected. Most conservation projects fail when the needs of the local citizenry are not considered, but conservation efforts in Guanacaste, Costa Rica, have shown that local citizens can benefit from protecting dry forest. Efforts in Guanacaste have also demonstrated methods by which invasive species can be controlled and eliminated when they are detrimental to the system – this has proven to be a difficult task in any ecosystem. Future efforts in conservation should focus on taxonomically diverse locations, such as

Bolivia, western Mexico, and southern Africa, and explicitly include benefits for local citizens.

Tropical Moist Forests

L G Saw, Forest Research Institute Malaysia, Kepong, Kuala Lumpur, Malaysia

Distribution of the Tropical Moist Forests

The tropical moist forests are limited by the tropics of Cancer and Capricorn (**Figure 1**). However, the distribution is not evenly dispersed across the Americas, Africa, and Asia, often being restricted by the climatic conditions surrounding the land area. The largest area of tropical forest is found in the Neotropics (4×10^6 km^2). The neotropical forests occur in three parts: the Amazon and Orinoco basins are the largest area, followed by a block which lies across the Andes on the Pacific coasts of Ecuador and Colombia, extending northwards through Central America as far as Veracruz in southernmost Mexico. The Atlantic coast of Brazil has a third area of rainforest, a strip less than 50 km wide on the coastal mountains, extending from Bahia in the north to Rio Grande do Sul in the south. The area has now been reduced to about 12% of its original extent.

The second largest block of tropical moist forests occurs in eastern tropics and is estimated to cover 2.5×10^6 km^2. Centered in the Malay archipelago, it includes all of the Southeast Asian countries into the Pacific islands and in a narrow coastal strip in Queensland, Australia. In Australia, the forest extends in small pockets into New South Wales but is mainly restricted to the wettest sites with most fertile soils. In the Malay peninsula, the forests extend into Myanmar, Thailand to the southern Himalayas in upper Myanmar, Assam, and southern China. Africa has the smallest block of the tropical moist forests, with an area of about 1.8×10^6 km^2. Centered in the Congo basin, this block extends from the high mountains at its eastern limit westwards to the Atlantic ocean, with outliers in East Africa. It extends as a coastal strip into West Africa and woodlands reach the coast at the Dahomey Gap. There are tiny patches of rainforest on the east coast of Madagascar and in the Mascarenes.

Environment of the Tropical Moist Forests

A number of interacting environmental features influence the distribution of vegetation, e.g., climate, temperature, and moisture. Tropical moist forests occur in climates where the mean temperature of the coldest month is more than 18°C. This excludes some tropical montane areas, although an alternative definition includes forests where the difference between the mean temperatures of the warmest and the coldest months is less than 5°C. Another important characteristic of tropical climates is that the diurnal range of mean daily temperature exceeds the annual range. The amount of rainfall and its distribution through the year defines different tropical climates. Rainforests develop where monthly rainfall exceeds 100 mm and short dry spells last only a few days or weeks. Where there are regular dry periods (60 mm rainfall or less), monsoon forests or tropical seasonal forests develop. Superficially, both forest formations appear similar but they have very different species compositions: tropical moist forests are species-rich with a heterogeneous physiognomy, whereas monsoon forests are relatively species-poor and have a simple structure, often containing

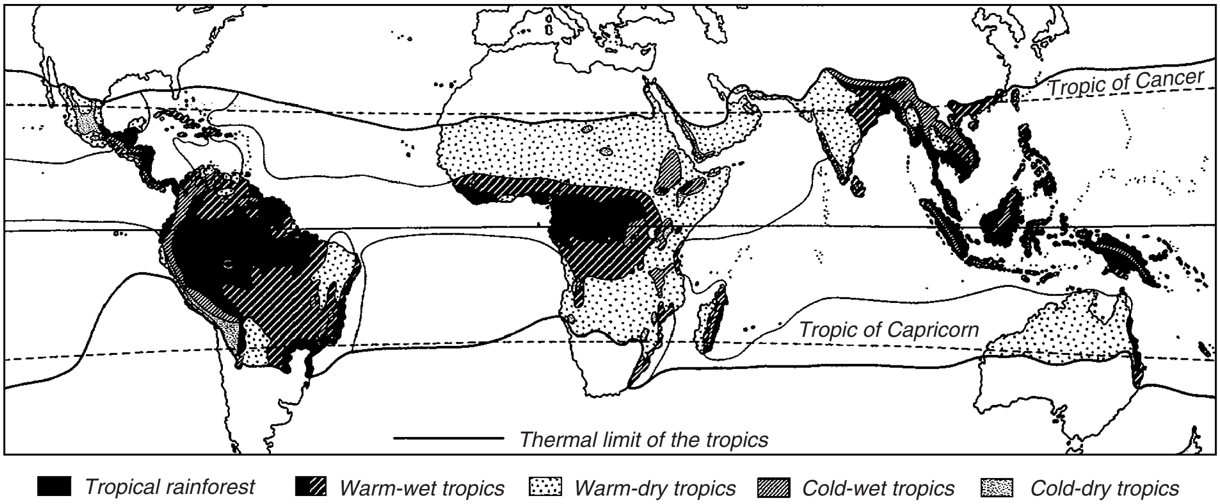

Figure 1 Distribution of tropical rainforest within hygrothermal zonations. Modified, with permission, from Lauer W (1989) Climate and weather. In: Lieth H and Werger MJA (eds) *Ecosystems of the World*, vol. 14B, *Tropical Rain Forest Ecosystems*. Amsterdam: Elsevier.

deciduous canopy trees. Tropical moist forests occur in ever-wet or perhumid climates.

Forest Formations

The structure and the species physiognomy of the major tropical moist forests are similar. This has often been described as forest formations. A forest formation is recognized by a particular combination of vegetation structure and physiognomy regardless of flora. Different species in the three areas have evolved similar responses to particular environments. The forest formations occupy different physical habitats, which are mostly sharply bounded; where this is not so there is a merging zone.

The formations develop from three interacting environmental factors: climatic, edaphic, and soil water influences (**Table 1**). Temperature regimes are more-or-less constant throughout the year in the tropical moist forests; the amount and distribution of rainfall in a region often determine the kind of major formation that develops. Seasonality of rainfall patterns has a tremendous demarcating effect on the type of formation developing. For example, in the extreme north of peninsular Malaysia in the states of Perlis and Kedah, a pronounced 2–3-month dry period results in a semievergreen rainforest that is predominantly Myanmarese and Thai. Here, deciduous trees form a good proportion of the forest. A short distance south in the state of Perak, the vegetation is lowland evergreen rainforest. Similarly, in the African rainforests, the percentage of contribution of deciduous trees rises as the climate becomes drier, as one moves north or south of the equator. A further factor that influences climate is the change in temperature regimes as elevation changes. Lowland evergreen rainforest is often restricted to elevations below 1200 m above sea level; beyond that, montane and subalpine forests develop. After climate, the substrate upon which the vegetation develops defines other forest formations. For example, soil water availability will restrict the type of plant community. In dryland areas, the climatic forest types develop in normal (mainly oxisols and ultisols) soils. However, with different availability of nutrients, other very distinctive formations develop. In podzolized sands, heath forest develops and other specialized formations are found over limestone, ultrabasic rocks, and quartzite rocks.

Where the water table is high and under maritime influence (i.e., salt water, swells) beach, mangrove, and brackish water forests may develop. Under inland freshwater swamp, depending on the degree of inundation, freshwater swamp and freshwater periodic swamp forests develop. An example of the kind of forest formations developing in Borneo indicates the dominance of particular species (**Figure 2**).

Dryland Forests

Tropical Lowland Evergreen Rainforest

This is the most luxuriant of all plant communities, and is dense evergreen forest 45 m or more tall, characterized by large numbers of tree species. Gregarious dominants are uncommon and usually two-thirds or more of the canopy individuals and two-thirds or more of the upper-canopy trees are of

Table 1 Forest formations of tropical moist forests. Reproduced with permission from Whitmore TC (1990) *An Introduction to Tropical Rainforest*. Oxford University Press

Climate	*Soil water*		*Soils*	*Elevation*	*Forest formation*
Seasonally dry	Strong annual shortage				Monsoon forests (various formations)
	Slight annual shortage				Semievergreen rainforest
Ever-wet (perhumid)	Dryland		Zonal (mainly oxisols, ultisols)	Lowlands	Lowland evergreen rainforest
				Mountains	
				(750) 1200–1500 m	Lower montane forest
				(600) 1500–3000 (3350) m	Upper montane rainforest
				3000 (3350) to treeline	Subalpine forest
			Podzolized sands	Mostly lowlands	Heath forest
			Limestone	Mostly lowlands	Forest over limestone
			Ultrabasic rocks	Mostly lowlands	Forest over ultrabasics
	Water table high (at least periodically)	Coastal saltwater			Beach vegetation
					Mangrove forest
					Brackish water forest
		Inland fresh water	Oligotropic peats		Peat swamp forest
			Eutropic (much and mineral) soils	$\pm$Permanently wet	Freshwater swamp forest
				Periodically wet	Freshwater periodic swamp forest

species individually contributing no more than 1% of the total number in the Neotropics and Asian blocks of the lowland rainforest. This formation is conventionally regarded as having three tree layers, although the layers may grade into each other: (1) upper layer of individual or grouped giant emergent trees sometimes >70 m; (2) main stratum at about 24–36 m; and (3) smaller, shade-tolerant trees below that. Ground vegetation is often sparse, and mainly of small trees and understory palms; herbs are uncommon. Some of the biggest trees have a clear bole of 30 m and reach 4.5 m girth, and may be deciduous or semideciduous, without affecting the evergreen nature of the canopy as a whole. Boles are usually cylindrical. Buttresses are common. Cauliflory and ramiflory are common. Leaves are often large and pinnate or variously dissected. Big woody climbers are frequent. Shade and sun epiphytes are occasional to frequent. Among the three regions of tropical lowland rainforests, the African block is less typical, as described above. Although the great majority of understory trees in the African forests are evergreen, a substantial proportion of the taller trees can be deciduous. Further, there can be a dominance of a single species in the canopy.

In this formation, tree diversity is the richest in the world. It is usual in this formation for tree diversity exceeding 150 species for trees (≥ 10 cm diameter at breast height) per hectare. In one particularly rich forest in Yanamomo, Peru, over 280 species per hectare have been recorded. More recently, large ecological plot studies have shown diversity of 817 species per 50 ha and 1171 species per 52 ha recorded for trees ≥ 1 cm diameter at breast height, in Malaysia. In comparison in more seasonal forest areas of India, Panama, and Thailand, the diversity was less than half of the Malaysian totals, ranging from 68 species to 305 species per 50-ha plot.

Floristic Composition of Lowland Evergreen Rainforests

Among the three blocks of evergreen rainforests, the African forest is less diverse, for example, the tree

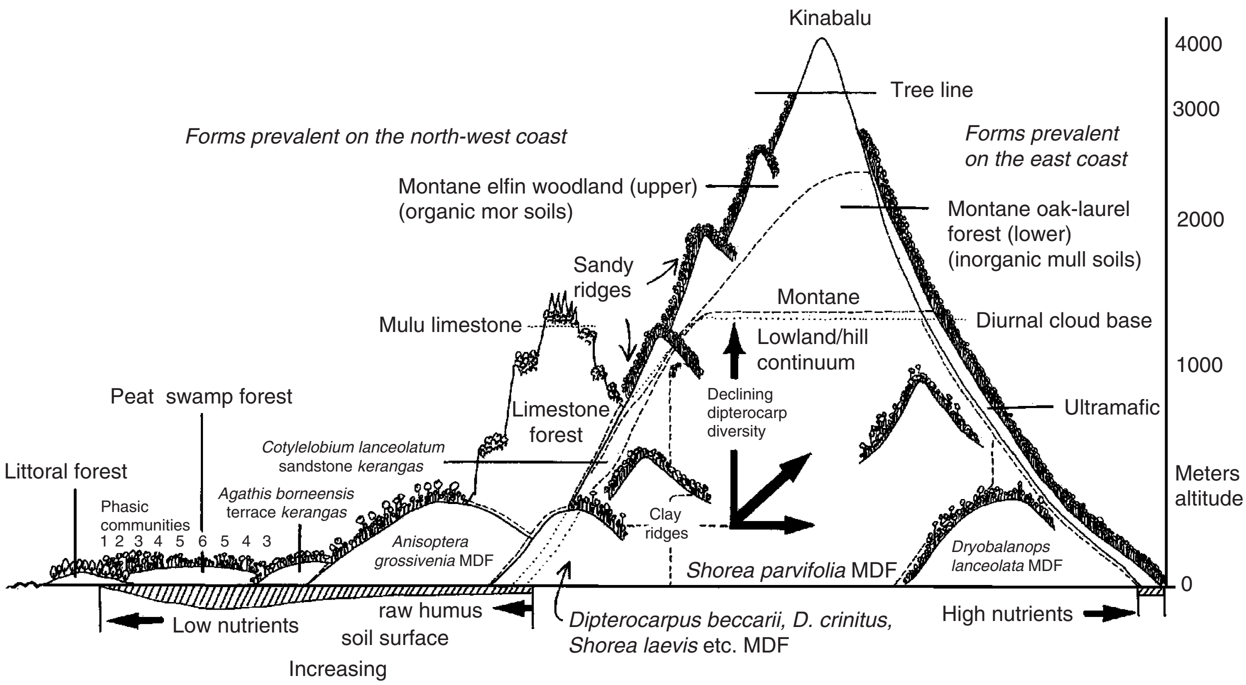

Figure 2 Diagram of the major floristic associations in Bornean forests. MDF, mixed Dipterocarp forest. The bold arrows indicate declining dipterocarp diversity with changes in nutrients levels in the soil, and altitude. Reproduced with permission from Ashton PS (1995) Biogeography and ecology. In: Soepadma E and Wong KM (eds) *Tree Flora of Sabah and Sarawak*, vol. 1. Kuala Lumpur, Malaysia: Forest Research Institute Malaysia.

diversity of the various lowland evergreen forests in the Ivory Coast is much lower than that in Malaysia and Surinam. By African standards, these Ivory Coast forests are floristically rather rich, yet they contain about a quarter of the number of tree species per unit area found in Malaysia. There have been many speculations over the poverty of the African forest flora. It has been suggested that forest flora was once much richer than today but has been reduced by progressive aridity since the Miocene, and especially by a series of severe dry episodes during the Quaternary. The African rainforest shares similar richness in legume species with the South American and in the absence of Dipterocarpaceae, a family so typical of Southeast Asian forests. However, it is particularly poor in palm species in its understory species. In contrast with rich bromeliad flora of South America, Africa has only one bromeliad species (*Pitcairnia feliciana*). Major families shared with South America include Euphorbiaceae, Meliaceae, Moraceae, and Sapotaceae. These probably represented old families which were present on both continents before rifting. A number of leguminous trees, including *Brachystegia laurentii*, *Cynometra alexandri*, *Gilbertiodendron dewevrei*, *Michelsonia microphylla*, and *Scorodophloeus zenkeri* may dominate the canopy of the lowland African forests as single species.

The flora of the eastern block, in particular, the Malesian region is rich with about 42 000 species of vascular plants. The flora of the Malesian region is also not homogeneous. There are marked differences from island to island. However, there are two floristic elements, one centered on the Sunda shelf and the other on the Sahul shelf. A strong zoogeographical boundary runs through these shelves, sometimes called Wallace's line. Dipterocarpaceae is probably the most important single distinction between the forests west and east of Wallace's line. Dipterocarpaceae west of Wallace's line dominates the rainforests in Malesia as upper-canopy or emergent trees like no other tree families. Species are also very diverse, particularly on the island of Borneo. Other groups that are centered on the Sunda shelf include some palm genera such as *Daemonorops*, *Iguanura*, and *Pinanga*, Magnoliaceae, and *Artocarpus* (Moraceae). Conifers are more abundant east of Wallace's line, more in the mountains, but some species may form dense stands in lowland forests. These conifers all belong to two families, Araucariaeae and Podocarpaceae. Among the palms, *Gronophyllum*, *Gulubia*, *Hydriastela*, *Metroxylon*, and *Siphokentia*, are confined to the east side of Wallace's line. The family Proteaceae is centered on the Sahul shelf, except for *Heliciopsis* which has a Sundaic focus. Other plant groups, e.g., *Syzygium* (Myrtaceae), are equally abundant on both sides of Wallace's line. The north eastern Australian rainforests have similar affinity to New Guinea Island and with floristic composition of the Sahul shelf. With its present drier climate, some genera endemic to this rainforest include *Backhousia*, *Blepharocarya*, *Buckinghamia*, *Cardwellia*, *Castanospermum*, *Ceratopetalum*, *Doryphora*, *Flindersia*, *Musgravea*, and *Placosperma*.

As in the eastern block of rainforest, the neotropical rainforest is complex and not homogeneous. Floristic composition varied with the different forest types. Principally, in the *terra firme* forest Leguminosae is the most abundant family in terms of genera and species and the Lecythidiaceae in numbers of individuals. Other important families with larger-sized trees include Burseraceae, Celestraceae, Meliaceae, Myrtaceae, and Sterculiaceae. The understory, may include Euphorbiaceae, Myrtaceae, Palmae, and Rubiaceae. Some common genera include *Bertholletia*, *Eschweilera*, *Goupia*, *Parkia*, *Tabebuia*, *Tetragastris*, and *Vouacapoua*. The absence or presence of palms and lianas is sometimes indicative of the forest type in the rainforests of the Neotropics. Some of the common palms found in the forest include *Euterpe precatoria*, *Jessenia batuaua*, *Maximiliana regia*, *Oenocapus distichus*, and *Orbignya barbosioana*.

Heath Forest

Heath forest occurs on soils developed from siliceous parent material, which are inherently poor in bases and highly acidic, and of coastal alluvium or weathered sandstone origin. Such soils become podzolized. In some substrate, particularly those under sandstones, the soils become temporarily waterlogged, particularly during the rainy season. The streams draining from such forests are tea-colored owing to the presence of organic colloids that leached out from the soils. They are usually acid (pH <5.5), and with a low oxygen content. The most extensive heath forests are found in the upper reaches of Rio Negro and Rio Orinoco in South America. In Brazil, they are known as campina, campinarana, caatinga Amazonica, or campina rupestre. In the Far East, there are also large areas of heath forest in Borneo (called kerangas), less extensively in peninsular Malaysia, Sumatra, and New Guinea. African heath forests are less extensive areas and are found in coastal sands in Gabon, Cameroon, and Ivory Coast.

This forest is strikingly different from the lowland evergreen forest in having a very different flora, structure, and physiognomy. Depending on the depth of the heath soils and variability of water supply, the vegetation varies from low scrublands comprising sedges, grasses, and stunted gnarled trees to near-lowland rainforest formation. Characteristically, the forest is dominated by pole-sized trees, where the main story is formed by large saplings and small poles and forms a tidy and orderly stand. The canopy is low, uniform, and usually densely closed with no trace of layering. Single emergents may occur but often in areas with deeper soils. There are more trees with small leaves, many species with sclerophyllous leaves; deciduous species are absent. Big woody climbers are rare, but slender, wiry, independent climbers are frequent. Myrmecophytes are abundant, especially in the more open and stunted heath. Amongst the herbs are insectivorous plants, e.g., *Drosera, Nepenthes,* and *Utricularia*.

When the sandstone formation extends into higher elevations, the montane flora extends to the lower elevations. In many respects, the upper montane and heath forest have many features of structure and physiognomy in common.

Limestone Forest

The total extent of limestone is small and is often found in the lowlands. The largest areas are found in the Far East. They are absent in the humid tropics of Africa and are rare in Latin America, except in the Caribbean region. A distinctive feature of the limestone hills is the karst landscape. In the Far East, it occurs in Central Sumatra, peninsular Malaysia, Borneo (mainly in Sarawak and in small areas in Sabah), Java, the Lesser Sunda Islands, Celebes, the Moluccas, and New Guinea.

There are a diversity of habitats and soils within the limestone hills that sometimes support very specific animal and plant species. The alluvial soils at the base of the limestone hills, although derived from other rocks, are under the influence of run-off water and erosion from the limestone. The soils are often more fertile and more base-rich and often the vegetation is an extension of the adjacent forest. The second zone is the base of cliffs and ravines in the hills, sometimes with small scree slopes of limestone boulders. Here a few species may dominate, for example, in peninsular Malaysia the palm *Arenga westerhoutii* sometimes completely dominates the slope. The third zone is the limestone slope with its dense, irregular forest with trees clinging precariously, their roots penetrating to great depths in crevices. Sheer cliffs may bear scattered shrubs and a characteristic herb flora. In peninsular Malaysia and Borneo, Gesneriaceae with species adapted to desiccation are prominent, and *Cycas* and some *Pandanus* are often seen clinging to crevices of cliffs. The final zone is the summits of the limestone hills. It is a peculiar habit. It has a deep mat of peat-like humus, held together by tree roots and anchored to the limestone pinnacles underneath. It often contains many epiphytic plants and plants specializing in the drier and harsher environment; orchids and ferns may be common.

Limestone flora often contains many endemic plants. For example, the palm genus *Maxburretia* is completely restricted to the limestone hills of the Malay peninsula, each species being endemic to specific limestone hills. Similar examples, although not as restrictive, can be seen in many genera of Gesneriaceae, e.g., *Boea*, *Chirita*, *Monophyllaea*, and *Paraboea*.

Beach Vegetation

Two kinds of beach vegetation are recognized. One occurs on accreting coasts where new sand is deposited and plant cover is often of low herbaceous creeping plants (the *pes caprae* association). Species found in this habitat are often pantropical. At the inland margin of the sand beach, the second vegetation forms; in the Far East, for example, the *Barringtonia* association is found here. Inland it merges with the lowland rainforest. Its composition is very uniform throughout Malesia and many species extend from the coast of Africa through Malesia far into the Pacific. Many species have seeds or fruits adapted to water dispersal. The trees are sometimes loaded with epiphytes, particularly orchids, ferns and asclepiads (*Hoya* and *Dischidia*).

Swamp Forests

Mangrove Swamp Forest

Mangrove forest develops where there is coastal sedimentation of mud; mangroves are the usual initial colonizers. The mud is invaded by the tide twice daily, but the pneumatophore shoots of pioneer species of *Avicennia*, followed at a later stage by the many-stemmed stools of *Rhizophora*, trap sediment very efficiently (sometimes up to several meters a year). The vegetation is simple in structure, 5–25 m in height depending on the community, with comparatively even and unbroken canopy, a very poor understory layer which is frequently absent, and poor in species. The principal tree species are restricted to such habitats, and are frequently characterized by special root formations such as stilt roots (*Rhizophora*) and pneumatophores (*Avicennia*, *Bruguiera*, *Sonneratia*, and *Xylocarpus*). The vegetation is often very simple, with few species dominating the whole stand. There is also a distinct succession from the seaward front to the landward side. Mangrove forest is found throughout the tropics. The mangroves of Madagascar and eastern shores of Africa have a strong Asian affinity while those of the Atlantic shores of the USA and West Africa share similar floristic affinities.

In the Far East, on the edge of the mangrove and the upper tidal limit of estuaries, there is a forest with a number of distinctive species, amongst which *Nypa fruticans* is important and forms extensive pure stands, mainly along water courses in river estuaries.

Peat Swamp Forest

In parts of Sumatra, Malaya, Borneo, and west New Guinea a physiological setting exists which favored the formation of peat. Since sea level rose at the end of the last Ice Age, rivers deposit silt as levees and on flood plains. Swamps form behind the levees and became less saline and over time under anaerobic conditions peat develops from the accumulated litter. The process continues until the present day. Peat is semiliquid and low in nutrients because the only input is from rainfall. Peat reaches 13 m thick in the most developed domes, a formation that is better understood in Southeast Asia where the domes occur in large areas, particularly in east Sumatra, Malaya, Borneo, and New Guinea. Less in extent are the peat swamp forests found in the USA and Africa.

Structurally and floristically, the peat swamp forest is not a uniform formation. In Borneo, for example, there exists a catena of at least six types of phasic communities which are moderately sharply distinct in structure, physiognomy, and flora. In general, the forest has a three-layered tree structure. Most of the tree families of the lowland forest are found in the peat swamp forest. However, there are species that specialize in such environments. Palms are poorly represented; those that occur are either swamp specialists or species restricted to this formation (e.g., *Cyrtostachys renda*, *Korthalsia flagellaris*).

Freshwater Swamp Forest

The soil surface of land covered by the freshwater swamp forest formation is regularly to occasionally inundated with mineral-rich fresh water of fairly high pH (nonacidic). There may be peat present in the soil but one key difference of this formation from the peat swamp forest is that in the latter, rain is the only source of water reaching this forest, which is nutrient-poor. Freshwater swamp occurs throughout the tropics, where the river system runs into low-lying areas and regular flooding produces the condition for this formation to develop. As with the peat swamp forest formation, this is a varied formation, often dependent on the degree of inundation and the kind of parent material in which the vegetation develops. The Amazon, which has annual floods and is influenced by tides to some 600 km inland, has very extensive and diverse freshwater permanent and periodic swampy forests. Igapó is applied to black and clear water areas and várzea muddy water inundation. Várzea is formed by flooding with muddy water rivers such as the Amazonas and the Madeira, and igapós on sandy soil and clear water. The várzeas have soils that are more fertile. The Zaire basin is about one-third occupied by swamp forests. The greatest extent of this formation in Asia is where the biggest rivers are, e.g., in Indo-China, Thailand, and Myanmar (Mekong and Irrawaddy), and in New Guinea (Fly and Sepik). In recent years, much of this habitat has been destroyed due to conversion to agriculture.

Global Trends in Rainforest Areas

Increasing human population in the last hundred years has had a profound impact on the tropical rainforests. In many tropical societies, land-use patterns have shifted from a low-impact traditional use of forestlands to a more intensive industrial use. Tropical forests are being altered at a rapid pace in one of two different ways. Some areas are converted to other uses; others are logged but left to regenerate. Land conversion poses the greatest threat. There are major differences between regions in the rate at which tropical moist forests are disappearing. In Southeast Asia, the major conversion has been from planned conversion of forest areas to industrial agriculture plantation crops such as rubber and oil palm. More recently, areas have also been converted to tree plantation crops to produce pulp. Most often *Acacia mangium* is planted. In the neotropics, large areas have been converted to pastures for cattle farming. Industrial tree crops are also planted in large areas, often using species of *Acacia mangium*, *Eucalyptus*, and tropical pines. These are examples of planned conversion often initiated by government policies. Forest conversion also comes about that is not centrally planned. In many countries, peasant farmers moved into rainforest, usually to practice shifting cultivation, and often illegally. These people often moved into new forest areas following commercial logging. Forests are also destroyed for dams and mines.

Harvesting timber from the forest will alter the nature and dynamics of the rainforests. Commercial logging in tropical rainforests can take a number of forms, almost all of which involve the removal of selected trees rather than the clear felling of whole stands. This is different from temperate forestry operations where clear felling is much more common. In the past, such practices, i.e., selective felling, were not intensive and often forests regenerated. In peninsular Malaysia, for example, under the Malayan Uniform System, it was possible to return to harvest a forest area after about 60 years of first harvesting. Changing market forces and more mechanized logging operations in recent years have now increased logging intensities. This has resulted in the slow recovery of logged-over forests. However, many countries are now considering better ways of managing the forests. Studies have indicated that when properly managed, forests, can provide both services and products for the present and the future.

To conserve the rainforests, increasingly, many tropical countries are looking into sustainable forest management (SFM) practices. Tropical rainforests are a renewable resource, which can be utilized while retaining their diversity and richness. Bringing such principles into forest management has become a strong challenge for many developing countries in the tropics.

Tropical Montane Forests

M Kappelle, Utrecht University, Utrecht, The Netherlands

Introduction

Mid and high-elevation regions near the equator such as are found in the Andes and on Papua New Guinea support tropical montane forests (TMF), which range from relatively dry woodlands to extremely wet forests. TMF forms a major component of several of the world's biodiversity hotspots (e.g., Meso-America and the northern Andes), as it represents an extremely species-rich system, which is highly endangered due to human interference. The most important and diverse of all TMF types is the tropical montane cloud forest (TMCF). This conspicuous ecosystem filters global air masses in such a way that they seize and incorporate water and nutrients from mist and fog into their cycles. It may be even richer than the tropical lowland rainforest (TLRF) when diversity is measured as species density on a per-unit-area basis. TMCF is well known for its important fresh-water resources, which feed the many rivers passing through major mountain cities in the Andes such as Bogotá and Quito, which in turn depend on these resources to supply their human populations with sufficient drinking water. However, today these fragile forests are among the most endangered ecosystems worldwide, due to destructive anthropogenic forces causing forest loss and habitat fragmentation, ultimately leading to species extinction and loss of environmental goods and services which are vital to the regional and local human populations.

The present article presents a brief overview of TMF, emphasizing its most important representative, the TMCF type. A bioclimatic definition is presented and its overall aspects are discussed. Subsequently, its geographic distribution and main determinants are treated. Details on climate, soils, and topography are elaborated. Furthermore, past trends in forest cover are dealt with. This is followed by a detailed discussion of the TMF structure, species composition, dominance, and dynamics as a result of disturbances. Regional subtypes and boundaries with other forest types are listed. Next, the ecological/environmental and sociocultural importance of this specific forest ecosystem is analyzed. Past and current TMF use practices are assessed and some sustainable forest management systems identified. Finally, threats to the survival of species and the integrity of the ecosystem as a whole are evaluated and current and future conservation strategies discussed. Such an analysis ultimately permits the setting of priorities in conservation and sustainable development for the benefit of the peoples living in and depending on TMF systems.

Definition

Forests on Tropical Mountains

TMF is latitudinally restricted to the tropics and may only be found, in its strict sense, at northern and southern latitudes between the tropics of Cancer and Capricorn. In a wider sense, TMF reaches a northern latitude of 23° in Mexico and a southern latitude of 25° in Argentina. Within this latitudinal range, TMF is altitudinally restricted to montane elevations. This is the most difficult part of the elaboration of a concise definition, for scholars have not been able to define the altitudinal limits of the montane belt unanimously. In general, as a rule of thumb, it is assumed that montane forests occur between 500 and 4000 m above sea-level. However, there are places on earth, especially on volcanic islands, where montane forests may occur at 300 m elevation (e.g., in the Caribbean), while there are sites in certain tropical mountain chains such as in the South American Andes where small pockets of montane forests occur in wind-protected valleys at elevations over 4000 m. In the latter case, these montane forests are better known as tropical subalpine forests (TSF) as they often occur just below – or amongst – the treeless, tropical alpine grasslands and shrublands.

Tropical Montane Cloud Forests

In contrast, TMCF – the cloudy version of TMF – was well defined a decade ago. Specialists now agree that TMCF differs significantly in composition and structure from rainforests in tropical lowlands (TLRF). It typically occurs as a narrow altitudinal belt in tropical highlands where the atmospheric environment is characterized by persistent, frequent, or seasonal cloud cover at vegetation (or ground) level, i.e., the tree crowns are regularly bathed in mist and fog ('canopy wetting'). Although little is known about the hydroecological effect of the mist-forming, enveloping, and wind-driven clouds on the hydrological input in this ecosystem, it has been widely recognized that the frequent cloud and mist presence causes a considerable increase in atmospheric humidity within the forest interior – a phenomenon presently known as 'horizontal precipitation.'

Characterizing Tropical Montane Forests

Limiting climatic factors such as horizontal precipitation (cloud stripping), a reduced photosynthesis due to reduced solar radiation, a periodic water shortage (vapor deficit), strong diurnal temperature oscillations, a general reduction of the evapotranspiration rate, exposure to strong winds, and a limited nutrient uptake, are the most important environmental factors which determine the large array of differences in forest structure and composition when cloudy TMF is compared to TLRF. Some of these striking differences include a particular, often elfin-like physiognomy characterized by a reduced tree stature, an increased tree stem density, frequently gnarled trunks and branches of stunted trees with dense crowns and small-sized, sclerophyllous and coriaceous leaves. At first sight, the branches of trees and shrubs appear typically draped with pendant mosses covered with water droplets and filmy ferns. In fact, a complex mosaic-like assemblage of vascular and nonvascular epiphytes (orchids, bromeliads, ferns, mosses, liverworts, algae, lichens, and fungi) blankets the surface of host trees and shrubs (**Figure 1**).

The epiphytes contribute to an enormous extra above-ground biomass which may retain a significant quantity of additional water from clouds (i.e., the above-mentioned process of cloud stripping). All these diagnostic features, together with the forest's low productivity and low nutrient cycling rates, characterize the general structure and functioning of the TMCF and hence the most typical of all TMF varieties.

Figure 1 Epiphytic communities of vascular and nonvascular plants on tree branches in Colombian tropical montane forests at elevations of (a) 1980 m, (b) 2550 m, and (c) 3370 m, studied by Jan H.D. Wolf. Courtesy of Gerard Oostermeijer.

Distribution

Geographical Distribution

TMF as well as TMCF occurs between 500 and 4000 m altitude on all three tropical continents (Africa, America, and Asia) and in equatorial

Oceania. The majority of TMF sites are found between 1200 and 2800 m elevation. They are found from central Mexico (Eje Neovolcánico Transversal) south-eastward along the Central American mountain chains (Guatemala, Costa Rica), and further south along the Andes to northern Argentina (Salta-Tucumán). They appear especially well developed in the northern Andes (Venezuela, Colombia, Ecuador, and Peru), on both the eastern and western flanks of their cordilleras. In Central Africa they occur in mountainous countries like Uganda (Bamenda Highlands, Rwenzori Mountains), and in East Africa along the so-called Eastern Arc (e.g., Mount Kilimanjaro, Mount Kenya) and at the drier Ethiopian highland plateaux. Further to the east, they are encountered on the higher parts of Southeast Asia (e.g., Mount Kinabalu in Sabah, East Malaysia; Kalimantan and Irian Jaya in Indonesia; Philippines; Papua New Guinea). They inhabit the mountaintops of many oceanic islands where exceptionally wet, marine, equatorial conditions prevail, as is the case in the Caribbean region (Jamaica, Puerto Rico) and the Pacific Ocean (Fiji, Hawaii; **Figure 2**).

The Massenerhebung Effect

It is well known that TMF formations occur at higher elevations on taller mountains. The upper limit of lowland forest may be brought down to varying degrees below the temperature-determined uppermost limit when the fog characteristic of TMF environment occurs at lower levels. This little understood phenomenon is known as the Massenerhebung or telescope effect, first described for the Alps in Europe. Apparently, the compression and depression of the forest belts on small mountains, such as on tropical islands (e.g., Hawaii) and along coasts, seems mainly associated with a lowering in the level at which cloud habitually forms. More specifically, the altitudinal distribution of TMCF is related to the cloud level itself, which in turn is dependent upon the humidity at the foot of a mountain. The greater the humidity is at the mountain's base, the lower the cloud level occurs (**Figure 3**).

Climate

The average temperature in TMF and cool-humid TMCF depends principally on elevation, as temperature decreases with increasing altitude. Average annual temperatures range from 8°C at 3400 m to 20°C at 1000 m. Average annual rainfall is correlated with slope orientation and fluctuates between 500 and 10 000 mm, although yearly precipitation generally ranges from 1000 to 3000 mm. Ascending air masses bring increased precipitation to mountain slopes (windward slopes; e.g., under the influence of trade winds in the Caribbean) unless they are sheltered from the wind (leeward slopes; rain shadow). As has been said, the net precipitation or throughfall in TMCF is significantly enhanced beyond rainfall contribution through direct canopy interception of cloud water (horizontal precipitation), a process also known as cloud stripping. It is therefore not surprising that TMF is particularly rich in epiphytes, which obtain water directly from the perhumid atmosphere.

Soil

TMF soils are quite different from tropical lowland soils. On tropical mountains, the often reddish-brown loamy lowland soils on flat plains become replaced by more yellowish, acid and peaty soil types with organic upper horizons on steep slopes in rugged terrain. TMF soils are frequently water-logged and suffer from podsolization, a soil-forming process, which causes the leaching of nutrients (lixiviation) from upper soil horizons to lower levels. These nutrient-poor, water-saturated soils may experience an anaerobic environment, which in turn originates impeded root respiration, a reduction in below-ground bioactivity, and lower decomposition levels. The final result is the accumulation of humus in the topsoil (histosols) and/or loss of nutrients at top- and mid-soil levels (podsols). However, on a number of mountains (e.g., volcanoes) nutrient-rich soil types may prevail (andosols), as intrusive rocks intermingled with marine sediments become exposed and weathered. Soil characteristics in TMCF appear to correlate strongly with plant community distribution.

Present Forest Cover

Over the last few decades TMF and particularly TMCF has suffered greatly from human interference. Large-scale deforestation for timber, fuelwood, and charcoal production in combination with forest conversion to pastureland has caused uncontrolled habitat fragmentation and severe land degradation. Today, TMF covers an estimated 200 million ha throughout the tropics. This is only 30% of the 700 million ha of the globe's tropical montane landmass. Throughout the 1980s the annual TMF deforestation rate was 2.5 million ha. TMCF makes up less than 1% of the world's closed canopy forests, while in the neotropics it presently covers only 65–75 million ha, about a third to half of which occurs in Colombia. Further research using high-resolution satellite imagery is urgently needed to assess precisely the area currently covered by TMF and TMCF in particular.

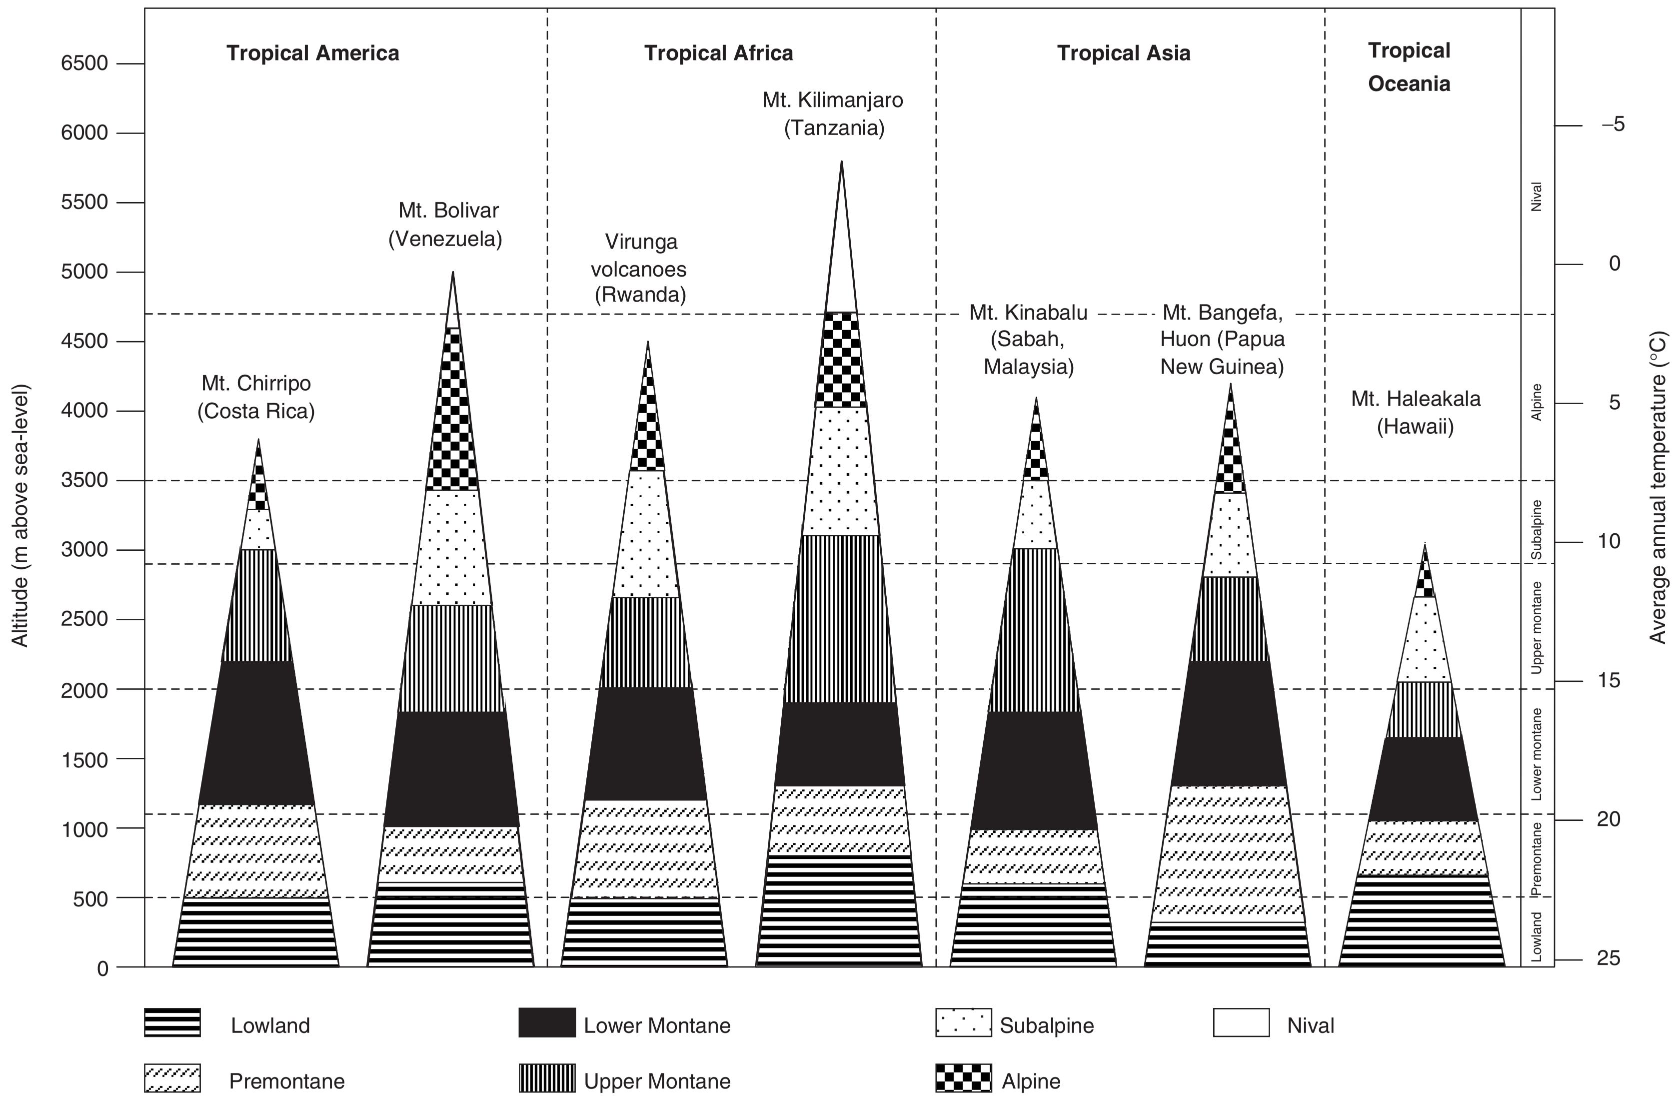

Figure 2 Altitudinal vegetation zonation on selected mountains on all tropical continents. The tropical montane forest (TMF) is strictly found in the lower and upper montane belts, but may occur locally in adjacent zones of the premontane and subalpine belts. The transitional subalpine belt (just below the upper TMF tree line, separating the TMF from alpine scrub) is regionally and locally also known as the ericaceous belt, while the transitional premontane belt (separating the lowland forest from TMF formations) has also been named as the (foot) hill zone or submontane belt.

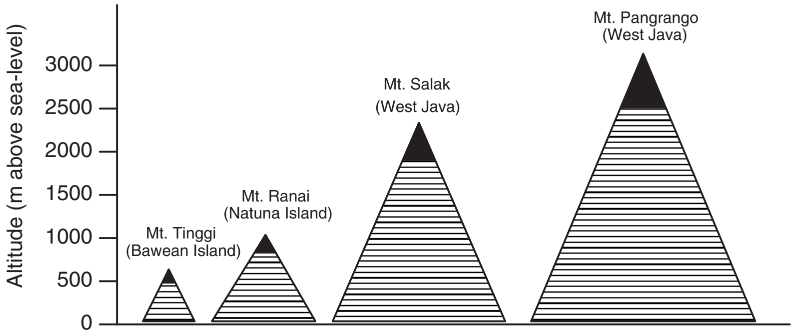

Figure 3 The Massenerhebung or telescope effect of tropical vegetation zonation, exemplified by the occurrence of mossy montane forest at contrasting altitudes on different-sized mountains in South-East Asia. Description and Major Features

Forest Formations along an Altitudinal Gradient

When climbing a high tropical mountain, one passes through nearly all climatic and vegetation zones of the world over a relatively short distance. It is therefore no surprise that tropical mountains are extremely rich in species and ecosystems. One may observe a series of forests with different structure, physiognomy, and composition. As the late Tim Whitmore clearly stated, one of the most striking features is the change from mesophyll-dominated forest with an uneven billowing canopy surface to a lower, more even, often pale-colored, microphyll-dominated canopy, of more slender trees, usually with gnarled limbs and very dense subcrowns. At mid-elevation in the northern Andes, the transitional tropical premontane forest (TPMF; 500–1200 m above sea-level) and its adjacent lower montane forest (TLMF; 1200–2400 m) occur with a broad ecotone against the 30–40-m-tall lowland forest formation (TLF; **Table 1**).

At higher elevations, closer to the upper forest line, upper montane forest (TUMF; 2400–3600 m) occurs. The change from frequent cloud cover at vegetation level in TLMF to more persistent cloud cover in TUMF is one of the major factors determining the common boundary between both TMF belts at 2200–2600 m altitude. TUMF is often only 10–25 m tall or less, and its shorter version is sometimes called 'dwarf forest,' 'elfin forest,' 'montane thicket' or – when nonvascular epiphytic plants abound – 'mossy forest.' Its trees may be swathed in bryophytes (mosses, liverworts) and filmy ferns.

On the highest peaks TUMF is replaced by a shorter, much more gnarled formation, stunted by the wind, with even tinier, often xeromorphic leaves (nanophylls). This formation is known as subalpine rainforest (TSF), and has been observed at such geographically disjunctive places as Costa Rica, Ecuador, and New Guinea. The upper tree line (also known as the timber line) on the tallest mountains can be found around 4000 m elevations, although this line is often depressed by human-set fire. Above the tree line occurs a treeless, alpine, cold, wet and misty biome, often dominated by giant stem rosette plants belonging to genera such as *Espeletia, Lobelia*, and *Senecio*, shrubs, forbs, bunch grasses, bamboos, sedges, mosses, liverworts, and beard-like lichens. This biome or ecosystem is regionally known as the paramo (Latin America), the afroalpine (Africa), or tropic-alpine (southeast Asia) ecosystem. It is a tundra-like, peaty system extending up to the rocky snowline at about 4500 m elevation, above which the nival belt extends with its mountain glaciers and snowy summits.

Structure and Physiognomy

The structure of the average high-elevation TMF and TMCF has a dwarfish appearance. Small, flattened, sometimes bonsai-like trees display curved trunks due to soil creep on steep slopes. They occur clumped together in an almost impenetrable setting. Twisted branches with thick (pachyphyllous), hard (sclerophyllous), tiny (microphyllous to nanophyllous) leaves, located in thick bunches on dense subcrowns are heavily loaded with woody and herbaceous epiphytes. Without doubt, the abundance of epiphytes causes an enormous increase in aboveground forest biomass and may act as a sponge, retaining water from clouds and fog.

Maximum canopy tree heights range generally from 7 m at 3400 m elevation (Peru) to 20 m at 1000 m (Monteverde, Costa Rica). Stem densities (diameter at breast height (dbh) > 5 cm) are higher in TMF than at lower elevations in TLF and may fluctuate between 500 stems per hectare at 2700 m elevation in Colombia and Costa Rica and 1000 stems per hectare at 3300 m in Ecuador. If all stems over 2.5 cm dbh are included, a total of 1600 stems per hectare may be recorded (Peru). In the case of 15–35-year-old secondary TMF at 500–3000 m altitude, values of 2500–3500 stems per hectare (dbh > 2.5 cm) seem normal (Costa Rica, Puerto Rico). However, TMF structure data may differ significantly over different slopes (windward versus leeward), along different rainfall gradients, and at different altitudes (temperature variations).

Next to the generally more elfin TMF formations, other TMF types exist in which huge, 35–55-m-tall trees prevail. An example is the tropical montane fagaceous-bamboo forest type found in Central and South America as well as in certain parts of Southeast Asia. In Costa Rica this TMF type is dominated by different species of white and black oak (*Quercus*) in its canopy and *Chusquea* bamboo in its 3–6-m-tall understory. Similar fagaceous-dominated TMF is observed in Andean Colombia where oak trees (*Quercus, Trigonobalanus*) are accompanied by *Chusquea* and *Neurolepis* bamboos, in Indonesia (Sumatra, Kalimantan, Java), where *Castanopsis* and *Lithocarpus* trees form dense stands, as well as on Papua New Guinea, where *Nothofagus* trees spread shade over an understory of climbing *Nastus* bamboos. Other fagaceous–bamboo-dominated montane forests are distributed over more subtropical regions, such as parts of Chile (*Nothofagus* trees with *Chusquea* bamboos), the Himalayas (*Quercus* trees with *Arundinaria* bamboos), and Japan (*Fagus* trees with *Sasa* bamboos).

In Costa Rican TMF at 2500 m elevation (Talamanca mountains), giant oaks (*Quercus*) grow in large quantities and show dbh over 2 m. Below the tall, epiphyte-blanketed oak crowns appears a subcanopy layer with a large number of 10–25-m-tall tree species from both temperate and tropical origin. Temperate plant genera and species begin to appear in TMF at 2000 m elevation. Examples in Costa Rica are alder (*Alnus*), oak (*Quercus*), and willow (*Salix*). Here, values of basal area are among the highest found in tropical forests worldwide: at several places, a basal area value higher than $50\,m^2\,ha^{-1}$ was measured. Values of 25 (Ecuador) to 40 (Puerto Rico) $m^2\,ha^{-1}$ are more likely for TMF between 1000 and 3000 m above sea-level.

Besides the more common and widespread moist TMF formations (including wet, rain, and cloud forests) discussed so far, there occur in some places seasonally dry tropical montane woody vegetation types (woodlands, bushlands, thickets, shrublands, and other xeromorphic communities). This is especially the case in sections of Africa but also in northern Meso-America (e.g., in Mexico and some parts of Guatemala), where conifers such as the pine tree *Pinus hartwegii* dominate the forest structure and intense droughts and fire appear to be the most frequent disturbance factors.

Biological Diversity and Endemism

TMF species-richness decreases with latitude, with lower per-unit-area values for countries around the tropics of Cancer and Capricorn (e.g., Argentina, Mexico) and highest near the Equator (Costa Rica, Indonesia, Papua New Guinea, Peru). At the same time, TMF species diversity is highest at mid-elevation and decreases towards subalpine elevations (**Figure 4**).

In the neotropics, the northern Andes appear to be a center of speciation, from which originated the radiation of numerous species into the peripheral TMF areas at higher latitudes. Endemism is low at the generic level but high at the species level. Some plant genera such as found in the orchids (e.g., *Epidendrum*) and piperoids (e.g., *Peperomia*) are extraordinarily rich in species. About a decade ago, a new tree family restricted to the neotropical TMF was found

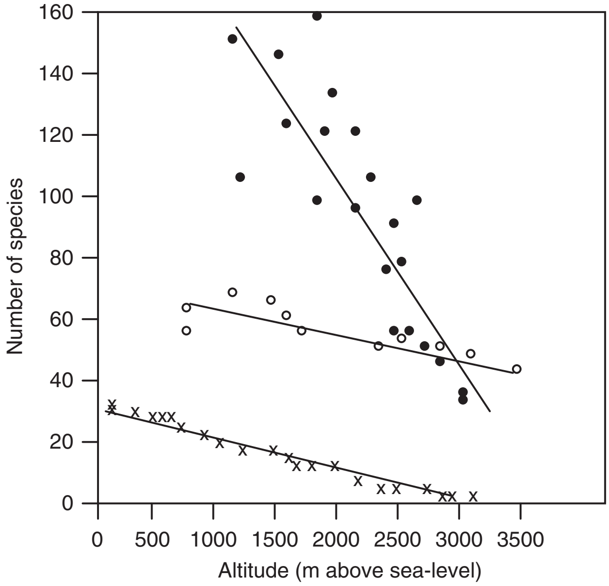

Figure 4 Species-richness in tropical montane forests plotted as a function of altitude, with regression lines. Closed circles represent tree species (diameter at breast height ≥ 2.5 cm) in 0.1 ha plots in Andean forests (data from Gentry AH in Churchill SP, Balslev H, Forero E, and Luteyn JL (eds) (1995) *Biodiversity and Conservation of Neotropical Montane Forests*. New York: New York Botanical Garden); open circles represent numbers of syntopic bird species in Andean Peru, and crosses represent rodents in montane New Guinea (birds and rodents according to Rahbek C in Körner C and Spehn E (eds) (2002) *Mountain Biodiversity: A Global Assessment*. New York: Parthenon).

(Ticodendraceae, Costa Rica). A major reason for these high levels of endemism is the fact that many TMF sites are situated on mountain tops where species populations became isolated from their metapopulations at the end of the ice ages when Pleistocene climatic fluctuations took place. They could therefore evolve into new, locally restricted (endemic) species.

Plant Growth Forms, Species Richness, and Composition

If we take a look at the main plant families and genera making up the average neotropical TMF, we may encounter a large number of broad-leaved canopy trees, subcanopy trees, understory shrubs, a series of ground herbs, some hemiepiphytes, and a few giant native coniferous trees (needle-leaved gymnosperms; **Table 2**).

A very important life form in these forests is the tree fern, which has been considered diagnostic for TMCF. These woody, stemmed, 2–7-m-tall pteridophytes with their enormous leaf rosettes occur in almost all TMCF types around the world. Other conspicuous understory elements include large monocotyledons such as understory bamboos, often-dwarfish palms and colorful heliconias. Bright-green, pteridophytic *Selaginella* species and terrestrial mosses (Polytrichaceae) preferring damp, cool climates may carpet the forest floor. Woody climbers are few, but herbaceous vines may abound.

Vascular epiphytes are extremely diverse and include an almost infinite number of orchids, bromeliads, ferns (including the filmy ferns of the genus *Hymenophyllum*), aroids, ericads, cyclanths, gesneriads, and piperoids. Whereas the number of flowering epiphytes decreases with increasing altitude (lower temperatures), pteridophytic plant groups such as ferns and club mosses (Lycopodiaceae) become more abundant. Epiphytic bryophytes, including mosses (Musci) and liverworts (Hepaticae), are ubiquitous and cover the trunks, branches, and twigs of trees and shrubs. In addition, a diverse set of epiphytic and epilithic yellow, red, brown, green, and white-colored foliose, fruticose, and crustose lichens complete the rich spectrum of TMF life forms.

Animal Diversity

Faunal diversity is also striking. The diversity among birds and amphibians is especially remarkable. Recent research results show that the highest avian biodiversity in South America is found at the transition between Amazon TLF and TMF in the adjacent eastern slopes of the Andes. The Convention on International Trade in Endangered Species (CITES) and The World Conservation Union (IUCN)-listed, endangered spectacled bear (*Tremarctos ornatus*) known from the Andes in South America and the mountain gorilla (*Gorilla gorilla beringei*, with 620 individuals in 2000) inhabiting the Virunga volcanoes on the border of the Democratic Republic of Congo, Uganda, and Rwanda in Africa are probably the best-known 'flagship' mammals still living in TMF, although with populations hunted down, in an ever-decreasing habitat. Other species still to be found in TMF and TMCF include a tapir, large cats (puma, jaguar, ocelot), several deer, marsupials, monkeys, rodents, rabbits, mice, and a fair number of bats, among many others. Studies on TMF arthropods (insects, spiders) have only just begun and species numbers have to be estimated. In most cases, little is known about the distribution, natural history, and population ecology of TMF animal species and further attention from scholars is urgently needed.

Disturbance Regimes

TMF and especially TMCF in the neotropics are often affected by natural disturbance regimes, including factors such as storms and hurricanes. Storm-induced landslides are a common phenomenon on steep slopes in TMF areas and may cause local forest disturbance.

Table 2 Most important vascular plant families and genera observed in neotropical montane forests (data from the author)

Life form	*Family*	*Genus*
Needle-leaved trees	Pinaceae	*Pinus*
	Podocarpaceae	*Podocarpus*, *Prumnopitys*
Broad-leaved trees	Annonaceae	*Guatteria*
	Betulaceae	*Alnus*

Studies conducted in the TMF of the Luquillo mountains in Puerto Rico demonstrate the importance of disturbance, both natural and anthropogenic, in controlling both the structure and functioning of these forests. On a smaller scale, the same is true for tree fall gaps caused by the natural death of senescent TMF trees. However, many successional plant species, pioneers as well as late-secondary elements, appear to be well adapted to the sudden occurrence of natural gaps, which they may colonize within a short period of time. A whole gamut of fast-growing pioneer herbs and soft-wooded shrubs may fill a gap within a few weeks or months, particularly in the wet season, although full recovery following a large-scale disturbance may take decades or up to a century or more. A study of TMF recovery taking place after a period of clearing, burning, and years of grazing in Costa Rica resulted in a conservative estimate of 65–85 years as the theoretically minimum time needed for recovery of the terrestrial structure and floristic composition of the forest. An additional 50 years may be necessary for a natural recovery of the full epiphytic biomass and flora present before the disturbance took place (**Figure 5**).

Conservation and Utilization

Forest Conversion and Habitat Loss

TMF has suffered a long history of transformation by human beings. Particularly in the Andes, TMF conversion took place long before the arrival of the Hispanic culture some 500 years ago. Near Bogotá, Colombia, large groups of gatherers and hunters lived in the TMF altitudinal belt some 12 500 years before the present time, while indigenous artifacts in the TMF zone at the flanks of the Llalo volcano in Ecuador date from some 14 000 years before now. Intensive maize agriculture started in the Colombian Andes some 2500–3000 years ago.

The current situation of TMF is alarming, as it has become one of the most threatened tropical ecosystems worldwide. Over the centuries, as mountain roads were constructed, TMF has been cleared to harvest timber, fuelwood, and charcoal, and cut and burned for crop and grazing land. The loss of about half of the Mexican TMF, and especially its mesophyllous TMF, is just one of many striking examples. In Colombia, only 10–20% of the original TMF cover (i.e., as present in pre-Columbian times) remains today. Due to habitat fragmentation, endemic bird and frog species concentrated in TMF may become threatened with extinction. In Central American TMF the dwindling resplendent quetzal (*Pharomachrus mocinno*) has become the flagship bird species in conserving remnant TMF fragments. The golden toad (*Bufo periglenes*) – now believed to be extinct due to climate change (e.g., loss of cloud cover) and habitat loss – has become the symbol of the destructive human impact on TMCF worldwide. Moreover, invasive alien species have become an

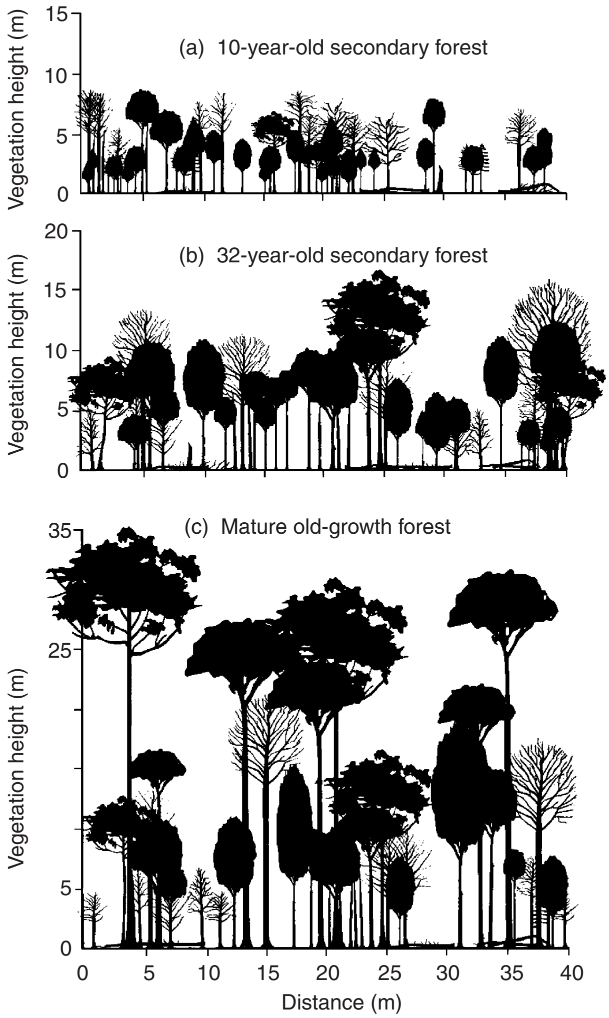

Figure 5 Schematic lateral profiles of three successional stages of tropical montane oak-bamboo forest at 2700–2900 m elevation in Costa Rica (Talamanca mountains). (a) 10-year-old secondary forest (following clearing, grazing, and abandonment); (b) 32-year-old secondary forest (following clearing, grazing, and abandonment); (c) over-250-year-old mature forest (data from the author).

increasing threat to native and often endemic plant and animal species (e.g., the African kikuyu grass which was introduced in tropical montane America).

Sustainable Forest Management

It appears to be extremely difficult to manage TMF in a sustainable way, due to the unfavorable conditions in climate (high rainfall), topography (steep slopes in rugged, highly dissected terrain) and soils (fragile, susceptible to erosion). Moreover, TMF has an important hydrological function, especially in the upper watersheds where water resources are accumulated which serve as drinking and irrigation water for human communities and as generators of hydroelectricity for households. Once mountain roads are constructed and the TMF has been removed, these hydrological services vital to people living down-slope are almost irrevocably lost. Soil erosion and landslides take place and may lead to the ultimate rise of badlands, which cannot be used by humans. Down-slope, runoff of sediment-loaded water (e.g., mud flows) may cause uncontrolled flooding, affecting mid-elevation and lowland villages. Many slopes in areas formerly covered by TMF have been converted into badlands and are now one of the best examples worldwide of how we have mismanaged nature and its natural resources.

Therefore, it is of utmost importance to develop sustainable ways of TMF use. Currently, numerous projects directed at sustainable forest management are underway worldwide. A successful example in TMF areas is the growth and use of secondary forests on previously grazed but now abandoned pasturelands where once old-growth, mature TMF grew. These naturally regenerated, restored forests are subsequently used in a selective way by coppicing and controlled fuelwood extraction, as elements of agroforestry systems or as bird-watching sites to be visited by ecotourists.

Valuation of Traditional and Potential Uses of Biodiversity

On all tropical continents (America, Africa, Asia, and Oceania), TMF products and services have extensively been used for many centuries and probably millenniums, to maintain local human populations. Traditionally, but also in modern times, rural communities have gathered numerous timber and nontimber forest products from TMF, including food, fodder, fiber, fuel, medicine, dyes, gums, oils, antioxidants, spices, poisons, ornamental plants and pets. Examples are found among populations in Central America, the Andes, the African Eastern Arc, the Himalayas, Western Ghats, Indonesia and Papua New Guinea.

An ethnobotanical survey of traditional knowledge in a Costa Rican TMF revealed the use of almost 25% of all 590 species of plants by a local farming community for medicinal, food, ornamental, and construction purposes or as sources of combustibles, dye, fodder, gum, oil, and poison. Indeed, among the planet's TMF species are many wild relatives of some of the world's major food plants (e.g., wild potato and tomato plants in the Andes, avocado trees in Central America, and coffee shrubs in Africa). The preservation of their genetic resources in protected areas is essential to society.

TMF harbors species of plants, animals, and microorganisms, many of which are endemic and/or threatened, and many of which are not yet known to science. They may have a potential in future medicine and may only be revealed after being discovered and screened by biodiversity prospecting and biochemical analysis. These species only flourish if they can maintain minimum viable populations in minimum-sized habitats where ecological integrity is guaranteed. Therefore, it is of utmost importance to conserve and, where necessary, restore their habitat in today's fragmented TMF landscape mosaic.

Conservation and Sustainable Development

At present, only about one-third (23 million ha) of the neotropical TMCF area has some kind of protected status. If we are to preserve a large part of TMF's variety of life as expressed in its genes, species, and ecosystem types in the long term, we will need to elaborate a conservation strategy in which not only networks of protected core areas, buffer zones, and corridors form a fundamental component, but also participatory planning strategies in which different local and regional stakeholder groups and decision-makers are involved, in order to establish a broad-based, consensus-oriented conservation framework. This is particularly vital as a prerequisite for long-term conservation and sustainable use, for it is the recognition of the overall set of environmental goods and services offered by TMF to the local and regional peoples – and thus strategies including compensation payments to forest-owners for these goods and services – which will make its conservation economically necessary, sociopolitically feasible, and ecologically successful.

Woody Legumes (excluding Acacias)

S Harris, University of Oxford, Oxford, UK

Introduction

The Fabaceae (or Leguminosae) is the second largest family of flowering plants. Furthermore, no family, except perhaps the Poaceae, has a wider geographical distribution in a broader range of habitats. Legumes are distributed throughout every continent, except Antarctica, and in almost every habitat from the freshwater lakes of Amazonia, through the tropical and subtropical forests of the New and Old Worlds to the deserts of Central Asia and the arctic-alpine vegetation of the temperate region. The reason for the ecological success of the family has been suggested as the ability to form root nodules with nitrogen-fixing bacteria, although not all Fabaceae fix nitrogen. Together with their ecological diversity, the Fabaceae have habits that range from annual herbs through lianas to shrubs and very tall trees (at approximately 88 m, the tallest tropical angiosperm is the Southeast Asian tree *Koompassia excelsa*). In tropical and subtropical regions, legumes are primarily woody, whilst in temperate regions they are herbaceous. It is the herbaceous legumes that have the most obvious economic value to humans (particularly the genera *Phaseolus* and *Glycine*). However, the economic value of woody legumes is also immense, particularly in the tropics, and ranges from timber, fuelwood, and forage production to sources of resins, toxins, and dyes. The present article, which focuses on the woody legumes (excluding the genus *Acacia*), will provide an overview of Fabaceae systematics together with information on their ecological and reproductive diversity. Finally, the utility of woody legumes is reviewed.

Systematics

The Fabaceae comprises approximately 640 genera and 18 000 species, which have traditionally been divided into three morphologically distinct subfamilies (Mimosoideae, Caesalpinioideae, Papilionoideae) (**Table 1**), although some classification systems have also recognized these subfamilies as families. Molecular and morphological data strongly support the monophyly of the Fabaceae, although the monophyly of only two (Mimosoideae, Papilionoideae) of the three subfamilies is supported. Subfamily Caesalpinioideae is paraphyletic, with some genera more closely related to the Mimosoideae and some to the Papilionoideae than they are to each other. The three subfamilies have disproportionate distributions of species with the tree habit; more than 80% of subfamilies Caesalpinioideae and Mimosoideae are trees, whilst less than 40% of the Papilionoideae are trees. Furthermore, the Caesalpinioideae and Mimosoideae are primarily tropical whilst the Papilionoideae are primarily temperate.

Each subfamily is divided into tribes (**Table 2**); the Papilionoideae contains the largest number of tribes, of which fewer than half contain tree species. Molecular data indicate that temperate herbaceous lineages are more recently derived from woody tropical lineages, although it is unclear how many origins of the herbaceous habit have occurred. Furthermore, within the Papilionoideae, *Swartzia* and the tribe Sophoreae appear to be basal groups.

The Fabaceae contains some of the largest and most diverse genera in the plant kingdom, e.g., *Acacia*, *Astragalus*, and *Mimosa*. Furthermore, these genera may contain high numbers of endemic species, for example, *Mimosa* in central Brazil.

Table 1 Characteristics of the three subfamilies in the Leguminosae

	Mimosoideae	*Caesalpinioideae*	*Papilionoideae*
Genera/species (approximate)	64/2950	153/2175	425/12 150
Habit	Trees or shrubs, some herbs	Trees or shrubs, some herbs	Herbs or shrubs, some trees
Leaves	Usually bipinnate	Usually pinnate or bipinnate	Pinnate to trifoliate, occasionally unifoliate
Corolla	Actinomorphic. Petals just touching. Not showy	Usually zygomorphic. Petals overlapping, upper petal usually innermost. Usually showy	Mostly zygomorphic. Petals overlapping, upper petal outermost. Showy
Stamens	Ten to many. Showy	One to 10. Usually not showy	Ten. Not showy
Pollen	Monads, tetrads, polyads	Monads	Monads
Pleurogram	Present	Usually lacking	Lacking
Root nodule occurrence	60–70%	25–30%	>95%

Table 2 Distribution of woody taxa among the Fabaceae tribes; only those tribes containing trees are shown

Tribe	*Habit*	*Distribution*	*Example genera*
Caesalpinioideae (four tribes total)			
Caesalpinieae	Trees or shrubs, rarely herbs	Primarily tropical	*Erythrophleum* *Caesalpinia* *Parkinsonia*
Cassieae	Trees or shrubs, rarely herbs	Tropical and subtropical	*Ceratonia* *Dialium* *Senna*
Cercideae	Trees or shrubs	Mainly tropical, one genus north temperate	*Cercis* *Bauhinia*
Detarieae	Trees; some suffrutices	Tropical	*Cynometra* *Afzelia* *Brachystegia*
Mimosoideae (five tribes total)			
Parkieae	Trees	Tropical	*Parkia* *Pentaclethra*
Mimoseae	Trees or shrubs, rarely herbs	Tropical and subtropical, rarely temperate, most numerous in tropical South America and Africa	*Mimosa* *Prosopis* *Entada*
Acacieae	Trees or shrubs, rarely herbs	Mainly tropical and subtropical	*Acacia* *Faidherbia*
Ingeae	Trees or shrubs	Mainly tropical	*Inga* *Calliandra* *Albizia*
Papilionoideae (31 tribes total)			
Swartzieae	Trees, rarely shrubs	Tropics	*Swartzia* *Mildbraediodendron*
Sophoreae	Trees or shrubs, rarely herbs	Tropics	*Sophora* *Myroxylon* *Ateleia*
Dipteryxeae	Trees	Neotropics, mainly Amazonia	*Dipteryx* *Pterodon*
Dalbergieae	Trees or shrubs	Tropics, mainly tropical America	*Dalbergia* *Macherium* *Pterocarpus*
Millettieae	Trees or shrubs	Mainly tropical	*Derris* *Lonchocarpus* *Millettia*
Robinieae	Trees, shrubs or herbs	Temperate and tropical New World, *Sesbania* pantropical	*Sesbania* *Gliricidia* *Robinia*
Psoraleeae	Small trees or shrubs, rarely herbs	Widespread, rarely tropical	*Psoralea*
Amorpheae	Small trees, shrubs or herbs	New World	*Amorpha* *Dalea*
Carmichaelieae	Small trees or shrubs	New Zealand	*Carmichaelia*
Brongniartieae	Trees or shrubs	New World	*Brongniartia*
Podalyrieae	Small trees or shrubs	South Africa	*Podalyria*
Genisteae	Small trees, shrubs, or herbs	Worldwide	*Genista* *Ulex*

Ecology

The morphological diversity of legumes reflects ecological diversity, where species occupy habitats as diverse as the deserts of Central Asia, estuarine tropical forest to temperate and alpine forests. However, it is in the tropical habitats that the greatest diversity of tree legumes is found. Legumes are important ecosystem components wherever they are found, although some habitats are dominated by tree legumes, for example, the miombo woodlands of southern Africa. In other cases, legumes may be infrequent; for example, despite the value of the timber, large-scale commercial exploitation of *Ormosia* species in Southeast Asia is limited because the low density of individuals makes selective harvesting uneconomic.

In addition to their dominant role in some natural habitats, woody legumes may also be important components of pioneer and secondary forest vegetation, for example, *Mimosa* species in the neotropics. Furthermore, changes in human activities (e.g., pasture management) may cause considerable changes in legume domination. Another major effect of humans on the distribution of woody legumes has been the intercontinental movements of species, for example, neotropical species being moved to Africa and Asia. The consequences of such movements have been unpredictable; some species can be highly productive in part of the introduced range whilst destructive in other parts of the range, for example the high value of *Leucaena leucocephala* as a fodder in Australia but its major role as a weed in Hawaii.

Legumes generally form symbiotic relationships with the bacterial genus *Rhizobium*, producing root nodules and fixing atmospheric nitrogen, although this is not always the case, particularly in the Caesalpinioideae (**Table 1**). In addition to root nodules, legumes may also have mycorrhizae.

Reproductive Biology

In legumes, the pollination unit is either the inflorescence or the flower, and pollen is usually released as monads (single cells), although in the Mimosoideae pollen is also often released as tetrads or polyads (groups of pollen grains). Mechanisms to promote outcrossing in legumes include: (1) protogyny, where the stigma is receptive to pollen before pollen in the same flower is released; (2) andromonoecy, where male and hermaphrodite flowers occur on the same plant; and (3) self-incompatibility, where successful fertilization is determined by the genotype of the pollen. Rarely are legumes dioecious (e.g., *Ateleia*). The structure of the legume inflorescence suggests that the majority of species are pollinated by insects, including Coleoptera, Diptera, Hymenoptera, and Lepidoptera, although others are pollinated by mammals (e.g., *Parkia*) and nectarivorous birds (e.g., *Erythrina*). However, some legumes (e.g., *Ateleia herbert-smithii*) are wind-pollinated. In addition to sexual reproduction, vegetative reproduction may also be important in both natural (e.g, *Albizia*) and artificial (e.g., *Gliricidia sepium*) ecosystems.

Seed dispersal in legumes is usually by gravity or mechanical means. Many genera have elastically dehiscent fruits, whilst others may be dispersed by water (e.g., *Entada*) and wind (e.g., *Centrolobium*, *Pterocarpus*). However, mammals (e.g., for *Inga*, *Tamarindus*) and birds (e.g., for *Pithecellobium*) may play an important role in seed dispersal. Humans are an important means of long-distance dispersal of legume seed, whether it is seed for establishing plantations (e.g., *Calliandra*), cultivation of ornamentals (e.g., *Delonix regia*), movement of multipurpose species (e.g., *Gliricidia sepium*), or transport by their livestock (e.g., *Mucuna*).

Many legume seeds have hard seed coats (particularly Caesalpinioideae and Mimosoideae) and need to be scarified before they will germinate. Scarification may occur naturally by passage through animal guts, although for plantation establishment it is necessary to use other treatments (e.g., damaging the seed testa or treatment with boiling water). Many legume seeds may be lost through predation of the developing ovules by beetle larvae (Bruchidae) at the early stages of fruit development.

Utilization

Timber

The morphological and ecological diversity of legumes are reflected in their wood properties, ranging from hard, durable woods (e.g., *Xylia*) to soft, perishable woods (e.g., *Erythrina*). Potentially, therefore, legume woods are suitable for all purposes, from building (e.g., *Koompassia*) to boat construction (e.g., *Copaifera*, *Pterocarpus*) and carving (e.g., *Dalbergia*). For example, legumes provide some of the most highly prized woods for the manufacture of fine furniture, marquetry, and veneers, including the rosewoods (*Dalbergia*) of South America and Southeast Asia, Jichimu (*Ormosia*) of China, and *Afzelia* of Africa and Southeast Asia. Trade in some species has threatened natural populations (e.g., *Pericopsis mooniana* in Southeast Asia and *Dalbergia latifolia* in India), whilst the properties of some genera have influenced how they are extracted from forests. For example, the wood of *Cynometra* species is so dense that trunks sink in water and hence they must be moved over land rather than floated down rivers.

Tannins and Resins

The pods of *Caesalpinia* species (e.g., *C. brevifolia*, *C. coriaria*, *C. spinosa*) and the bark of *Robinia pseudoacacia* are important sources of vegetable tannin (used in leather and adhesive manufacture). Species of *Hymenaea* and *Copaifera* are important sources of resin for the manufacture of high-quality varnishes, particularly as copals.

Human Food and Ornamentation

Tree legumes are minor sources of human foods, particularly in their native areas; for example, the immature pods of *Leucaena* species are used as a vegetable in Mexico and *Prosopis juliflora* pods are used for the manufacture of flour, syrup, and coffee substitutes (**Figure 1**). Some species (e.g., the pulp of *Tamarindus indica* fruits) have both local and international markets. The fruits of *Ceratonia siliqua* are an important source of edible gum (locust gum) and are used as a cocoa substitute. Tree legumes can also be important sources of nectar for honey production (e.g., *Robinia*, *Calliandra*) or habitats for bees (e.g., *Koompassia*). Brightly colored legume seeds (e.g., *Erythrina*, *Ormosia*, *Adenanthera*) are often used in ethnic jewelry whilst *Dipteryx* seeds are a source of perfume.

Fodder

Legume trees are important food components of animal diets in natural populations, whilst there are significant economic uses of the foliage and green pods as livestock fodder of many genera (e.g., *Calliandra*, *Gliricidia*, *Leucaena*, *Prosopis*, *Ulex*). In the case of *Leucaena*, a nonprotein amino acid called mimosine is found which at high concentrations may result in reduction in weight gain, hair loss, and abortion in nonruminant animals. Furthermore, fodder species may also have additional uses, e.g., fuelwood and charcoal. Legumes may also be important shade trees in some agroforestry systems, e.g., *Inga* species as shade trees for coffee production in South America.

Ornamentals, Dyes, Poisons, and Medicines

Legume species are planted throughout the tropics as street trees, e.g., *Delonix regia* and *Albizia lebbeck*, whilst others (e.g., *Laburnum*, *Robinia*, *Wisteria*) are important temperate ornamentals. Indigo (*Indigofera tinctoria*; Asia) and logwood (*Hymantoxylum campechianum*; Mexico) provide two of the most important plant-derived dyes, whilst historically other important dyes have been isolated from the genera *Caesalpinia* and *Genista*. *Derris elliptica* and *Lonchocarpus* species are used as fish poisons in South America but have recently attracted attention as environmentally friendly insecticides. Numerous traditional products are derived from legume trees. For example, *Erythrophleum suaveolens* bark is used as an ordeal poison throughout Africa. The seeds of *Sophora secundiflora* (mescal bean) are used by native North Americans to induce hallucinations, although the psychoactive alkaloid (cytisine) is very toxic. Many legume genera (e.g., *Cassia*) yield both locally and internationally important medicines.

Weediness

Many woody legumes have become serious weeds, particularly in the tropics. Genera introduced for forestry purposes may have unforeseen weedy

Figure 1 Examples of inflorescences from the three legume subfamilies. (A) *Leucaena greggii*, a mimosoid legume; (B) *Bauhinia* sp., a caesalpinoid legume; (C) *Pterodon pubescens*, a papilionoid legume.

consequences, e.g., *Leucaena leucocephala*, *Parkinsonia aculeata*, *Prosopis juliflora* and *Robinia pseudoacacia*, whilst changes in management practice may make previously valuable species potential weedy species, e.g., *Ulex europaeus* in Scotland. The weediness of woody legumes means that their use in agroforestry and amenity situations must be considered very carefully.

WINDBREAKS AND SHELTERBELTS

B Gardiner, Forest Research, Roslin, UK

Historical Background

The use of trees for personal shelter or for the shelter of livestock is as old as the history of humanity although this has tended to be opportunistic. Planting for shade around habitation or along roads has a long and established history, but only recently have there been systematic efforts to improve climatic conditions through tree planting. Over the last 200 years there has been a much more systematic approach to the use of trees to shelter agricultural crops and human habitation as part of the European agricultural reforms of the eighteenth, nineteenth, and twentieth centuries, particularly in Germany. Part of the motivation has been the expansion of agriculture onto land previously not used for crop production. This has included the prairies of North America, the steppes of Russia and the Ukraine, and the heathlands of Denmark. More recently shelterbelts have been planted extensively in parts of China, Japan, New Zealand, and Australia. In addition, shelter from trees and the way they modify microclimate is a critical component of agroforestry systems and is of particular importance in the drier tropics and subtropics.

Shelter Basics

The principal aim of planting trees for shelter is to modify the local microclimate. Trees can provide shelter from the wind, precipitation, blowing snow, and the sun. They are also effective at capturing dust and pollution (see Further Reading section for recent reviews of current knowledge).

Wind is the flow of air in response to atmospheric pressure differences, and modifying this flow is the principal way in which shelterbelts are used to affect microclimatic conditions. Modifying the airflow not only affects wind speed but also turbulence intensity, temperature, humidity, and soil erosion. At the same time the shelterbelts may affect the amount of sunlight falling on adjoining fields and heat loss due to radiation.

Shelterbelts and windbreaks present a porous obstacle to the approaching airflow, creating an increase in pressure ahead of the belt and a decrease behind (**Figure 1**). The high pressure slows the

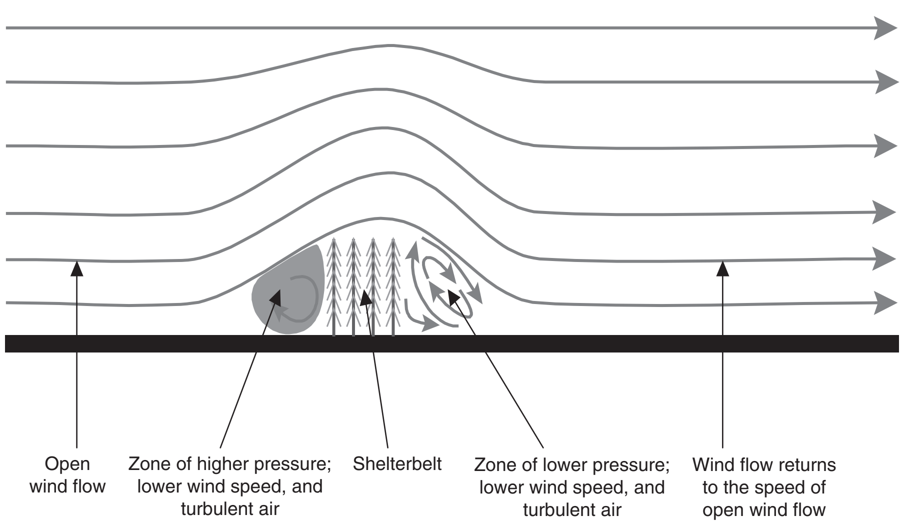

Figure 1 Flow pattern over shelterbelt or windbreak. Crown Copyright 2004.

approaching flow down and forces it to be deflected upward in a region referred to as the displacement zone (**Figure 2**). Above the top of the shelterbelt the wind is accelerated and the increased wind shear leads to an increased production of turbulence. Some of the approaching flow filters through the shelterbelt with a reduced velocity due to the drag provided by the trunks, branches, and foliage. If the shelterbelt is extremely dense then almost no air penetrates through the wood and a stagnant slow circulating eddy is formed behind the shelterbelt. The more open the shelterbelt is, the weaker this feature becomes until it disappears completely and the wake zone begins immediately behind the shelterbelt. The wake zone is the region in which fast-moving air displaced above the shelterbelt begins to mix with the slower-moving air that has filtered through the shelterbelt. Downstream of the shelterbelt, within the wake zone, the wind speed gradually increases until it is the same as the wind speed upwind. The wake zone is the main area where there are microclimatic benefits of shelter.

Microclimatic Benefits

A summary of the main microclimatic changes associated with shelterbelts is given in **Table 1**.

The wind speed is reduced ahead of and behind the shelter. However, turbulence levels may be increased in the cavity zone, which can lead to increased lodging and abrasion damage to crops. Within the shelterbelt itself the wind speed of the flow through the trees is generally reduced. However, if the wood has a very open understory squeezing of the flow between the canopy and the ground may increase the wind speed under the canopy.

The daytime temperature and relative humidity are generally increased in the cavity and wake zones. However, close to and within the shelterbelt there may be shading from the sun, which will reduce the temperature. This may be a disadvantage if solar heating is important, but if crop scorching or sunburn to animals is a consideration it may be of benefit. Within the shelterbelt the night-time temperatures will be raised because the canopy reduces radiation transfer to the atmosphere. However, the night-time temperature may be reduced in the cavity zone if the belt is very dense because it will restrict mixing of cold air near the ground with warmer air above.

Within the wake zone the reduced wind speed and turbulence leads to a reduction in the movement of gases to and from the ground. This means that moisture levels are higher and there is reduced water

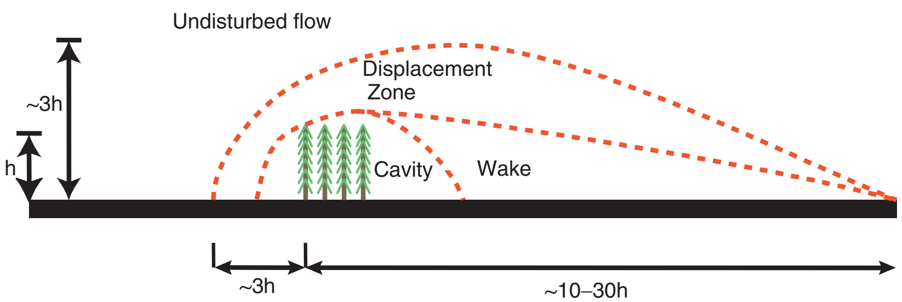

Figure 2 Description of flow zones in vicinity of shelterbelt or windbreak. Crown Copyright 2004.

Table 1 Changes in microclimatic conditions in different areas adjacent to a shelterbelt. Crown Copyright 2004

Area	*Increased*	*Reduced*
Displacement zone	Windspeed above shelterbelt Turbulence	Windspeed at ground level Sunlight close to shelterbelt
Inside shelterbelt	Windspeed (only for very open shelterbelt) Nightime temperature	Windspeed Daytime temperature Sunlight
Cavity zone	Turbulence Daytime temperature Humidity Lodging and abrasion Waterlogging on wet soils	Wind speed Night-time temperature Sunlight close to shelterbelt
Wake zone	Daytime temperature Humidity Carbon dioxide	Windspeed Turbulence Erosion Water loss

loss from the soil. Close to the shelterbelt, within the cavity zone, this may lead to waterlogging if the soil is particularly wet or to increased plant growth if the soil is prone to drought. The reduced wind speeds also lead to reduced soil erosion.

Factors Controlling Shelterbelt Performance

Height

The height of the shelterbelt, together with its porosity, is the most important factor controlling performance of a shelterbelt. The area ahead of and behind the shelterbelt over which it is effective is a direct function of shelterbelt height. The higher the shelterbelt the larger is the area of shelter.

Porosity

In simple terms, porosity is a measure of how open the shelterbelt is and how easily the air can flow through it. The porosity of the shelterbelt directly influences the intensity and area of shelter produced by the shelterbelt. Porosity is affected by planting density, canopy distribution, species mix, shelterbelt width, and time of year.

A dense shelterbelt will result either from closely spaced trees and shrubs or a large width of woodland or a combination of both factors. Shelterbelts tend to have lower porosities when they are young. With time the porosity tends to increase as the trees grow and mortality occurs. In addition, a shelterbelt of deciduous trees may have a low porosity in summer but a much higher porosity in winter.

In a dense shelterbelt the majority of air is forced over the trees by the high pressure ahead of the shelterbelt. So little air passes through the shelterbelt itself that the flow separates and a cavity zone and a large drop in pressure is created behind the wood. This low pressure causes the high-speed wind above the shelterbelt to return quickly to the surface giving a short region of shelter but with very reduced wind speeds.

A medium-density shelterbelt allows much more air to flow through the belt. This reduces the chance of flow separation behind the wood so that the cavity zone may not exist and the wake zone begins immediately. The pressure changes across the shelterbelt are also less severe than with the dense belt and, therefore, the return of the faster-moving air towards the ground is more gradual. The result is the maximum area of shelter that any shelterbelt can provide but the intensity of the microclimatic changes are less dramatic.

An open shelterbelt has a limited area of shelter and the reduction in wind speed downwind may be minimal. If the lower part of the shelterbelt canopy is completely open it is possible actually to increase the wind speeds within and just downwind of the wood compared to the open field values.

Width

Width is generally not of such direct importance as height except in the way it affects porosity. A two-row shelterbelt is as effective as a six-row belt provided they both have the same porosity and it also uses less land. In extremely windy climates the leading rows of trees may be stunted in their growth and, therefore, a wider shelterbelt will be necessary to obtain the required height.

Very wide shelterbelts (width $>2\times$ height) do not provide more shelter than a narrow belt because they behave very similarly to a dense shelterbelt and wind speeds recover very quickly in their lee. Furthermore, the turbulence intensity over wide shelterbelts is greater and can lead to problems of lodging and plant abrasion.

However, an advantage of wider shelterbelts is that it is much easier to replace them when they get old and trees begin to die while at the same time retaining some shelter. With a narrow shelterbelt there will inevitably be a period of little shelter when the belt is replaced.

Length

To be effective, the shelterbelt must be longer than the length of the area requiring shelter. This is due to the triangular shape of the sheltered zone behind the shelterbelt. The air speeds up around the edge of the shelterbelt resulting in higher wind speeds and turbulence levels at the ends of shelterbelts. Behind the shelterbelt this high-speed turbulent air begins to encroach into the sheltered wake zone in an identical manner to the air that was displaced over the shelterbelt.

Orientation

The orientation of the shelterbelt to the wind affects the area provided with shelter. The greatest area of protection is provided when the wind strikes the shelter at right angles but this is reduced when the wind strikes at a smaller angle. Therefore, the shelterbelt is ideally located when it is perpendicular to the wind direction of particular concern (the long axis of the shelterbelt should be at right angles to the wind). However, it is possible to construct shelterbelts that provide protection from more than one direction.

Another effect of orientation is on porosity. A narrow shelterbelt is most porous to the wind when the wind strikes it at right angles. As the angle is reduced the porosity decreases because the effective width of the shelterbelt is increased. The effect is more marked with wide shelterbelts.

Openings

Any opening in a shelterbelt has the same effect as the ends of the shelterbelt by increasing the wind speed and turbulence through the gap. The wind speeds within the opening may be significantly higher than the upwind values. If an opening is required for access then it should be angled through the shelterbelt or a 'dog-leg' included.

Profile

The ideal profile for a shelterbelt is generally straight-sided. This provides the maximum shelter for the minimum use of ground. A profiled edge will tend to deflect more air over the shelterbelt and allow less to flow through the trees. The result is to produce a sheltered area very similar to that achieved with a dense shelterbelt.

Types of Shelter

Clearly the benefits of shelterbelts have to be balanced against the disadvantages. To ensure benefits are maximized careful shelterbelt design is required. Poor design can lead to a potential benefit becoming a disadvantage. In **Table 2** a summary of the type of shelterbelts to use for different purposes is presented. In general, semipermeable shelterbelts (porosity 40–60%) are used where a large area of moderate shelter is required. Typical enterprises are

Table 2 Shelterbelt types, their impact on windspeeds and their application. Crown Copyright 2004

Shelterbelt type	*Features (porosity/height/length)*	*Porosity profile*	*Area of windspeed reduction*	*Reduction of open windspeed*	*General application*
Windbreak	Semipermeable As tall as possible As long as necessary	60–40%	20–30 times height of the wood	20–70%	Crops Improved pasture
Windshield	Close to impermeable As tall as necessary As long as necessary	$<40\%$	Up to 10 times height of the wood (maximum shelter at 3–5 times the height)	Up to 90%	Lambing/calving areas Feeding areas Farm buildings
Hybrid	Impermeable understory; canopy semi-permeable As tall as possible As long as necessary	$<40\%$ understory 60–40% canopy	5 times (approx.) height of the understory 20–30 times height of the canopy	Up to 90% 20–70%	Where a combination of applications suit both windbreak and windshield shelterbelt types

Table 3 Benefits and disadvantages of shelterbelts for crops. Crown Copyright 2004

Benefits	*Disadvantages*
Increased ambient temperature leading to improved germination and growth rates	Competition with crops for light, moisture, and nutrients leading to reduced crop yields close to belts
Reduction of moisture loss and control of snow drifting	Increase in lodging due to increased turbulence
Reduction of mechanical damage leading to improved crop quality	Reduction in pollination for certain crops
Increased soil organic matter by production of leaf litter	Land taken out of production
Trapping or recycling nutrients	Waterlogging of soil close to dense belts
Reduction of soil erosion	High costs of establishment and management
Reduction of crop lodging	
Promotion of mineralization of soil nitrogen	
Retention of heat in the soil and air thereby extending the growing season	
Reduction of soil acidification in certain soil types	
Improvement of pollination efficiency for certain crops	
Control of spray drift	
Reduction of infiltration of water to groundwater systems preventing the rise of saline water tables	

Table 4 Benefits and disadvantages of shelterbelts for livestock. Crown Copyright 2004

Benefits	*Disadvantages*
Increased yield of pasture and root crops used for feed	Overcropping close to shelterbelt
Earlier grass growth in spring	Spread of disease by concentration of animals close to shelter
Reduced heat loss leading to increased animal productivity (milk production and weight gain)	Increase in insect pests in low wind speed region behind dense belts
Reduced mortality of newborn animals and shorn sheep	Reduction in air temperature on clear nights behind belts
Increase in range of breeds that can be utilized	
Shade provision reducing overheating and sunburn	
Increased animal welfare by provision of protection from wind, rain, snow, and sun	
Increased fertility due to better condition and provision of more comfortable conditions	
Reduction in heat loss on clear nights if animals able to move under trees	
Shelter for wildlife and game animals (deer, pheasants, etc.)	

Table 5 Benefits and disadvantages of shelterbelts for buildings and roads. Crown Copyright 2004

Benefits	*Disadvantages*
Reduced heat loss during cold weather leading to energy efficiencies	Land use
Shading in summer providing a reduction in requirements for air conditioning	Damage to buildings by the roots of trees planted too close
Improved conditions in the vicinity of buildings such as lower wind speeds and increased temperatures	Shading by trees reducing the heating benefits of the sun
Reduction in building damage from driving rain and diurnal temperature fluctuations	Increased snow build-up from poorly designed or positioned snow belts
Increased animal comfort in barns sheltered by trees	
Roads kept free of snow drifts	
Visual screening of buildings and roads	
Reduction in noise levels	
Capture of pollution such as dust, soot, spray, and gases	

the protection of crops and improved pasture. Dense shelterbelts (porosity $<40\%$) are used where intense shelter is required over a short distance, such as for the protection of lambing and calving and buildings. In some cases it is beneficial to have some of the features of both a semipermeable and a dense shelterbelt. This can be achieved with a hybrid shelterbelt in which the upper part of the belt is relatively open and the bottom of the belt is made dense by planting shrubs or slow-growing shade-tolerant trees.

Generally shelterbelts should be kept as narrow as possible. This is partly to minimize the land used but also to maintain the effective area downstream. Wide forests are found to be very ineffective at providing a large area of shelter. However, where snow retention is the objective, a wider wood can provide a larger area of snow accumulation. (Snow accumulation is useful in protecting roads from drifting or helping to stop snow blowing off farmlands where it accounts for a significant part of the total precipitation, such as the northern prairies of the USA). It has been found that multiple shelterbelts have no cumulative benefit but rather the increased turbulence behind upwind belts can slightly reduce the effectiveness of subsequent shelterbelts.

Shelterbelt Use

Shelter of Crops

Shelter can provide positive and negative benefits to crops as summarized in **Table 3**.

Shelter of Livestock

Much less work has been carried out on the benefits of shelterbelts for livestock in comparison to crops (see **Table 4**).

Shelter of Buildings and Roads

The benefits of shelter for buildings and roads are summarized in **Table 5**.

WOOD FORMATION AND PROPERTIES

Contents

Formation and Structure of Wood

A Zink-Sharp, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Introduction

Close examination of a piece of wood with a microscope reveals a minute cell structure that usually escapes casual observation. Remarkably, it is this minute cell structure that is responsible for many of the physical properties and characteristics of a piece of wood. All materials exhibit some degree of dependence on the fine structure of their components; however, this tendency is very pronounced with wood. An understanding of the appearance, properties, and potential of wood for use requires complete comprehension of both the physical properties and the fine structure. Knowledge of the formation processes is also required for complete awareness because wood is produced in a biological environment and the tree is subject to varying growth conditions. The formation of wood and its anatomical structure on the micro- and macroscopic scale are described in this section. Chemical and physical properties are described elsewhere (*see* **Wood Formation and Properties**: Physical Properties of Wood; Mechanical Properties of Wood.

Tree Growth and Wood Formation

Features of Woody Plants

Woody tissue is formed in a variety of plants, but it is the wood in trees that is of interest here. Characteristics of all woody plants include the following:

- possess vascular tissue that is specialized conducting tissue consisting of xylem (wood) and phloem (inner bark)
- are perennial and live for a number of years

- have a persistent stem that endures from year to year and does not die back
- have a means of secondary thickening of the stem by subsequent growth in diameter.

The basic structural and physiological unit of plants is the cell. Wood is a collection of various kinds of cells that are typically elongated and consist of an outer cell wall encompassing a hollow cell cavity. Wood cells are the result of secondary diameter thickening of tree stems. They exhibit an orderly arrangement that is characteristic of tree species, and each type of cell has a specific function.

Basic Processes in Tree Growth

Tree growth parallels the seasons in many parts of the world. It begins in the spring, slows in midsummer, and usually stops entirely in the autumn. A well-defined sequence of activities takes place during each growth season. Growth is activated when temperatures warm to an average of about 6° or 7°C and growth hormones are produced in the buds. At about the same time, water and dissolved minerals begin to move up the stem from the roots to the buds, then the buds swell due to formation and growth of cells, and soon thereafter, leaves emerge from the buds. The process of photosynthesis now begins in the leaves. During photosynthesis, water and carbon dioxide from the atmosphere are combined in the presence of chlorophyll and sunlight to make several different types of sugar.

Products of photosynthesis include oxygen that is released to the air and basic sugars, such as glucose, mannose, galactose, xylose, arabinose, and other five- and six-carbon sugars. The glucose units produced during photosynthesis are used to form cellulose, a linear, long-chain polymer with a degree of polymerization ranging as high as 30 000 monomer units. Glucose and the other five- and six-carbon sugars and sugar derivatives are used in synthesizing lower molecular weight hemicelluloses. These are branched polymers, with degrees of polymerization only in the hundreds. The tree transports the sugars to growth regions at branch and root tips and to the growth region that sheaths the main stem where they will be used to fuel cell formation and development.

New cells are formed in trees in growth areas called meristematic regions. There are two meristems involved in height and diameter growth, the apical meristem and the vascular cambium. Apical meristems are responsible for growth in height. They are composed of specialized dividing cells found at branch tips. As new cells are formed at the branch tips, the apical meristems are pushed outward, where they continue to divide and form new cells. In this manner, branches lengthen, the crown expands, and the tree gets taller and broader. Height growth begins just after the leaves emerge and is rapid at first, but slows as the growth nutrients are diverted to other regions in the tree.

Trees expand in diameter through cell enlargement and repeated cell division in the vascular cambium. This meristematic region is a thin layer of cells that lies just underneath the inner bark. It completely sheaths the entire tree and consists of specialized cells that divide to form new phloem (inner bark) to the outside and new xylem (wood) cells to the inside. Each growing season, the vascular cambium forms new layers of wood and inner bark over the entire surface of the stem and the branches. The result is an increase in stem and branch diameter (**Figure 1**).

Diameter growth in trees found in temperate zones occurs in two stages. This in turn results in two growth zones familiar to us as annual tree rings. These two growth zones are the earlywood and latewood portions of a tree ring. Cell formation during the early spring is rapid and focused on quantity. As a result, the earlywood cells form a large portion of an individual growth ring, and the cells themselves are often thin-walled and large in diameter. Toward the late summer, cell formation slows and a different scheme is used to produce new cells. Cells formed late in the growing season make up the latewood portion of tree rings. Usually there are fewer latewood cells produced per ring than earlywood, and they are thicker walled and smaller in diameter.

Growth rings or annual rings are characteristic of all temperate zone trees but this is not the case in trees growing in tropical regions where growth can be continuous year round. In this case, the wood may

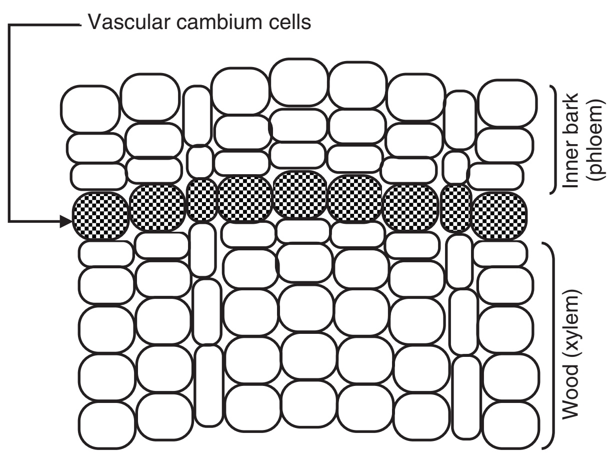

Figure 1 Diagram of a cross-section through the vascular cambium of a tree. Division of the cambial cells results in diameter expansion of the tree stem.

appear not to have any growth rings at all. Some notable exceptions are teak (*Tectona grandis*), padauk (*Pterocarpus* spp.), Honduras rosewood (*Dalbergia stevensonii*), Brazilian tulipwood (*Dalbergia fructescens* var. *tomentosa*), and sapele (*Entandrophragma cylindricum*), among others. In these woods, growth rings appear distinct due to specialized cell types and cell structure rather than two stages of growth annually.

Growth in trees is rapid in early spring but starts to decline as the end of the growing season draws near (approximately mid-July to October in the northern hemisphere). Eventually all growth stops when the meristem regions become dormant. The exact mechanisms that trigger initiation of dormancy are unknown, but there are common processes that occur. Production of growth hormones decreases and growth inhibitors accumulate. This combination results in a reduction in growth rate and eventually halting of growth. The factor that is thought to lead most reliably to dormancy is reduction in the photoperiod (length of day).

Formation and Development of Wood Cells

As mentioned earlier, wood cells in the stems of trees originate through division of the vascular cambium cells. This division can occur in one of two directions – parallel to the cambial ring or perpendicular to it. Division parallel to the ring is called periclinal and results in formation of a pair of cells – a new cambium cell and either a new xylem or phloem cell. Anticlinal division is division perpendicular to the ring and creates a pair of vascular cambium cells that provide for increasing the circumference of the cambium as the tree stem enlarges. The two types of division can take place in the same cambium cell, but do not occur simultaneously. **Figure 2** illustrates a highly idealized vascular cambium dividing periclinally to form two new cells. One of the cells becomes a new cambium cell and the other begins to mature into a new wood or bark cell. If the newly formed cell is to the outside of the cambium, it will become a bark cell, and if it is toward the inside, a wood cell.

Within a few days of formation, the new wood cell undergoes a sequence of changes involved in the maturation process. The shape of the cell changes, it increases in diameter, most cells elongate, and all cells enlarge. A newly formed wood cell consists of a thin, membrane-like wall called a primary wall and a fluid-filled center. A secondary wall is added to the inner surface of the delicate primary wall once the new cell reaches full size and shape. The secondary wall is constructed using macromolecules (cellulose, hemicelluloses, and lignin) that are synthesized from biopolymers found in the fluid-filled center of the developing cell. Progressive layers are added to the cell wall from the inside. Eventually the fluid filling is expended and the cell has a thickened, rigid wall and a hollow center. Cell formation and maturation continues during the growing season, with the vascular cambium producing new wood and bark cells as rapidly as the conditions allow. Earlywood cells are formed first in the early spring, and those formed later are the latewood cells. Cell formation and maturation continues until growth is terminated at the end of the growing period.

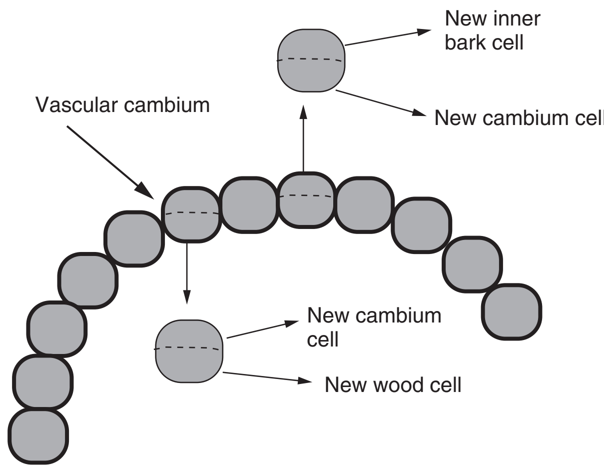

Figure 2 A highly simplified diagram of the vascular cambium dividing periclinally to form new cambial cells and new wood or bark cells.

Microscopic Structure

Chemical Structure

At the chemical element level, wood cell walls are made of carbon, hydrogen, and oxygen. Percentages vary with species, but average carbon content is 49%, hydrogen is about 6%, and oxygen is 44%, based on dry wood weight. There are other chemical elements found in wood but in very minor quantities. As mentioned above, carbon, hydrogen, and oxygen are combined in the fluid-filled center of a developing cell to synthesize macromolecules of cellulose, hemicellulose, and lignin. Cellulose and hemicellulose together make up the polysaccharide fraction of wood substance. Cellulose accounts for roughly half the dry weight of wood substance. Cellulose is a high molecular weight, linear polymer synthesized from the glucose produced during photosynthesis. Cellulose is present in all the higher plants, many of the algae, and some of the fungi. In a wood cell wall, cellulose occurs in both a crystalline and a noncrystalline (amorphous) form. Hemicelluloses are also formed using sugars produced during photosynthesis. In general, hemicelluloses are branched carbohydrate polymers that constitute from 35% to 50% of the total dry weight of wood substance. Lignin is not a polysaccharide but rather a complex, high molecular weight amorphous polymer built upon phenylpropane units. Lignin content varies from 15% to 35% of the dry weight. Percentages of the various chemical components differ with tree species and growth conditions.

The three macromolecule groups – cellulose, hemicelluloses, and lignin – are incorporated together to assemble the cell walls. An extremely efficient incorporation scheme is employed by wood cells for fabrication of their walls that is sometimes referred to as the 'reinforced matrix process.' Molecular chains of crystalline cellulose aligned lengthwise are encased in a shell of hemicellulose to construct a long filament. This core of cellulose and hemicelluloses is then surrounded in an amorphous matrix of lignin. In this manner, the lignin matrix is reinforced with cellulose and hemicellulose filaments. These filaments are usually called microfibrils, but just fibrils by some.

Cell Wall Structure

Microfibrils The basic building-block of wood cell walls is the cellulose microfibril. As mentioned above, the core of a microfibril is composed of groups of cellulose crystallites encased in hemicelluloses. During cell wall formation, microfibrils are encased in an amorphous matrix of lignin. Individual microfibrils are approximately 10–12 nm wide and about 5–6 nm thick. A typical wood cell wall consists of several layers of microfibrils in parallel aggregates. As seen in the next section, orientation of the microfibril aggregates varies within and across layers. Microfibrillar orientation greatly affects the properties of wood on all scales of structure and properties, however mechanical properties and the relationship between wood and water are most significantly impacted.

Cell wall layers A wood cell wall is not homogeneous in structure or chemical content. It is a rather complex, layered composite consisting of an outer primary wall and from one to three secondary inner layers. All wall layers, however, are composed of cellulose microfibrils embedded in the lignin matrix. The layers are continuous, but when a wood cell wall is viewed on the cross section with an electron microscope, it is possible to distinguish discrete layers within the cell wall. **Figure 3** is a drawing of a wood cell and the cell wall in cross-section. The outermost layer, the primary wall, is the first formed layer; it is high in lignin and pectin, it is very thin – on the order of 0.1 μm in thickness, and it has a random, netlike microfibril orientation. Once the cell reaches full, mature size, the secondary cell wall layer develops. Thickness of the secondary wall is highly variable, it is dense and rigid, and it consists of highly ordered layers of microfibrils aligned in nearly parallel aggregates. The number of secondary wall layers depends on cell type and to some extent, growing conditions. Cell walls that have the most advanced layer structure have three secondary layers, designated S_1, S_2, and S_3 (**Figure 3**).

Orientation of the microfibril aggregates varies from layer to layer in a cross laminate pattern (**Figure 4**). Microfibrils in the S_1 layer are oriented in parallel clusters that are roughly perpendicular to the cell axis. The S_2 layer microfibrils are nearly parallel to the cell axis, and the orientation in the S_3 is again nearly perpendicular to the cell axis. As mentioned, the cell wall is a continuum but discrete layers can be

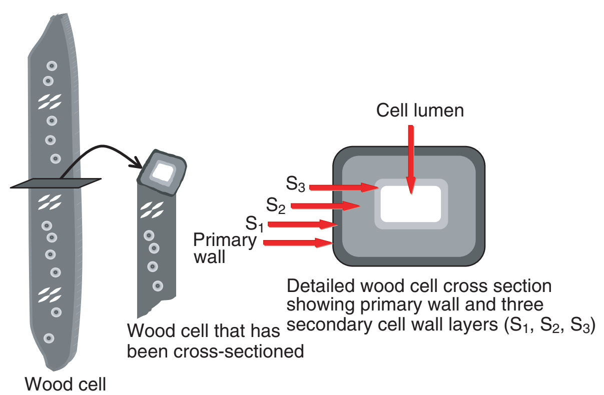

Figure 3 Diagram of a wood cell and the cell wall in cross-section.

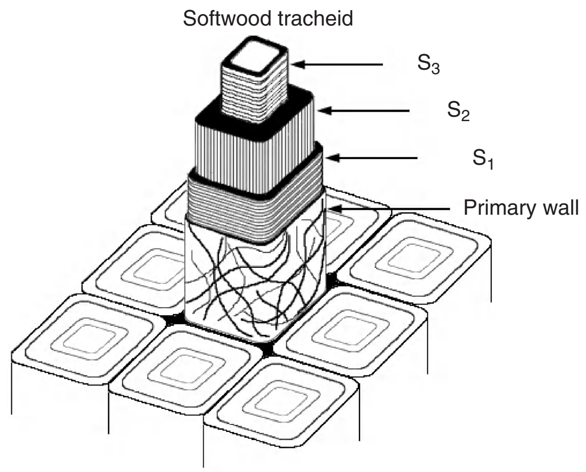

Figure 4 Diagram of cell wall layers and microfibrillar orientation within the layers.

identified in microscopic images. This wall structure is typical of almost all wood cells found in the needle-bearing trees (gymnosperms) and many of the cells found in the wood of the broadleaf trees (angiosperms).

Cell Types and Features

Due to the way in which wood cells are formed in the cambium and performance requirements of the tree, stem wood cells resemble tapered, rigid tubes in function and appearance. They are systematically assembled in tree stems in patterns that are reflective of tree type. Their cross-sectional shape varies from round to hexagonal, and their length varies from less than 1 mm to as long as 7 mm in certain trees. The majority have their long axis parallel to the tree stem, but up to 30% are oriented radially in the stem.

Trees are found in two botanical classifications based on seed type, the angiosperms and the gymnosperms. Angiosperms have seeds encapsulated inside an outer fruit, and gymnosperms have exposed seeds. In practice however, angiosperms are more commonly called hardwoods and gymnosperms, softwoods. While in general there are many similarities between the two groups, the fine structure and features are significantly different. The differences are found in the amount of cell diversity and in the arrangement schemes. **Figure 5** reveals these differences in fine cell structure. In the softwood (**Figure 5a**) the microstructure is fairly uniform and one cell type dominates the cross-section, the softwood tracheid. Tracheids occupy over 90% of softwood volume and are formed in uniform radial alignments. They average 3–5 mm in length and vary from 0.03 mm to 0.45 mm in diameter. Tracheids are rectangular to hexagonal in cross-section and are tapered at their ends. The ribbons of cells running vertically in **Figure 5a** are called wood rays. They are composed of a group of radially oriented cells called ray cells and are responsible for radial transport of fluids in the tree stem. Wood rays in softwoods are practically indistinguishable because they are almost always one cell wide, i.e. uniseriate. They occupy approximately 7% of the volume of softwood stems. Aside from the two cell types visible in **Figure 5a** (tracheids and ray cells), there is really only two other noticeable differences in cell structure: tracheid diameter and wall thickness. Tracheids formed early in the growing season in softwood trees found in temperate zones, i.e., the earlywood, are larger in diameter and have a thinner cell wall than those formed later in the growing season.

Pines (*Pinus* spp.), Douglas-fir (*Pseudotsuga* spp.), larches (*Larix* spp.), and spruces (*Picea* spp.) genera have a specialized feature called resin canals. These are basically a space between cell corners that has been surrounded by specialized resin-secreting cells, as seen at the arrows in **Figure 5b**. Resin canals are oriented both longitudinally and radially in those genera that normally exhibit them. They can be found also in other softwood trees that have been injured in some way. Resin canals that result from injury are called traumatic resin canals and are almost exclusively longitudinal in orientation.

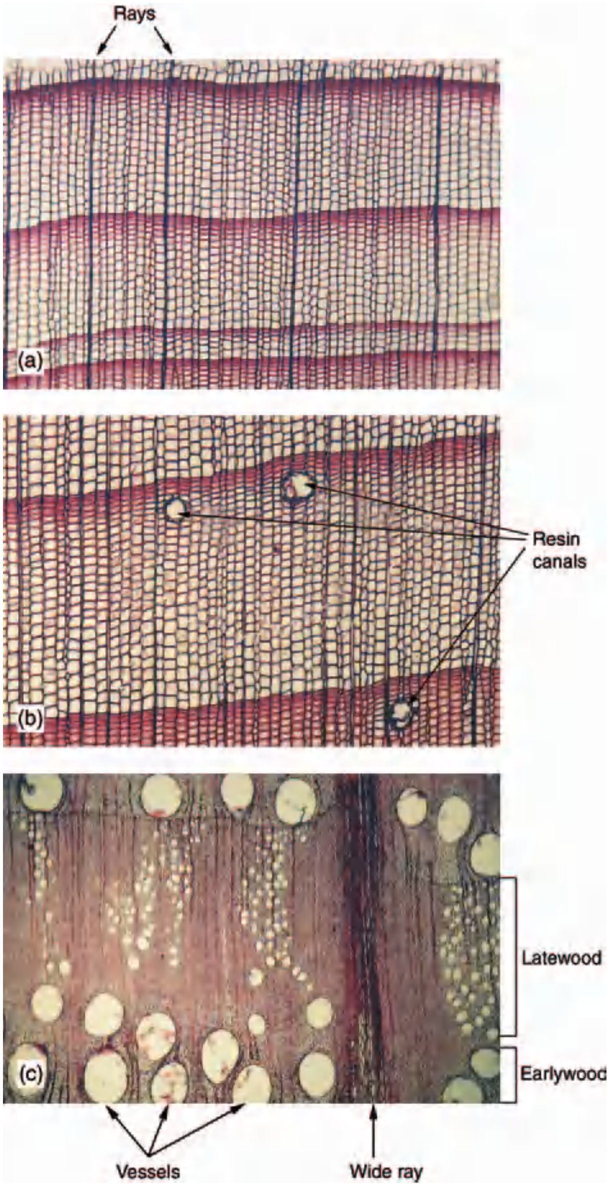

Figure 5 Differences in fine structure of cross-sections of wood as seen with a light microscope. (a) Nonresinous softwood, redwood (*Sequoia sempervirens*) (magnification × 80); (b) resinous softwood, red spruce (*Picea rubens*) (magnification × 100); (c) hardwood, white oak (*Quercus alba*) (magnification × 80).

Figure 5c illustrates the increased complexity of a hardwood in cross-section. Cell structure, features, and arrangements are considerably more diverse.

The uniform radial alignment found in softwoods is absent and there are very large-diameter cells mixed with smaller, thicker walled cells, and multiseriate rays mixed with uniseriate rays. The ray on the right of the micrograph is an example of the very wide rays found in oak (*Quercus*). Not all hardwoods exhibit these extremely wide rays, but almost all have rays that are many cells wide. The very large diameter, round cells on the bottom of **Figure 5c** are specialized transport cells called vessels. There are two groups of vessels visible in **Figure 5c** indicating the earlywood and latewood portion of the growth ring. Vessels are unique to the hardwoods and function as vertical fluid passageways for the trees. They are perforated at the ends with a variety of perforation types that vary from a simple opening to intricate, lacey patterns. Vessels occupy from 5% to 60% of total cell volume of hardwoods. Several other longitudinal cell types surround the vessels and rays in hardwoods. They are fibers, parenchyma cells, and hardwood tracheids. Tracheids and fibers serve as vertical transport and support for the tree and parenchyma serve primarily as nutrient storage. Fibers account for 20–70% of total hardwood cell volume, parenchyma from 1% to 33%, and hardwood tracheids from 27% to 70%. Each type of tree is characterized by a fine structure specific to it, so the actual percentages of any one cell type are almost entirely dependent on tree type.

Vessels in cross-section are sometimes referred to as pores. The difference in pore diameter within a growth ring is used to further classify hardwoods into ring porous, semi-ring porous, or diffuse porous subgroups. **Figure 6** illustrates the subclassification scheme based on porosity within a growth ring. Vessels within a growth ring of a ring porous wood exhibit very large differences in diameter in the earlywood versus the latewood portion of the ring (**Figure 6a**). Semi-ring porous woods exhibit earlywood vessels that are just slightly larger than the latewood vessels (**Figure 6b**). **Figure 6c** illustrates a diffuse porous wood in which the difference in vessel diameter is barely noticeable. Diffuse porous wood is the predominate growth pattern in the world and ring porous woods are usually found only in the temperate zone. Of course, there are a few notable exceptions; for example, teak and Brazilian tulipwood are ring porous woods that grow in tropical regions.

All cell elements regardless of tree or cell type display openings in the side walls, called pits, that allow for passage of fluids and water vapor between individual cells as well as radially in the tree stem. Pits possess microscopic features specific to tree and cell type. For example, the shape and pattern of pits between hardwood vessel elements, called intervessel pitting, can sometimes be used to distinguish one tree from another, and the pitting that occurs where wood rays cross and connect to softwood tracheids is indicative of genus. Pits vary from simple openings in the cell wall to an intricate valved structure in softwood tracheids.

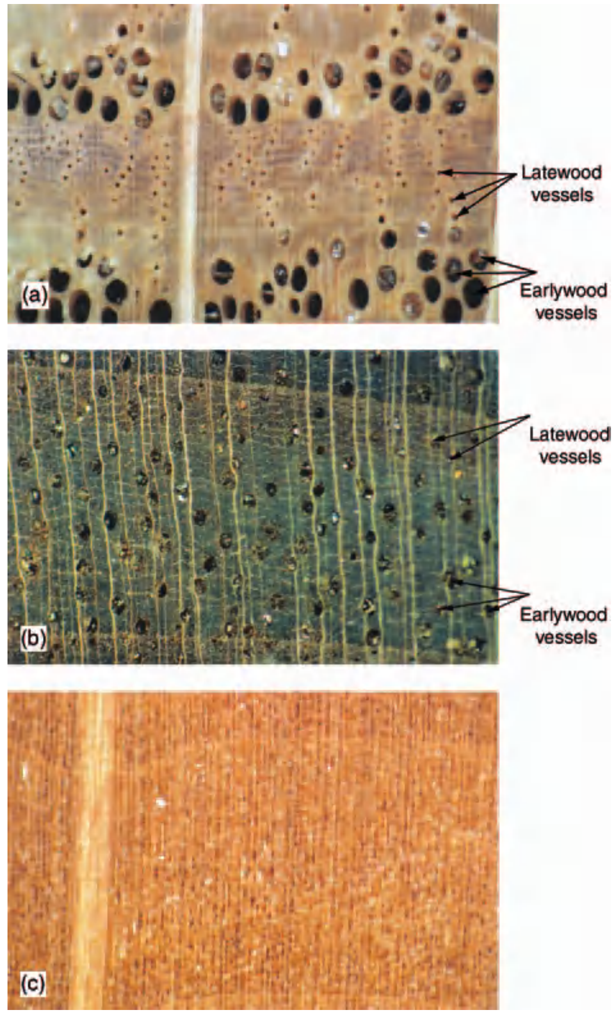

Figure 6 Classification scheme based on variation of vessel size across a growth ring. Magnification × 10. (a) Ring porous hardwood, red oak (*Quercus rubra*); (b) semi-ring porous hardwood, black walnut (*Juglans nigra*); (c) diffuse porous hardwood, red alder (*Alnus rubra*).

Three Surfaces to Microscopic Structure

Microscopic observation of slices or thin sections taken from a piece of wood reveals different anatomical structure depending on the direction of the original sectioning. An example of a section taken across the tree stem axis is a cross-section and, when viewed in a microscope, appears as in **Figure 7a**. A slice taken parallel to the tree axis and the wood rays is a radial–longitudinal slice (**Figure 7b**); observe the many pit openings along the tracheids.

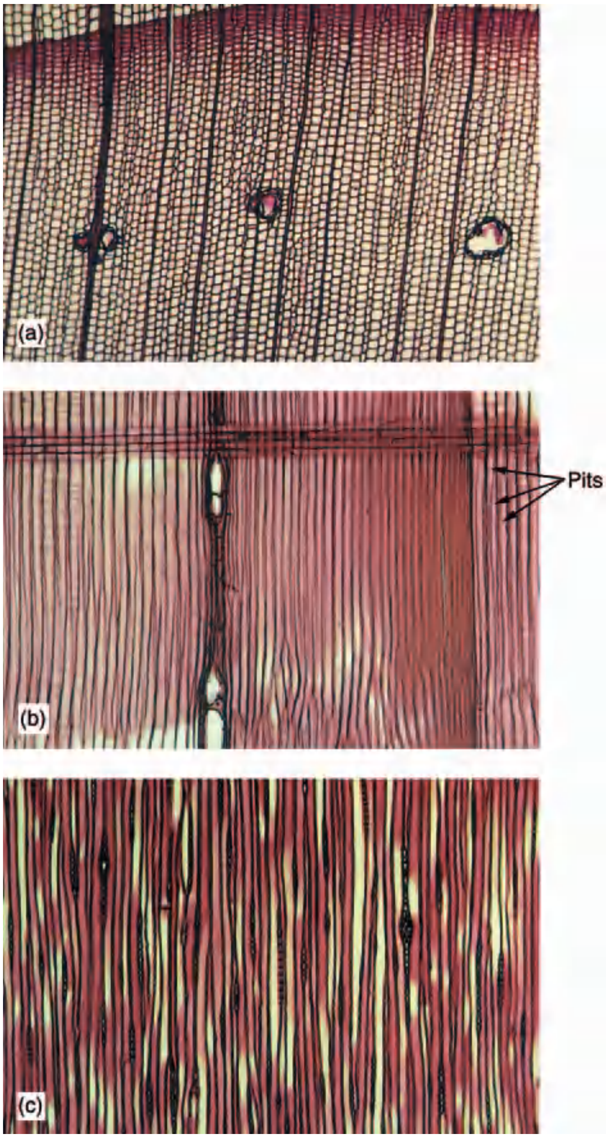

Figure 7 Microscopic images of the three surfaces of a softwood cube, southern yellow pine (*Pinus* sp.). Magnification × 100. (a) Cross-section; (b) radial surface; (c) tangential surface.

Figure 7c is the tangential section made from a cut parallel to the tree axis and a growth ring. Notice how the same piece of wood appears considerably different depending on which surface is being viewed. These differences have arisen from directional differentiation and the way in which the cells were created. Cell formation by the tree's vascular cambium results in elongated, pseudocircular cells that are arranged in a more or less radial ordering within rings around a central axis. Formation and elongation of radial cells perpendicular to the tree's axis further adds to patterning within a wood block.

There are many other, even finer structures and features in wood cells that are not described here. With an electron microscope and a great deal of time it has been possible to observe the extremely fine microscopic features of wood cells. Space simply does not allow a thorough description of the microscopic features (more information may be found in the books listed in the Further Reading section).

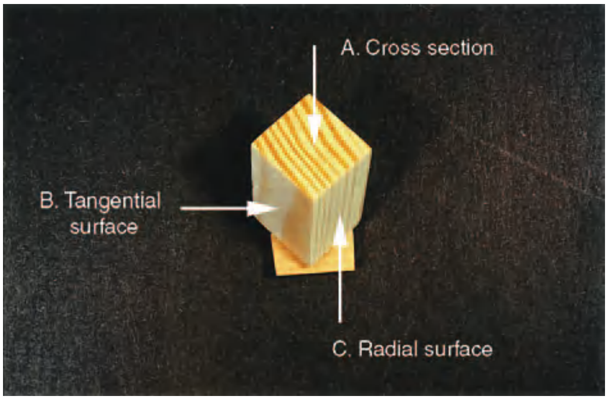

Figure 8 Photomacrograph of a southern pine cube illustrating the different macroscopic features of the three surfaces.

Macroscopic Structure

Anatomical structure visible without the aid of a microscope or hand lens can be thought of as macroscopic structure. Cell formation and directional differentiation have resulted in fine structure differences that translate into macroscopic structure and property differences as well. Examples are structural directions, growth rings, heartwood and sapwood, and ray patterns, among others.

Three Structural and Property Directions

Informal observation of a piece of solid wood reveals different surface characteristics depending on the surface being viewed. Microscopic cell structure is responsible for the three images visible in that single piece of wood. **Figure 8** illustrates surface features of each of the three faces of a wood block that has been cut parallel to both the rays and the growth rings. The surface on the top of the cube is the cross-section, the left face is the tangential surface, and the right face is the radial surface. Not only are the visual features different, the physical properties differ with, and are dependent on, the fine cell structure directions. Lumber grading, processing parameters, wood identification, physical property characterization, and dimensional stability are but a few of the areas in which knowledge of the surface and wood anatomy direction is important.

Growth Ring Structure

Growth rings are more or less distinct in trees depending on the degree of cell differentiation within an individual growth ring. **Figure 9a** indicates that growth rings are more easily distinguished in softwoods due to the usually marked difference in cell diameter and cell wall thickness in the earlywood and latewood growth regions. Ring porous hardwoods also exhibit distinct growth rings (**Figure 9b**), but growth rings are less easy to determine in the diffuse porous woods (**Figure 9c**). Physical and mechanical properties also differ within growth rings due to the cell structure differences. In general the latewood regions exhibit superior mechanical properties, higher density, more shrinkage, and darker color than the earlywood regions.

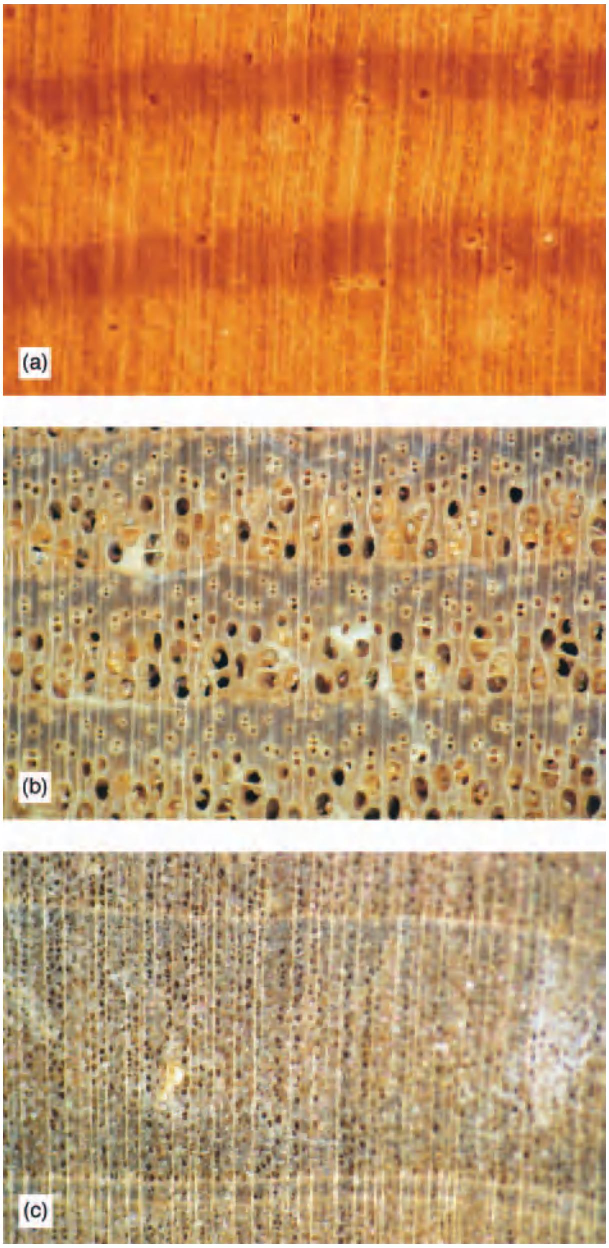

Figure 9 Photomacrographs showing distinct versus indistinct rings. Magnification × 10. (a) Softwood with distinct growth rings, southern yellow pine (*Pinus* spp.); (b) ring porous hardwood with distinct growth rings, black ash (*Fraxinus nigra*); (c) diffuse porous hardwood with indistinct growth rings, yellow-poplar (*Liriodendron tulipifera*).

Heartwood and Sapwood

Figure 10 illustrates two visibly different regions in a tree stem disk. The outer rim is lighter in color and is called the sapwood, and the inner, darker region is called heartwood. In twigs and very small, young trees, the entire xylem (wood) portion is involved in sap conduction upward and this wood portion is fittingly named 'sapwood.' As the tree ages, the entire sapwood portion is not needed to transport fluids to the leaves, so at the center of the tree, the cells cease to conduct, lose their nutrients, and eventually die. This transformation from living, conducting cell tissue to empty, dead cells is responsible for cells being converted into 'heartwood.' The transformation is accompanied by production of chemical compounds in the cell wall called extractives, disappearance of living nuclei, and reduction in nitrogen, starch, and sugar content. Notice however, there is no change in cell structure, i.e., cell structure in sapwood and heartwood is essentially the same, it is the chemical content that has been altered. Heartwood is usually darker in color than sapwood because some extractives in the cell walls of heartwood are usually, but not always, dark in color. In addition, extractives give heartwood increased durability, odor, and taste.

Rays

Also visible in **Figure 10** are wood rays extending from the vascular cambium inward toward the pith of the tree. As mentioned, wood rays in

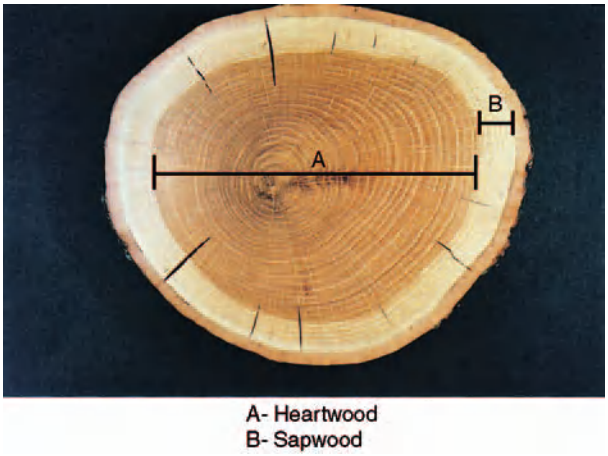

Figure 10 Photograph of a tree disk showing heartwood, sapwood, and rays of oak (*Quercus* sp.).

softwoods are very fine and essentially nondistinct macroscopically, but the rays in many hardwoods are very distinct and make dramatic patterns in finished products. Because the cells in wood rays have their long axis oriented perpendicular to the longitudinal cells, they reflect light differently and can also make unusual patterns on radially cut surfaces. The wood rays tend to form a plane of weakness within the otherwise longitudinally aligned cell structure, but at the same time, are thought to reduce radial shrinkage.

Juvenile and Reaction Wood

Juvenile Wood Features

Wood formed at the apical meristem (branch tips) and later incorporated into the main tree stem by diameter growth in the vascular cambium is significantly different from the outer stem wood. Because this wood is formed at growth shoots and at very early stages of stemwood formation, it is called 'juvenile wood.' It is also known as core, pith, or crown wood. It is formed in a cylindrical column around the pith and depending on species, is the first 5–20 growth increments in the tree stem. **Figure 11** illustrates the location of juvenile wood at the center of the tree stem disk. All trees have some portion of juvenile wood, but it is especially prevalent in plantation grown softwoods and where fast growth has occurred. Cell structure, chemistry, and wood properties all differ in juvenile wood when compared to mature wood. Cell length, cell wall thickness, and percentage of latewood per ring are lower in juvenile wood. This combination of structural features results in lower density. The S_2 microfibril angle is increased (more horizontal) over mature wood as is the percent of lignin in the cell walls.

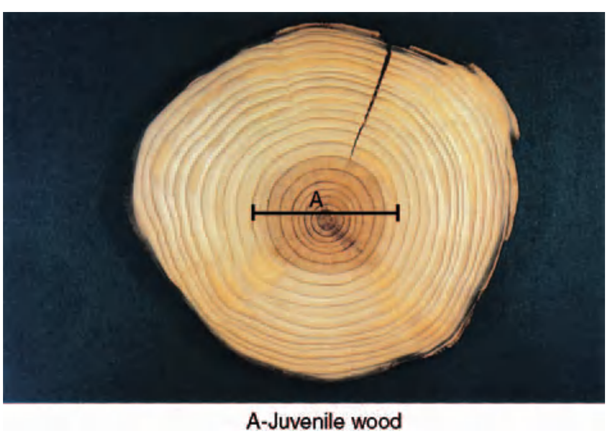

Figure 11 Photograph of a tree disk with juvenile wood, Table-mountain pine (*Pinus pungens*).

In general, juvenile wood is considered inferior to mature wood in terms of mechanical and physical properties. It is weaker, less stiff, more prone to warp, and is more problematic to process into paper and fiber products. Differences in the cell structure and chemistry of juvenile wood are again responsible for macroscopic features. There are select circumstances or situations in which juvenile wood is considered acceptable, and perhaps even, preferable. Low-density wood-based composites and some paper products would be examples of products in which juvenile wood performs acceptably and with consistency.

Reaction Wood

Wood formed in leaning stems is also significantly different from wood formed in nonleaning stems. Collectively this wood is called 'reaction wood.' When found in leaning softwood stems, it is called compression wood, and tension wood in leaning hardwoods. Compression wood is formed on the lower side of leaning softwood stems or branches and tension wood is usually on the upper side of

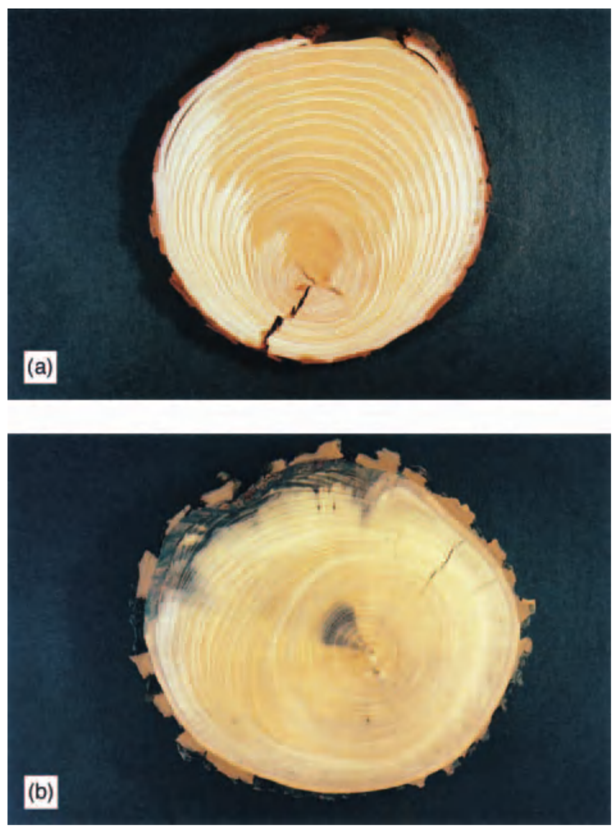

Figure 12 Photographs of cross-sections of reaction wood found in leaning tree stems. (a) Eccentric rings and discoloration of compression wood in spruce (*Picea* sp.); (b) eccentric rings of tension wood cross-section in ash (*Fraxinus* sp.).

leaning hardwood stems or branches. Characteristics of compression wood include eccentric growth rings, a high percent of latewood per ring, higher density, intercellular spaces, helical checking of the cell walls, a large microfibril angle in the S_2, and a higher lignin content. It is often 'dull' looking or darker in color. **Figure 12a** illustrates the eccentric rings and darkening of compression wood. Tension wood has eccentric growth increments, fuzzy cut surfaces, a gelatinous almost pure cellulose layer that may replace part of the cell wall, a higher percent of thick-walled fibers, and an increased cellulose content. Macroscopic features such as eccentric rings of tension wood of ash are shown in **Figure 12b**. Wood on the opposing side of the reaction wood is also 'unusual' in that it does not possess the same features of wood in the nonleaning stem portion. As with juvenile wood, the physical properties of reaction wood are reflective of the fine structure and chemistry and are considered inferior to those of mature wood.

Mechanical Properties of Wood

B Kasal, North Carolina State University, Raleigh, NC, USA

Introduction

This article covers mechanical properties of wood and wood-based materials. Wood is a nonisotropic material with directionally dependent elastic and mechanical properties. Rules governing wood as an anisotropic, orthotropic, and transverse isotropic material are outlined. Wood materials are classified into groups based on their structure. The relationship between mechanical properties of wood and moisture, temperature, and time are also covered.

Elastic Properties

Wood is an anisotropic nonhomogeneous material. Anisotropic means that the physical properties (including mechanical) are directionally dependent. Its nonhomogeneous character is related to wood being a porous material that is not continuous but contains voids. The anisotropy is cylindrical anisotropy (**Figure 1**) but it is often, for purpose of modeling, replaced by the orthogonal anisotropy (orthotropy). This is done to achieve simplicity and to avoid coordinate transformation from a cylindrical to Cartesian system. A cylindrical coordinate system can be superimposed on the tree cross section such that the longitudinal axis is oriented along the tree axis and the radius, R, is oriented in a radial direction. Angle φ will rotate counterclockwise and mechanical properties will be a function of R and φ. Strictly speaking, wood will only loosely follow anisotropy and transformation rules due to its natural variability. If we remove a block of finite dimensions (such as cutting a board from a log) and

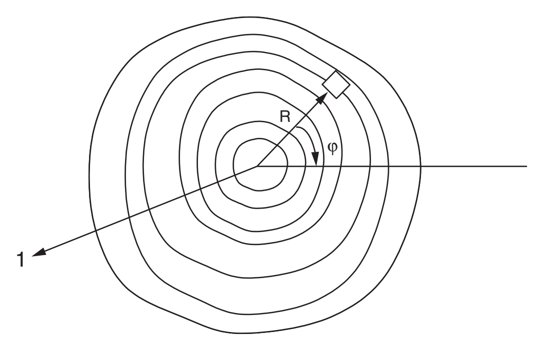

Figure 1 Cylindrical coordinate system superimposed on the tree cross-section.

let the radius, R, be relatively large with respect to the board cross-sectional dimensions (**Figure 2**) such that $R \rightarrow \infty$, we can then neglect the radius and superimpose a Cartesian coordinate system, where mechanical properties in any coordinate system rotated with respect to the original one will be a function of properties in directions 1, 2, and 3. From **Figure 2** it follows that the simplification requirements are never met and therefore discrepancies between different experimentally obtained elastic constants will occur. Orthotropic representation of wood also requires that the properties follow orthotropic symmetry rules. This means that one can superimpose three mutually perpendicular planes of symmetry and all properties (not only mechanical but also, e.g., electrical) will be symmetrical with respect to these planes. If the above assumptions are met then wood can be fully defined by 9 elastic constants (three moduli of elasticity E_1, E_2, E_3, three Poisson's ratios μ_{12}, μ_{23}, μ_{13} and three shear moduli G_{12}, G_{23}, G_{13}). The remaining constants (36 total) can be calculated using reciprocity theorem and material symmetry. Unlike isotropic materials, the shear modulus of wood is independent of other elastic parameters and must be determined experimentally. More details can be found in any standard text dealing with composite materials. The ratios of elastic moduli in longitudinal (L), radial (R), and tangential (T) directions are approximately 20:1.7:1 for softwoods and 13:1.7:1 for hardwoods. Stress, σ, can be calculated from the generalized Hooke's Law as $a_{ij}\varepsilon_j = \sigma_i$, where σ_i = stress tensor, a_{ij} = stiffness matrix, and ε_j = strain tensor, i, $j = 1, 2 \ldots 6$. Defining wood as an orthotropic material is not practical due to the large number of experimental variables that must be determined. In structural applications, it is impossible to distinguish between radial and tangential directions and wood is represented as transverse isotropic material. The transverse isotropic means that the material has isotropic properties in the transverse plane. Thus, only two moduli of elasticity (parallel and perpendicular to fibers), one shear modulus, and one Poisson's ratio are needed to define such material. One must pay attention to Poisson's ratios since values exceeding 0.5 have been reported in the literature. Such values are impossible to measure for elastic solids (value of 0.5 represents an incompressible fluid). Since wood is an inhomogeneous material with hollow cell structure, high values of expansion are possible resulting in apparent Poisson's ratio close to 0.5. Viewing wood material as rigid plastic foam can explain such high values. The values of Poisson's ratios for most common woods are listed in **Table 1**.

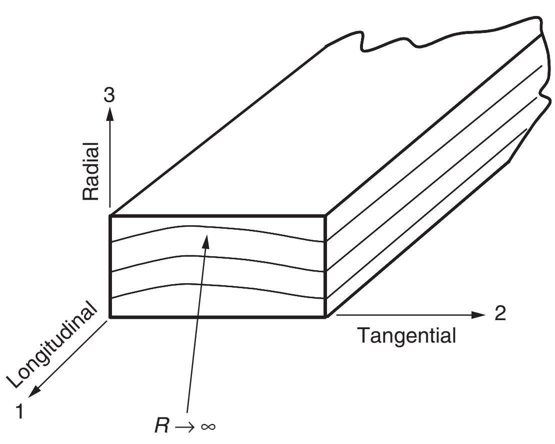

Figure 2 Orthotropic representation of solid wood cross-section.

Most wood composites are two-dimensional and can be considered as orthotropic or isotropic in two dimensions whereby the third dimension across the thickness is not considered (in two dimensional elasticity problems, the strain in the thickness is constant). **Table 2** lists various composite materials based on orientation of particles and their definitions. The elastic properties of wood composites are affected by their structure and the way the composites are manufactured. **Table 3** represents the range of elastic properties for some common wood composites.

Constitutive Equations

Wood and wood composites are generally regarded as brittle, elastic materials, with the exception of compression across fibers where large strains can be introduced without failing the material. Thus, Hooke's law can be used to describe a short-term stress–strain relationship and modulus of elasticity represents the slope of the stress–strain diagram. In compression perpendicular to fibers, the modulus of elasticity has meaning only at the pseudoelastic region of the stress–strain diagram. A typical stress–strain diagram for wood loaded in compression perpendicular to fibers direction is shown in **Figure 3**. The yield strain in compression across fibers is about 3%. The failure strains for tension and compression along fibers is in the range 2–3%. For tension across fibers, the failure strain can be less than 0.2%. Wood behavior in tension parallel, perpendicular and compression parallel to the grain is brittle and wood can be considered linearly elastic all the way up to the failure.

Strength

Strength is defined as the stress at failure. Therefore, the definition of failure plays an important role in defining strength. Because of the nonisotropic

character of wood and wood-based composites, several strength values are required to describe completely the strength of the material. These include tensile, compressive, and shear strengths. Since tensile and compressive strengths are not equal, bending strength is also used as an additional

Table 3 Elasticity properties of common wood-based composites

	E_1 *(MPa)*	E_2 *(MPa)*	μ_{12}	G_{12} *(MPa)*

[b] More than 7 layers.
Data from Bodig J and Jayne BA (1993) *Mechanics of Wood and Wood Composites*. Malabar, FL: Krieger; Wesche K (1988) *Baustoffe für Tragende Bauteile*, vol. 4, *Holz und Kunstoffe*, 2nd edn. Wiesbaden, Germany: Bauverlag GmbH.

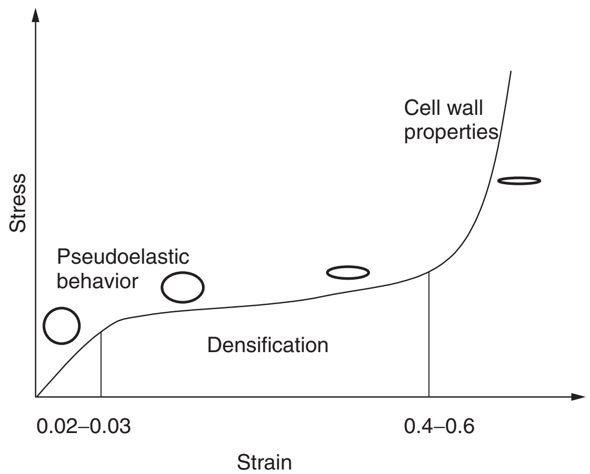

Figure 3 Typical stress–strain diagram of wood loaded in compression perpendicular to fibers.

parameter. Tensile and compressive strengths are defined in direction parallel and perpendicular to the fibers. Tensile strength in the direction perpendicular to the fibers is an unreliable quantity due to the likelihood of checks in wood. Failure can be relatively easily defined for all stresses, except for the compression perpendicular to fibers where the strength is defined as the stress at certain value of the strain. Thus, compressive strength in the direction perpendicular to fibers is a deformation-based quantity. Values of strengths for common woods are listed in **Tables 4** and **5**.

Shear strength depends on the orientation of the shear plane. Since the shear forces in an element always act in pairs, the shear stress will always act on two opposite planes in an elementary shear block. When a shear force acts in the direction perpendicular to fibers, rolling shear occurs. Shear through the thickness of wood composites (horizontal shear) is defined when shear force acts across the material thickness.

If wood or wood composites are under multiaxial stress (such as biaxial tension), a single value of strength is not sufficient to determine failure and a failure surface must be constructed. Various strength theories can be used to define the strength envelope with tensorial strength criterion being the most general. A generalized function describing the material strength can be written as $a_i\sigma_i + a_{ij}\sigma_i\sigma_j + a_{ijk}\sigma_i\sigma_j\sigma_k + \cdots = 1$. The coefficients a_i, a_{ij}, a_{ijk} represent the strength tensor components and σ_i, σ_j, σ_k are the stresses in directions 1, 2, 3 and planes 3, 4, 6. **Figure 4** shows a strength envelope for plywood loaded by in-plane forces. Note that for the most simple, two-dimensional stress state, the envelope will be in three dimensions and additional characteristic, a strength in biaxial tension, will be needed to define mutual interaction between stresses in two principal directions (along and across the face veneer fibers). Another way to determine failure is use of fracture mechanics. Fracture mechanics studies mechanisms of crack initiation, development, and growth. Several parameters are needed to describe the functions governing the various stages of crack development. The problem in applying fracture mechanics to wood and wood materials is that an infinite number of cracks of unknown dimensions is present in wood.

Variability of Mechanical Properties

Variability of mechanical properties must always be considered because variability is extremely high in wood and wood materials. For example, modulus of elasticity within a species may vary by 20–30% (variability is defined as a standard deviation divided by arithmetic average). One will always have an estimate of material characteristics (arithmetic average is one of the estimators to estimate mean, the value of which is never known). The high variability of mechanical properties requires that relatively large

[a] Definition of properties: impact bending is height of drop that causes complete failure, using 0.71-kg hammer; compression parallel to grain is also called maximum crushing strength; compression perpendicular to grain is fiber stress at proportional limit; shear is maximum shearing strength; tension is maximum tensile strength; and side hardness is hardness measured when load is perpendicular to grain.

[b] Specific gravity is based on weight when ovendry and volume when green or at 12% moisture content.

[c] Modulus of elasticity measured from a simply supported, center-loaded beam, on a span depth ratio of 14/1.

[d] Coast Douglas-fir is defined as Douglas-fir growing in Oregon and Washington State west of the Cascade Mountains summit. Interior West includes California and all counties in Oregon and Washington east of, but adjacent to, the Cascade summit.

[a] Results of tests on small, clear, straight-grained specimens tested green. For hardwood species, strength of specimens tested at 12% moisture content averages about 32% higher; for softwoods, about 13% higher.

Data from US Department of Agriculture (1999) *Wood Handbook: Wood as an Engineering Material*. Madison, WI: US Department of Agriculture Forest Service; Niemz P (1993) *Physik des Holzes und der Holzwerkstoffe*. Weinbrenner, Germany: DRW-Verlag.

number of tests must be performed to obtain a reasonable estimate of parameters. Likewise, any calculation of dependent elasticity parameters based on experimental data must account for the stochastic nature of these parameters. Various sources of variability exist: for example, variability 'within' refers to the variability between specimens from within one board; variability 'between' is the variability resulting from differences between boards. **Table 6** lists the average variabilities of some mechanical properties of clear wood specimens.

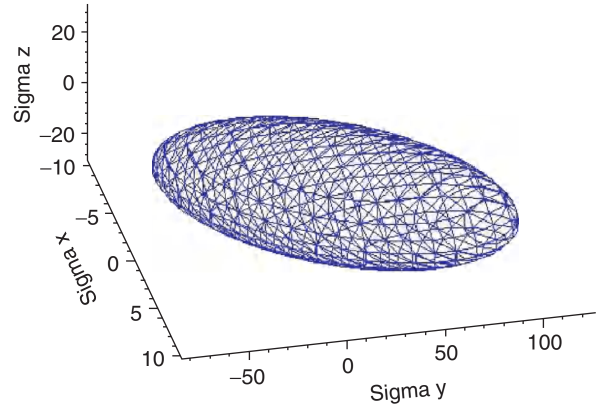

Figure 4 Typical strength surface for wood loaded by biaxial normal stress and shear.

Variability of mechanical properties of wood composites is significantly lower than that of solid wood but the same sources of variability exist.

Effect of Environmental Factors on Mechanical Properties

Environmental factors such as temperature, relative humidity of air (and associated equilibrium moisture content (EMC)), and their combination affect mechanical properties of wood and wood materials. Generally, the elasticity and strength parameters decrease with increased temperature and moisture content. Commonly, a linear function is used to approximate the change in mechanical properties with change in moisture content and temperature. It is assumed that moisture content change beyond fiber saturation point (FSP) will not significantly affect mechanical properties (**Figure 5**). One can calculate the mechanical property at any moisture content between 0% and FSP as

$$A_{MC} = A_{12}\left(\frac{A_{12}}{A_g}\right)^{\frac{12\text{-MC}}{M_P\text{-}12}}$$

where A_{MC} = property at desired moisture content, MC; A_{12} = property at 12% moisture content; A_g = property at MC above FSP; M_P = moisture content at which the properties of wood start to change when wood is dried from green (wet) condition (above FSP). This value can be taken as 25 for most species. The relationship between the

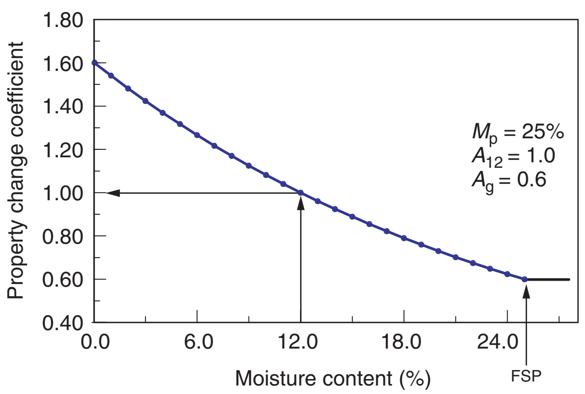

Figure 5 Effect of moisture content on mechanical properties of wood at constant temperature. For equations, see text. FSP, fiber saturation point.

MC and wood mechanical properties below FSP can also be approximated by a straight line. In general, values of mechanical properties of wood decrease with increased temperature. As with any polymeric material, the change in mechanical properties will depend on a glass transition temperature of individual wood components (*see* **Wood Formation and Properties**: Chemical Properties of Wood). The temperature effects can be either reversible (for temperatures below 100°C and relatively fast temperature changes, e.g. heating followed by immediate cooling) or irreversible (temperatures above 100°C or extended exposure to elevated temperature even below 100°C). Up to about 150°C, the decrease in elasticity and strength properties is approximately proportional to the increase in temperature and duration of heating.

The combined effect of moisture content and temperature is more complicated due to interaction between temperature and moisture content. **Table 7** shows the effect of temperature on bending strength of clear wood and **Figure 6** shows the effect of temperature and moisture content. Strength of wet wood decreases more rapidly with increased temperature than does strength of dry wood. **Figure 7** shows that temperature change affects various mechanical properties differently. From **Figures 6** and **7**, it follows that the time–temperature–moisture content interaction affects the rate at which mechanical properties of wood degrade. The relationships in the figures represent the trends and average properties. **Figure 8** shows the relative change in some strength and elasticity parameters of beech under elevated temperature and moisture.

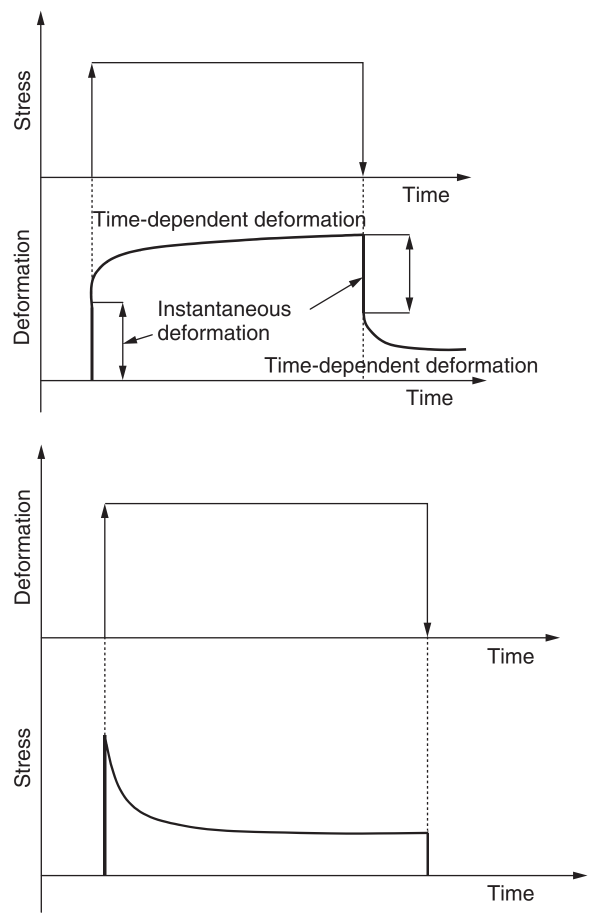

Figure 9 Creep and stress relaxation experiments.

Effect of Load History (Time) on Mechanical Properties of Wood and Wood Composites

Wood and wood materials can be considered viscoelastic materials. This means that the response of wood to the load will be affected by the load history. For example, deflection of a beam loaded by a constant load will increase with time (creep). If a fixed displacement is induced on a beam, then, over time, the load to maintain this displacement will decrease (stress relaxation). **Figure 9** shows the results of creep and stress relaxation experiments. The creep rate (or stress relaxation rate) increases with increased moisture contents (mechanosorptive creep) and temperature. Cyclic changes (temperature, moisture, or a combination of the two) further accelerate creep with increased creep rate during drying. However, wet wood will creep faster than dry wood if no changes in moisture content take place.

Increase in temperature will significantly increase the creep rate. Creep can be observed in wood composites where the total creep is a sum of the creep in wood material and wood–adhesive interface. Generally, creep rate of composites with nonwater resistant adhesives can be significantly higher than the creep rate for solid wood, especially under changing moisture conditions. Time delayed failure (creep failure) can occur as a result of creep or mechanosorptive creep. Various phenomenological models are used to model creep or stress relaxation of wood and wood composites (combination of dashpots, springs, and other elements such as ratchet element or frictional element) (**Figure 10**).

Dynamic Load and Fatigue

The apparent strength of wood and wood materials increases with increased rate of loading. The effect of load rate is shown in **Figure 11**. From **Figure 11** it follows that the apparent strength under impact load will be about 120% of the strength value obtained from the static test. Material (viscous) damping of wood and wood composites is very low, generally not exceeding 3%. Fatigue of the material is defined as number of cycles at given stress level (usually as a percentage of the ultimate stress) at which the material fails. The cycles can be zero or nonzero mean cycles. **Figure 12** shows the average fatigue life of wood loaded in bending by a cyclic load. The fatigue life is influenced by the environmental factors in the same way as the static parameters (monotonic load), except for the moisture content effect that is about twice larger for dynamically loaded wood.

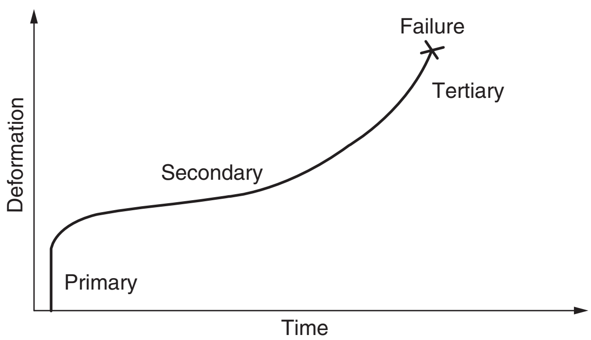

Figure 10 Primary, secondary, and tertiary stages of creep.

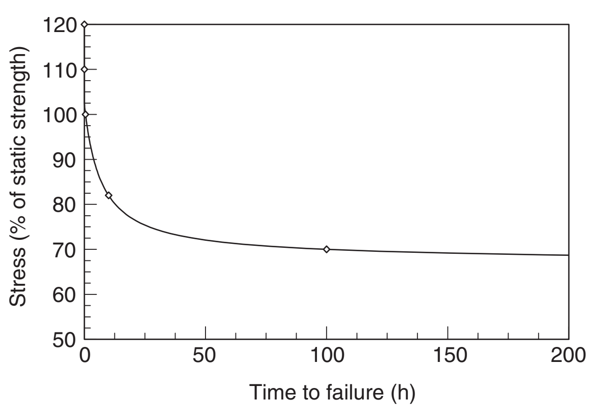

Figure 11 Time to the failure for small clear specimens of wood loaded in bending. Wood Handbook 1999.

Nonengineering Mechanical Properties

Other mechanical properties that can be defined are those associated with various end-use requirements and may include: abrasion properties, cleavage strength, nail or screw withholding capacities, dynamic impact resistance (toughness), hardness, etc. Since most of these parameters depend on testing procedures, the values have only comparative character.

Small Clear Specimens versus Full-Size Member Tests

Material properties of wood and wood composites are determined from standard tests of small clear specimens. Small clear specimens do not contain any defects such as knots or slope of grain and the values listed for small clear specimens, in most cases, will represent upper bounds for mechanical properties. In structural applications (*see* **Solid Wood Products**: Structural Use of Wood), members will contain natural defects and mechanical properties will be determined from full-size members containing the defects. The size, location, and number of the defects significantly affect the material strength and the variability of the properties.

Relationship between Mechanical Properties and Anatomical Structure of Wood

Wood anatomical structure significantly affects the mechanical properties of wood and wood

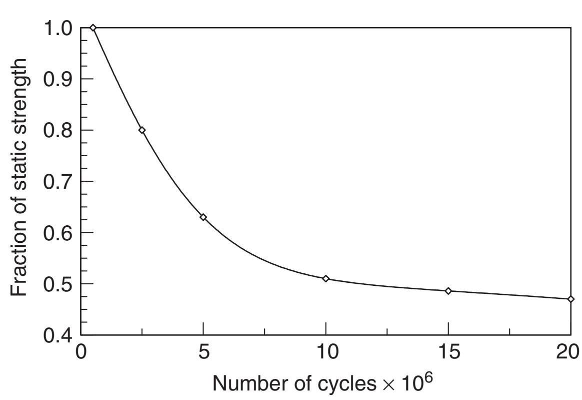

Figure 12 Fatigue life of wood. Data from Kollmann F (1952) *Technologie des Holzes und der Holzwerkstoffe*, 2nd edn. Berlin: Springer-Verlag.

composites. Parameters such as fiber length, wood density, orientation of microfibrils, and chemical composition of wood affect the properties of wood significantly. While a qualitative effect of anatomical features can be defined, the quantitative effect of these parameters is more difficult to establish. The mechanical properties are significantly affected by wood density, which is directly related to the cell wall thickness. Increasing the thickness of cell walls of latewood tracheids of pine by 36% and larch by 20% results in an increase in wood density by 18% and 20%, respectively. This increase in cell wall thickness will result in increase in compressive strength along fibers by 70–83%. **Figure 13** shows the influence of specific gravity on wood mechanical properties. The figures are based on average data and the relationships for individual species vary. The relationships are approximately linear. **Figure 14** shows the relationship between percentage of latewood and wood density and **Figure 15** demonstrates the effect of specific gravity on compressive strength. Other anatomical features, such as microfibril angle, ray size and proportion, and fiber length will significantly affect mechanical properties of solid wood. Slope of grain significantly affects mechanical properties and a simplified relationship between slope of grain and individual elastic or strength parameters known as Hankinson's formula is commonly used to estimate off-axis properties:

$$A_\alpha = \frac{A_0 A_{90}}{A_0 \sin^n(\alpha) + A_{90} \cos^n(\alpha)}$$

where A_α = property at angle α with respect to fibers, A_0 = property at zero angle with respect to fibers, A_{90} = property at 90° angle with respect to fibers, and α = angle.

Table 8 list values of exponent, n, based on the ratios of transverse and longitudinal properties $\frac{A_{90}}{A_0}$. The quantitative relationship between anatomical

features, chemical composition and wood mechanical properties is largely unknown.

Density significantly affects mechanical properties of wood composites and this is shown in **Figure 16.** All mechanical properties will increase with increased density with a linear trend.

Physical Properties of Wood

S Avramidis, University of British Columbia, Vancouver, Canada

Introduction

This article addresses the fundamental physical properties of wood (sorptive, fluid transfer, thermal, electrical, and acoustical) that directly affect its processing and service characteristics such as sawing, drying, preservation, machining, gluing, insulation, and mechanosorptive behavior in service as a structural member or as simple panel or piece of furniture. Processing optimization and enhanced design of wood-based products is expected to result from a better understanding of how wood interacts with the environment.

Moisture Content

Wood is a porous, hygroscopic, anisotropic, nonhomogeneous biopolymer of cellular structure. Water is always naturally found in freshly cut green wood since it is a necessary component of the living tree. Therefore, when wood is cut from a tree in the form of lumber, veneer, particles, or fibers, it always contains water, the oven-dry basis percentage of which is defined as the green moisture content (M_g). Generally speaking, moisture content, M, is defined as the weight of water in wood (W_w) divided by the oven-dry wood weight (W_o) times 100%:

$$M = \frac{W_w}{W_o} \times 100\% \qquad (1)$$

where W_o is obtained by placing the wood specimen in an oven at 103 ± 2°C for 24 h or until constant weight. The nominator of eqn [1] is then obtained by subtracting the W_o from the initial wood weight (W_i). The level of green moisture content is a function of wood species, type of wood (sapwood vs. heartwood, the former always at much higher M_g), and season of tree harvest, and for the temperate zone species it can range between 31% and 250%.

Water in wood can be divided into two types. The first is the water of constitution, which is the water included in the chemical structure of wood, and it is inherent to the organic nature of its cell walls. This type of water cannot be removed without modifying the chemical composition of wood, and the wood therefore losing its natural appearance. The second type comes in three different phases according to the moisture content level. The bound phase comprises the water molecules dissolved or adsorbed by the sorption sites (hydroxyls) mostly in the amorphous areas of the cellulose chains and the hemicelluloses. The free water, which is liquid water, is found in the cell lumina, and the vapor water is also found in the lumina when they are not completely saturated with free water.

In the hygroscopic range ($0\% \leq M \leq 30\%$), all of the water in wood is considered as bound, located within the cell wall. At about 30%, all sorption sites are considered to be saturated with water molecules and the moisture content is then called fiber saturation point (FSP) or M_{fsp}. Any additional water molecules taken up by wood normally appear as free water in the lumina and pits. It is below M_{fsp} where most of the physical and mechanical properties of wood are affected by moisture content, e.g., strength decreases, wood shrinks, electrical resistance increases, and the biodeterioration hazard diminishes as moisture content tends toward 0%.

Owing to its hygroscopic nature, freshly cut wood exposed to ambient conditions will tend to assume a moisture content which is in balance with the water vapor conditions in the surrounding atmosphere. This is a quite slow process (called sorption) that is highly dependent on the ambient temperature (T) and relative humidity (H). When green wood finally reaches the equilibrium state, two things have happened to its original water content: (1) it has lost a considerable amount of water (all of the free plus some bound water) by a process called desorption and (2) its final moisture content, which is then called equilibrium moisture content (M_e), is somewhere within its hygroscopic range. The speed of desorption is proportional to T and inversely proportional to H.

Throughout the hygroscopic range, the relationship between the equilibrium moisture content and relative humidity (or relative vapor pressure in the ambient environment) at constant temperature is represented by a sigmoid curve commonly called the sorption isotherm (**Figure 1**). The M_e values of a green piece of wood exposed to successively decreasing relative humidities (desorption) will always be higher than those of the same specimen exposed to successively higher humidities (adsorption), both cases under the same temperatures (**Figure 1**). This phenomenon is called hysteresis; and the area enclosed between the hysteresis loop represents the difference in free energy between adsorption and desorption.

It must be emphasized here that given enough time, the M_e value after exposure of green wood to the ambient environment always range between 0% and 30%. There is no free water in wood when it has reached equilibrium with the normal ambient environment. This M_e range is maintained during service unless wood comes into contact with liquid water.

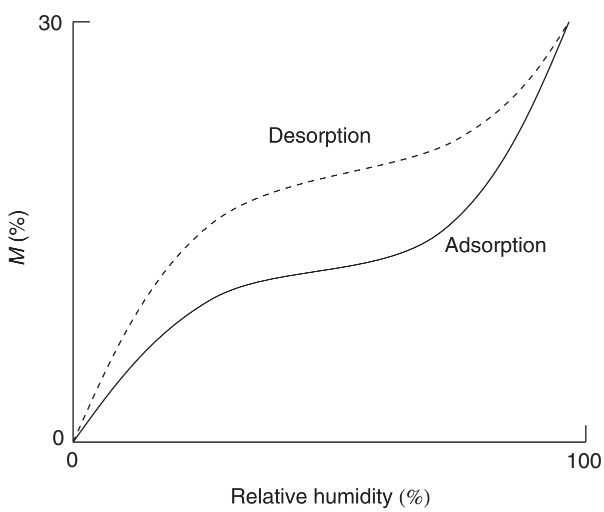

Figure 1 Typical moisture sorption isotherm for wood.

Density, Specific Gravity, and Porosity

Wood is made up of a mix of cells of a tubelike shape connected to each other in parallel and mostly oriented along the length of a tree. The cells are made of a thin wall and an empty area called the lumen. The existence of the cell wall material and the empty space in the lumen are the reasons why wood is classified as a porous material.

One important property that characterizes porous materials is density (ρ), defined as the amount of mass per unit volume and is expressed in kilograms per cubic meter. On the other hand, specific gravity (G) is the density of wood divided by the density of water and is dimensionless. Both ρ and G are used by the forest products industry interchangeably without considering the fact that both are highly dependent on moisture content and only in the case 0% moisture content (oven-dry or bone-dry) are numerically equal. This becomes evident from the equations that are used to calculate these two parameters:

$$\rho = \frac{W_M}{V_M}\,(\text{kg m}^{-3}) \tag{2}$$

$$G = \frac{W_o}{V_M \rho_w} \tag{3}$$

where W_M is the wood weight at moisture content M (kg), W_o is the oven-dry weight of wood (kg), V_M is the volume of wood at moisture content M (m^3), and ρ_w is the density of water (1000 kg m^{-3}). It is apparent, that eqns [2] and [3] are equal only in the case of oven-dry wood ($M = 0\%$) and above that, their difference increases as M increases (ρ always greater than G). A typical plot of both as a function of moisture content is shown in **Figure 2**. Once G is known, ρ can then be calculated from

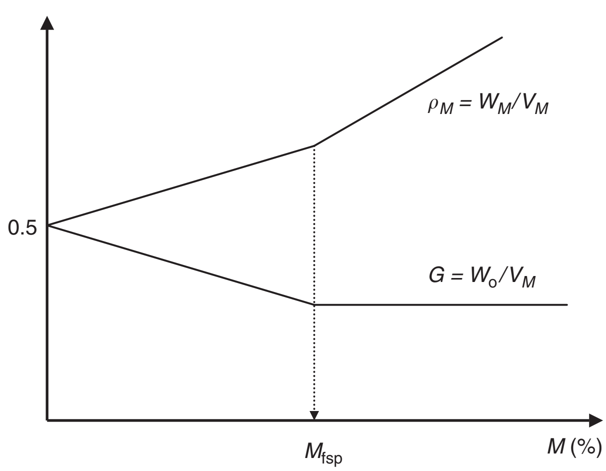

Figure 2 Change of wood density and specific gravity below and above the fiber saturation point.

$$\rho = G(1 + 0.01M)\rho_w \tag{4}$$

In industry, G is occasionally referred to as basic density. When knowing the specific gravity at one moisture content (M_1), we can calculate the specific gravity at another moisture content (M_2) by

$$G_2 = \frac{G_1}{1 + 0.01(M_2 - M_1)G_1} \tag{5}$$

valid only over the hygroscopic range.

The values for G of temperate zone hardwoods at 12% moisture content ranges between approximately 0.35 and 0.78, and for softwoods, between 0.34 and 0.62. The growth characteristics and age of trees within the same species and the location of wood also affect these values horizontally and vertically within the same tree. Density is a very important physical property since it directly affects dimensional changes, and mechanical, electrical, and acoustical properties, and furthermore the drying and machining characteristics of wood and wood-based products.

Porosity (V_a) is a number between 0 and 1 that indicates the fraction of void volume in wood. For example, a V_a that is equal to 0.6 indicates that 1 m^2 of wood is made up of 0.4 m^3 of solid cell-wall material and 0.6 m^3 of empty space (void volume) due to lumen and pit capillaries. Porosity is an important property because it helps with the estimation of the amount of liquids that can be introduced into the material for protection or for creating polymer-impregnated wood. It also provides an indirect indication of the ease of fluid flow through wood and of the thermal and acoustical insulation properties of wood.

Deriving from its definition, porosity is directly affected by density and moisture content their relationship given by

$$V_a = 1 - G(0.653 + 0.01M) \tag{6}$$

which is valid for all moisture contents above and below M_{fsp}. At full saturation of wood (all lumina are fully saturated with a liquid), porosity is equal to zero.

One of the highest porosity temperate-zone softwoods is northern white cedar with a V_a value of 0.77 and one of the lowest porosity softwoods is longleaf pine with a V_a value of 0.52. For hardwood, these values are 0.73 for black cottonwood and 0.40 for true hickory.

Dimensional Changes (Hygroexpansion)

Wood is a very unstable material when it gains or loses water molecules as a result of changes in ambient relative humidity and temperature. This is because the sorbed water molecules are mainly located in the amorphous areas of the microfibrils forming hydrogen bonds with the free hydroxyls (sorption sites). If water leaves wood because the air is quite dry, the cellulose chains tend to move closer to each other and this results in a reduction of the wood volume, i.e., shrinkage. The opposite phenomenon, adsorption, will therefore result in wood swelling.

Since the type of water that causes dimensional changes is bound water, this phenomenon is a characteristic of moisture content changes only in the hygroscopic range. Above M_{fsp}, free water accumulates in the wood pores and does not contribute to further separation of the amorphous chains and consequently, dimensional changes.

The amount of total volumetric swelling (V_{sw}) and shrinkage (V_{sh}) of wood over the hygroscopic range is a strong function of its specific gravity and moisture content and can be calculated from the following equations by assuming $M_{\text{fsp}} = 30\%$:

$$V_{\text{sw}} = 30G_{\text{o}} \tag{7}$$

$$V_{\text{sh}} = 30G_{\text{fsp}} \tag{8}$$

and between two moisture contents within the hygroscopic range:

$$V_{\text{sw}} = G_1(M_2 - M_1) \tag{9}$$

$$V_{\text{sh}} = G_2(M_2 - M_1) \tag{10}$$

The volumetric swelling (V_{sw}) and shrinkage (V_{sh}) between two moistures within the hygroscopic range can be calculated from the following equations:

$$V_{\text{sw}}^T = 2/3G_1(M_2 - M_1) \quad \text{and} \quad V_{\text{sw}}^R = 1/3G_1(M_2 - M_1) \tag{11}$$

$$V_{\text{sh}}^T = 2/3G_2(M_2 - M_1) \quad \text{and} \quad V_{\text{sh}}^R = 1/3G_2(M_2 - M_1) \tag{12}$$

where the superscript T denotes tangential direction and R denotes radial direction.

The anisotropic behavior of wood is evident when examining the total linear dimensional changes over the hygroscopic range. The total linear swelling from 0% to 30% moisture content is about 0.1% to 0.3% whereas the radial swelling ranges between 3% and 6% and the tangential between 6% and 12%. It is obvious that wood swells and shrinks very little in the longitudinal direction due to the same direction microfibrillar orientation, a trend that is not observed in the transverse direction (tangential and radial). Furthermore, there is a relationship of 2 to 2.5 between radial and tangential dimensional changes due to the presence of rays (one of the most accepted theories) that are restraining dimensional movement in the former direction. Abnormal and juvenile wood exhibit different levels of swelling and shrinkage, the latter exhibiting excessive longitudinal changes.

Dimensional instability is a major problem with wood that is exposed to wide variations of ambient relative humidity or it is in direct contact with liquid water. This can cause, in combination with anisotropicity, shape distortions and internal stresses that can manifest themselves as fissures through the structure of the wood. This problem can be avoided by dimensional stabilization, namely, the introduction of chemicals that introduce stability to wood at the microscopic level or by alteration and reduction of its hygroscopic nature and water affinity. Both methods have their advantages, disadvantages, and associated costs, and are mostly used for small-sized wood articles and specialty products. Examples of these stabilization processes are coating with film-forming finishes, heat treatment under vacuum or nitrogen, bulking with polyethylene glycol, acetylation, and formaldehyde crosslinking.

Fluid Flow through Wood

In drying and chemical treatment of wood (preservation, stabilization, veneer bolt steaming, pulping), we always have to deal with the flow of fluids (liquids and gases) to the surface of a timber or bolt from either its center or from the outside. In this case, the fluid is transferred mainly under a pressure differential through the interconnected void space of wood. It is important to emphasize here that although porosity is a measure of the scale of void volume in wood, high porosity does not suggest high flow rates. The voids must be connected to each other for this to happen; in other words, the pits should be 'open' to allow fluid flow from one lumen to the next. There are many examples where wood species with very high porosity value have a very low tolerance to fluid flow (refractory species).

Darcy's law governs the flow of liquids and gases through wood and the equations that describe this process under steady-state conditions are:

$$k_{\text{l}} = \frac{VL}{tA\Delta P}\left(\text{m}^3(\text{liquid})/\text{m Pa s}\right) \tag{13}$$

$$k_{\text{g}} = \frac{VL}{tA\Delta P}\left(\frac{P}{\bar{P}}\right)\left(\text{m}^3(\text{gas})/\text{m Pa s}\right) \tag{14}$$

where k_{l} and k_{g} are the superficial permeability coefficients to liquids and gases, respectively; V is the volume of flow (m^3); L is the length of wood (m); t is time (s); ΔP is the pressure drop across wood (Pa); and $\bar{P}$ is average pressure between the two ends of wood (Pa). The superficial permeability coefficient is a measure of how fast fluid will flow through various wood species, but as it can be seen in eqns [13] and [14], it is highly affected by the compressibility of the fluid (gases vs. liquids). A better way of expressing permeability levels is by excluding the effect of the fluid and converting this property to one that is only affected by the structure of wood, i.e., specific permeability (K), which is calculated by:

$$K = \mu_l k_l = \mu_g k_g \qquad (15)$$

measured in $m^3\,m^{-1}$, where μ is the viscosity of the measuring fluid (Pa s). It is obvious from eqn [15] that K is independent of the type of measuring fluid and once the superficial permeability is measured by, e.g., dry air the specific permeability can then be calculated.

Although Darcy's law is mainly used to measure the permeability coefficient of various species so that fluid flow under different pressures can be predicted, it must be emphasized here that the law applies to laminar flow which is not always the case in wood. Further to laminar or viscous flow, in wood with such small pore sizes, we may have turbulent flow, nonlinear flow due to kinetic energy losses at the entrance of short capillaries (i.e., pits), and slip flow or Knudsen diffusion due to mean free path of gases being larger than the size of a pore (i.e., margo membranes). Total levels of volumetric fluid transfer can then be a combination of two or more of the above types of flow.

Permeability is also a physical property that is greatly affected by the anisotropic nature of wood. Longitudinal permeability coefficients are 15 to 50 000 times larger than the transverse ones due to the orientation of the wood fibers. Not much difference exists between radial and tangential direction; however, the K values of the former are slightly higher due to the extra flow path provided by the rays. Sapwood is normally more permeable than heartwood and the species anatomy will also affect K. An example very commonly cited is the difference between red oak and white oak. Both have the same density and porosity, but red oak is more permeable by a factor of 10 000 due to the lack of tyloses which are very pronounced in white oak and greatly reduce fluid flow.

Aspiration and embolism are two phenomena that also reduce permeability. The former is the result of moving the torus/margo system of the bordered pits due to capillary forces during drying and permanently attaching them by hydrogen bonds to the cell wall thus closing any capability of communication between two adjacent lumina. The latter is the result of air bubbles plugging the pits thus not allowing further fluid flow through them. Both significantly reduce the value of K and hence reduce the uptake of liquid preservatives and pulping chemicals during wood processing.

Molecular Flow (Diffusion)

Molecular flow or diffusion is a mass transfer mechanism involved in processes such as drying below M_{fsp}, mechanosorptive behavior of wood in service, and flow of moisture through wall systems, amongst others. The flow of molecules is by activation and random and spontaneous 'jumps' from one sorption site to another under the influence of a concentration (or moisture) gradient. Bound diffusion through the cell walls is quite pronounced during drying and sorption, but also diffusion through the lumina (inter-gas) is also an important component of the total diffusive flux.

Fick's law describes the process of steady-state diffusion as follows:

$$D = \frac{wL}{tA\Delta C} \qquad (16)$$

where D is the diffusion coefficient ($m^2\,s^{-1}$), w is the weight of fluid transferred (kg), and ΔC is the driving force for diffusion, namely, the concentration difference ($kg\,m^{-3}$), and the other terms are the same as in eqn [14]. Since moisture diffusion is probably the most important for wood processing, ΔC can be substituted in eqn [16] by ΔM, which in turn will make more sense from the calculation point of view. After this, eqn [16] becomes

$$D = \frac{100wL}{tA\rho_w G_M \Delta M} \qquad (17)$$

The gross wood diffusion coefficient is a composite of bound water and inter-gas vapor diffusion and it is highly affected by moisture content, temperature, species and type of wood, and last but not least, direction. Specifically, D is directly proportional to moisture content and temperature since higher moisture levels will swell the cell walls thus creating new paths of flow and the higher temperature will provide the extra thermal energy required for faster molecular movement. The wood species and type (heartwood vs. sapwood) have an effect on D through density and chemical composition, which affect accessibility to sorption sites. Finally, longitudinal D values are higher that transverse ones at low moisture content values in the hygroscopic range, but the difference decreases by increasing moisture content toward the fiber saturation point.

It must be emphasized here that the process of diffusion is very slow when compared to bulk flow or heat transfer, and thus it is the controlling mechanism in drying where total processing time is concerned. Unfortunately, there are no reliable methods of improving the diffusion coefficient of wood at an industrial scale so that the drying speed of timbers can be increased. Attempts have been made with presteaming, hot water and surfactant solution dipping, ultrasonic field exposure, and freezing as possible methods with some success, more in improving permeability than diffusion.

Thermal Properties

Wood is always exposed to thermal loads either during processing, i.e., drying, heat stabilization, preservation, finishing, etc., or in service, i.e., as part of a wall system or a structural component, due to changing environmental temperatures. The amount of thermal energy absorbed and transferred through wood is affected by its thermal properties, namely, specific heat and thermal conductivity.

The specific heat of wood is defined as the amount of heat required to raise the temperature of 1 gram of wood by 1°C. The specific heat can be calculated from the following empirical formula:

$$c_p = \frac{1176 + 5859m}{1 + m} \qquad (18)$$

where c_p is the specific heat (kJ kg^{-1} K^{-1}); and m is the fractional moisture content between 0.05 and 0.30. Equation [18] is valid at $T = 30$°C. It is apparent that c_p is a strong function of moisture content, but it also is a function of temperature and wood species. Values of c_p will range between 1.3 and 1.9 (kJ kg^{-1} K^{-1}) at 30°C and between 0% and M_{fsp}.

Transfer of thermal energy through wood by conduction takes place by molecular interaction in the cell walls. Fourier's law describes steady-state flow of heat as follows:

$$K_\theta = \frac{HL}{tA\Delta T} \qquad (19)$$

where K_θ is the thermal conductivity coefficient (W m^{-1} K^{-1}); H is the quantity of heat transfer (J); and ΔT is the driving force, temperature difference, that drives heat flow (°C). K_θ will range between 0.08 and 0.17 W m^{-1} K^{-1} for oven-dry hardwoods and 0.08 and 0.14 W m^{-1} K^{-1} for oven-dry softwoods. For moisture content of 12%, the ranges are 0.10 to 0.21 W m^{-1} K^{-1} and 0.09 to 0.17 W m^{-1} K^{-1} for hardwoods and softwoods, respectively. For comparison, the K_θ of water is 0.59, and of dead air, 0.024 W m^{-1} K^{-1}.

Wood is a good thermal insulator; however, K_θ increases as wood density and moisture content increase. Furthermore, it is also affected by the anisotropic behavior of wood, that is, K_θ is greater in the fibers direction (longitudinal) than across (transverse) the timber.

Wood can also be a source of thermal when it burns (exothermic reaction) and this heat release per kg of wood is called heat of combustion (Q_c) measured in kJ kg^{-1}. During combustion, gases are released by thermal decomposition of wood that ignite and burn and ash is left as a solid byproduct. Spontaneous combustion can take place when wood is heated to 275°C in the presence of oxygen. This temperature is highly affected by the moisture content of wood, the species (anatomy), extractive types, and content, density, and wood dimensions. Fire resistance of wood can be increased by partially filling the lumina with special chemicals (fire retardants) that either increase its ignition point or delay its burning rate.

The Q_c value between species does not differ much and is about 19 600 kJ kg^{-1} when wood is oven-dry (no moisture present). When water is adsorbed in the wood cell walls, Q_c tends to decrease and when free water is present in the lumina ($M > 30\%$), Q_c normally drops to about 15 000 kJ kg^{-1}.

Continuous and long exposure of wood to elevated temperatures can also result in thermal degradation. This phenomenon is manifested by chemical breakdown of mostly hemicelluloses and cellulose with time and a loss of mass and strength. The rate of thermal degradation varies between wood species and increases with temperature and time of exposure. Controlled thermal exposure in the absence of oxygen can result in crosslinking reactions in the amorphous areas of cell walls, thus resulting in improved dimensional stability.

Electrical Properties

Wood, when dry, is an excellent electric insulator. However, this advantage diminishes when moisture content increases within the hygroscopic range and above the fiber saturation point (**Figure 3**). At a moisture content of 7%, the Douglas-fir's electrical resistance, a measure of the ease with which electric current flows through wood under the influence of a voltage differential, is 22 400 MΩ but it decreases to 0.60 MΩ at 24% moisture content. This dramatic

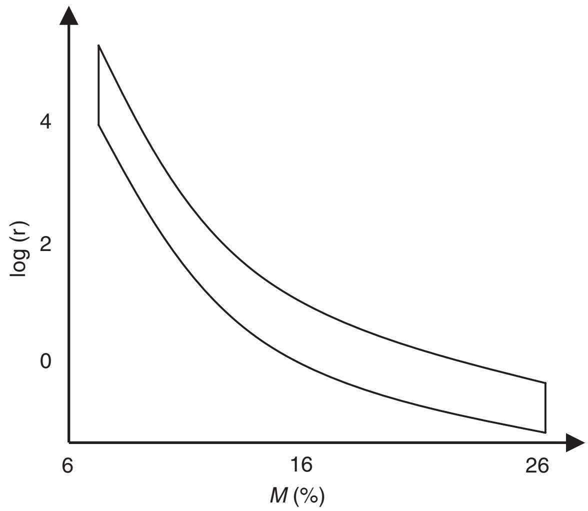

Figure 3 Curves of logarithm of electrical resistance against moisture content for most North American wood species.

drop as a function of moisture content is used by the industry to measure the amount of bound water present in wood with a specially designed piece of equipment call pin-type resistance moisture meter (or *M*-meter). The *M*-meter directly measures electrical resistance between the tips of two metal pins and through a conversion formula, calculates and displays the moisture content of the wood matter between the pins.

The electrical resistance is a strong function of species, temperature and fiber direction (anisotropicity). This is why when resistance *M*-meters are used, they need to be calibrated for species and temperature and also the pins should be placed parallel to the fiber direction. Density has no clear effect on electrical resistance.

When wood is placed within an alternating field, thermal energy is produced within the piece of wood due to the friction of the water molecules in the cell walls and lumina. The friction is the result of their dipolar nature and thus the rotation, vibration, and linear motion of ions when under an electric field of high frequency. This phenomenon is called dielectric heating. The amount of heat generated is predicted by the loss factor of wood that is one of the material's dielectric properties. The loss factor is strongly affected by moisture content (proportional relation), field frequency, species, and, to a lesser degree, wood temperature. This is a complicated dielectric property of wood that is quite difficult to measure directly. However, dielectric heating has served the wood processing industry in accelerated gluing and drying processes such as radio-frequency vacuum drying.

Wood also has piezoelectric properties, like quartz crystals, where electric polarization appears under compressive or tensile stress or mechanical strain develops under the application of electric field. The intensity of piezoelectricity in wood depends on its degree of crystallinity and the degree of orientation of crystallites. This phenomenon has been used in the development of nondestructive methods of evaluating local wood strain and the influence of knots, density, fiber angle, etc., on a dynamic system.

Acoustical Properties

The acoustical properties of wood relate to the production of sound with direct impact, and to the behavior of wood in relation to sound produced by other sources that is transmitted through air impacting wood in the form of sound waves.

Wood is seldom used as a direct source of sound. The pitch of sound produced is dependent on the frequency of the wood vibration. This frequency is a function of the wood dimensions, moisture content, density, and stiffness. When sound waves are produced by another source, they impact the surface of wood and a portion of their acoustic energy is absorbed by wood whereas the rest is reflected. Of the absorbed sound, some will be converted to thermal energy and some will be transmitted through the piece of wood. The density and thickness of the wood substrate and the frequency of the sound waves affect the amount of sound absorbed. The transmission of sound is quite fast, namely, 3500 to 5500 m s^{-1} in the longitudinal direction and 2300 to 3200 m s^{-1} in the transverse direction, as compared to 340 m s^{-1} through air and 1400 m s^{-1} in water. Sound velocity level is strongly affected by density, direction in relation to fiber, wood defects and abnormal growths, and moisture content.

Industry has used the strong relationship of sound transmission to various wood attributes in order to develop nondestructive evaluation techniques that estimate stiffness and strength of wood, internal decay in trees and timbers, fiber angle and the presence of juvenile and reaction wood, among other attributes, with variable level of success.

Chemical Properties of Wood

I S Goldstein, North Carolina State University, Raleigh, NC, USA

Introduction

The chemical properties of wood are inextricably associated with and dependent upon its chemical composition. Fortunately, the major wood components are not numerous, and with only minor variations are found across all woody species. The chemical behavior results from the interaction of the structural features known as functional groups with either other chemical entities or physical factors such as heat and light. After a description of the chemical components of wood including their relevant functional groups, the most important chemical interactions will be discussed.

Composition of Wood

The chief components of woody plant cell walls are cellulose, hemicelluloses, and lignin. In bark these structural components may be exceeded by suberins and phenolic acids. The final category of wood components is known as extractives. These materials are much less abundant, variable in structure or quantity, usually soluble, and often species or genus specific.

Cellulose

Cellulose is the chief cell wall component, and comprises 40–45% of the wood. It is a long chain polymer of glucose units linked together by glycosidic bonds, a type of acetal ether linkage (O–C–O–C). The other, and most important, functional group in cellulose is the hydroxyl (–OH). Each glucose unit in the chain has three free hydroxyl groups that are capable of reacting with others in a neighboring chain or with water to form hydrogen bonds (H–O–H—H–O–C). Unlike starch which is also a glucose polymer, but with an α-configuration leading to an amorphous structure, the β-configuration in cellulose leads to stiff and straight chains that can form highly ordered crystalline regions. Cellulose contains disordered or amorphous regions as well.

Hemicelluloses

Associated with the cellulose in the cell wall are carbohydrate polymers known as hemicelluloses. They consist for the most part of sugars other than glucose, both pentoses and hexoses, and are usually branched and of much lower molecular weight than cellulose. In softwoods they comprise 25–30% of the wood in decreasing abundance as mannose, xylose, glucose, galactose, and arabinose. In hardwoods the hemicelluloses account for 20–35% as xylose, mannose, glucose, and galactose. The functional groups as in cellulose are glycosides and hydroxyls, with the addition of acetyl ester groups formed by the reaction of acetic acid with hydroxyls.

Lignin

Lignin is the third major wood cell wall component (20–30%). It serves as a cement between wood fibers, as a stiffening agent within the fibers, and as a barrier to the enzymatic degradation of the cell wall. Lignins are three-dimensional network polymers of phenylpropane units. More than two-thirds of the linkages are ether bonds, the rest are carbon–carbon bonds. Some free phenolic hydroxyls are found on the phenyl groups, but most have been etherified with methanol to methoxyl. Softwood and hardwood lignins differ in methoxyl content and in the degree of crosslinking. Hardwood lignins have more methoxyls, but these groups block potential reactive sites and reduce crosslinking. There is evidence that covalent linkages exist between lignin and the hemicelluloses.

Bark Components

Bark fibers contain cellulose, hemicelluloses, and lignin, but in much lower concentration. The cellulose content may be as low as 20–30%. Two other components unique to bark, suberins and phenolic acids, account for this. Suberins consist of long-chain esters. Their content varies from 2–8% in pine, fir, and oak to 20–40% in birch, and 35–40% in cork oak. Phenolic acids are high molecular weight phenols, but lower in weight than lignin. They have a high carboxylic acid content, and lower methoxyl content. They may comprise 50% of the weight of conifer bark.

Extractives

Extractives are the extraneous wood components that may be dissolved in water or organic solvents. They are often genus or species specific. Major categories include sugars, fatty acids and their esters, acids, aldehydes, alcohols, terpenes, tannins, quinones, and volatile oils.

Chemical Interactions of Wood and its Components

It is customary in considering the interactions of wood and chemicals to concentrate on the result of the chemical action. The chemical technology of wood is usually divided into such categories as fractionation of wood into its separate components, the conversion of the wood components into various low molecular weight or polymeric products, or the deterioration of wood by chemicals.

However, all these processes possess a common feature. They all begin with the interaction of a chemical reagent with the bonds and functional groups present in the wood. The structures of wood and its components have been defined above. Chemical properties of wood may thus be related to specific reactions of reagents and reactive sites in the wood. Physical factors such as heat, light, and ionizing radiation can also effect chemical changes in wood and its components.

Water

Wood–water relationships are usually considered from a physical or mechanical perspective, involving either drying or dimensional change. However, the underlying phenomenon is chemical in nature, involving the formation of hydrogen bonds between the hydroxyl groups in water and the many hydroxyl groups in the 75% of wood that is carbohydrate in nature.

All the hydroxyl groups are not available for hydrogen bonding and thus adsorption of water. In the crystalline regions of the cellulose, hydroxyls in adjacent linear chains hydrogen bond with each other. This prevents the dissolution of cellulose in water, in contrast to starch whose helical or branched chains cannot bond to each other by hydrogen bonds. In the noncrystalline or amorphous regions of the cellulose, and in the hemicelluloses, the hydroxyl groups are free to bond with water, and the bound water can bond to more water, leading to adsorptions of up to 30% of the wood weight at the fiber saturation point with commensurate changes in wood volume.

Hydrogen bonds are much weaker than covalent bonds, but in the aggregate they represent large amounts of energy, and require large inputs of heat for their disruption in the drying process in kilns. Even at low relative humidities the driving force of hydrogen bond formation ensures that wood contains appreciable quantities of bound water.

Hydrolysis

Hydrolytic reactions are the most important in their effect on the properties of wood. Both carbohydrates and lignin are susceptible. In carbohydrates the affected groups are the acetal and ester linkages. The acetals are more important because of their greater abundance and their structural role in chain formation. Both acids and alkalis can cause hydrolysis, but the chain scission by acids has the greatest impact on wood properties.

Ester hydrolysis by alkali liberates free hydroxyl groups on the hemicellulose with a reduction in alkalinity in the solution. In acid hydrolysis, however, the liberation of free acetic acid can increase the acidity leading not only to further ester hydrolysis, but also to cleavage of acetal linkages and lignin bonds in the autohydrolysis reaction. At its maximum extent acetic acid liberated by steam can completely hydrolyze the hemicellulose to its constituent monosaccharides and convert the lignin into soluble fragments.

Acid hydrolysis of the acetal linkages in wood polysaccharides proceeds by fission of the glycosyl oxygen bond between the rings. Because of steric factors the rate of hydrolysis of crystalline cellulose is several orders of magnitude less than that of simple glycosides or noncrystalline polysaccharides. However, in the amorphous regions of the cellulose and the hemicelluloses the acetals are subject to ready attack. Under alkaline conditions acetal hydrolysis is much slower and proceeds only at higher temperatures.

Hydrolysis of the lignin linkages under both acidic and alkaline conditions has been studied extensively because of its importance in the pulping of wood. The various ether linkages respond differently to different reagents. Some respond to mild hydrolysis with hot water or dilute acetic acid. Others are cleaved by acid sulfite pulping, while alkaline reagents at elevated temperatures as in Kraft pulping break ether linkages between the phenylpropane units with liberation of phenolic hydroxyl groups. Cleavage of C–C bonds can also occur during acid hydrolysis, as well as in trace amounts under alkaline conditions.

Oxidation

Both the carbohydrate and lignin components of wood are affected by oxidizing reagents. Mild oxidants such as chlorine, bromine, or iodine convert the aldehyde end groups in the wood polysaccharides to carboxylic acids. Nitrogen dioxide converts primary hydroxyl groups to carboxyl groups. Periodic acid is a specific oxidant for adjacent diols. Stronger oxidants such as nitric acid, potassium dichromate, and potassium permanganate cause extensive degradation of carbohydrates to a series of dicarboxylic acids.

Molecular oxygen in the presence of alkali generates hydroperoxides which can result in stepwise depolymerization of polysaccharides known as peeling. Carbonyl groups are introduced into polysaccharides by the action of chlorine, hypochlorite, and ozone. Hydrogen peroxide and chlorine dioxide react much more slowly and are less degrading, so they are favored in pulp bleaching.

Oxidations of lignin may be placed in three categories: degradation of lignin to aromatic carbonyl compounds and carboxylic acids, degradation of aromatic rings, and oxidation of specific functional groups.

The first category includes oxidations with nitrobenzene, molecular oxygen, or metal oxides under alkaline conditions. Aromatic ring degradation results from exposure to peracetic acid, nitric acid, chlorine, chlorine dioxide, ozone, and the anions of hypochlorous and chlorous acids. Neutral permanganate can oxidize both side chains and rings. Periodic acid and alkali peroxides oxidize specific functional groups. Lignin oxidation is also involved in the photodegradation of wood and the enzymatic degradation of lignin.

Strong oxidants such as permanganate and dichromate in acidic solution degrade lignin completely to carbon dioxide and dibasic acids. A group of oxidants between the strong ones and the side chain oxidants, attack primarily the aromatic nuclei of the lignin. Because they show a relative selectivity in attacking lignin more rapidly than carbohydrate, chlorine, nitric acid, chlorine dioxide, sodium hypochlorite, peracetic acid, hydrogen peroxide, and ozone have found utility in the bleaching of the residual lignin in pulp after removal of most of the lignin by pulping.

Decrystallization

The crystallinity of cellulose is an inherent property that governs its mechanical properties, affinity for water, and accessibility to chemical reagents. Since the crystallinity is the result of interchain hydrogen bonding, changes in crystallinity reflect decreases or increases in this bonding.

Although water alone cannot break the interchain hydrogen bonds, decrystallization can be brought about by many reagents. The extent of decrystallization may vary from partial swelling to increase chemical accessibility to complete dissolution that permits reprecipitation and the formation of regenerated cellulose fibers such as rayon.

These reagents include concentrated sodium hydroxide; amines; metalloorganic complexes of copper, cadmium, and iron; quaternary ammonium bases; concentrated mineral acids (sulfuric, hydrochloric, phosphoric); concentrated salt solutions (beryllium, calcium, lithium, zinc); and mixtures of organic solvents.

An increase in crystallinity is unusual, but it does occur after hydrolysis of amorphous cellulose. The broken chains have greater freedom to form more highly organized structures.

Discoloration

Staining or discoloration of wood may result from chemical processes that convert originally colorless or light-colored, naturally occurring extractives into intensely colored products.

Most of the so-called chemical stains result from oxidation of certain wood extractives by air during air seasoning or kiln drying. Colors observed include shades of brown, blue, green, yellow, and red. Affected species include both hardwoods (oak, birch, maple, alder, basswood, gum, etc.) and softwoods (pines, hemlock).

Wet wood can also discolor by contact with iron or copper when tannins are present to form black iron tannate or reddish copper tannate. These metals may also initiate oxidation of the wood by free radical mechanisms.

Other Functional Group Reactions

The functional groups in wood and its components can also enter into the normal reactions of the various groups. Thus hydroxyl groups may undergo esterification or etherification. Cellulose esters of both inorganic and organic acids are important industrial products, most notably cellulose nitrate and cellulose acetate. Cellulose ethers such as methylcellulose and carboxymethylcellulose are also important. These reactions have also been carried out on whole wood. Organic chemicals that have been used to react with the hydroxyl groups include acid anhydrides and chlorides, aldehydes, alkyl chlorides, carboxylic acids, epoxides, isocyanates, lactones, and nitriles.

The carboxylic acid and phenolic hydroxyl groups in wood contribute to its natural acidity. These acidic groups can act as ion exchange agents with sodium in alkaline solutions, or with copper and zinc in wood-preserving solutions.

Reducing end groups such as aldehydes in wood sugars are the agents which convert hexavalent chromium in some wood preserving formulations to insoluble forms.

Surface Chemistry of Wood

The utilization of wood and wood fibers involves in more cases than not the interaction of the woody material with natural and synthetic polymers in the form of adhesives and coatings. The chemistry of the wood surface may influence the conversion of liquid formulations to solid form, and certainly plays a critical role in the wetting and bonding of these substances to the wood surface. Aside from the bonding forces themselves, such factors as pH, moisture content, and extractives have a direct influence on bonding.

The bonding forces may be of three types. London, van der Waals, or dispersion forces act between all atoms and are mainly responsible for the cohesion of all materials. Dipole–dipole interactions between positive and negative charge centers are especially important in wood with its many hydroxyl groups. In the hydrogen bond the positive proton is shared between two electronegative atoms, most frequently nitrogen or oxygen. Finally, true chemical bonds, either covalent or ionic, may form between the functional groups in the wood and those in the coating or adhesive.

Most important resins used with wood are of the thermosetting type whose cohesive strength exceeds that of the wood. They include urea–formaldehyde, melamine–formaldehyde, phenol–formaldehyde, diisocyanates, polyisocyanates, and polyamides. Their polar groups can form strong hydrogen bonds with the hydroxyl groups in wood, and their functional groups can interact with the wood.

The polymeric adhesives and coatings are generally applied in liquid form, and then cured to solids. The acidity of some species of wood can interfere with these reactions, especially those that are base catalyzed. Both soluble and insoluble acids have been implicated. Wood extractives that compete with the resins for formaldehyde can also disrupt the curing process.

Modification of the wood surface to introduce more functional groups capable of covalent bond formation has been studied. Activation of the surface by heat, acids, or oxidants may be followed by three approaches. Direct covalent bonds may be formed between two wood surfaces. Bifunctional monomers may be used to join the surfaces. And finally, polymeric chains may be used to bridge the surfaces.

Chemical Effects of Physical Factors

The chemical properties of wood and the wood itself may be modified by physical factors. Heat is most important, but light and ionizing radiation also cause changes in the wood chemistry.

Heat

Chemical reactions involve the breaking of bonds in the reactants and the formation of new bonds in the reaction products. These processes are accelerated by thermal energy or heat since the bonds represent states of minimum energy. However, even in the absence of external reagents the chemical bonds holding molecules together are subject to scission and rearrangement when sufficient thermal energy is applied.

In the case of wood a description of the effect of heat is complicated by the variations in composition between species. Examination of the behavior of the individual components can provide insights that may be extended to whole wood.

As wood is heated above room temperature the water adsorbed by the hygroscopic wood components is first driven off. At higher temperatures the wood components start to decompose with the evolution of gases. Hemicelluloses show initial decomposition at about 120°C, lignin above 130°C, and cellulose above 160°C. The gases evolved during this slow, low-temperature pyrolysis are not flammable. Water vapor and carbon dioxide predominate, with lesser amounts of carbon monoxide and traces of organic acids being present. It is evident that dehydration and decarboxylation are taking place. Wood that has been heated above the boiling point of water for extended periods becomes less hygroscopic and more dimensionally stable with some sacrifice of strength.

Above 200°C the rate of decomposition increases until rapid exothermal weight losses occur at 260°C, 280°C, and 330°C, probably representing the different behavior of the separate wood components. With the onset of rapid pyrolysis, flammable gases are evolved such as carbon monoxide, methane, formaldehyde, formic and acetic acids, and methanol. Also evolved are highly flammable tars containing furfural and other furan derivatives from the decomposition of pentosans, levoglucosan from the decomposition of the cellulose, and aromatic fragments such as phenols, xylenols, guaiacols, cresols, and catechols from the decomposition of the lignin.

In the presence of air these flammable gases and tars evolved during rapid pyrolysis can further react with oxygen in the process we call burning, adding their heat of combustion to the degradation process, and intensifying it. The residue becomes charcoal, with carbonization becoming complete at 400–500°C and the crystalline structure of graphite developing.

In the presence of acidic or alkaline compounds the decomposition takes a different course. Instead of the liberation of flammable gases and tars the modified pyrolysis leads to increased amounts of charcoal by dehydration of the cellulose and hemicelluloses. The increased char formation occurs at the expense of flammable volatile tars. The cellulose is preferentially converted to carbon and water. When this dehydration occurs at temperatures below the normal decomposition temperature of wood, the wood has been effectively flameproofed.

Light

Exposure to light causes photodegradation and photooxidative degradation. Ultraviolet light interacts with lignin resulting in discoloration and deterioration. In a surface phenomenon, since light does not penetrate beyond 200 μm, the free radicals generated interact with oxygen to form hydroperoxides which in turn decompose. The results are large color changes and chemical degradation.

Wood is an excellent light absorber. Cellulose absorbs strongly below 200 nm. Hemicelluloses are structurally similar, so their ultraviolet absorption characteristics resemble those of cellulose. Lignin and polyphenols absorb light strongly below 200 nm and have a strong peak at 280 nm, with absorption continuing through the visible region. Extractives absorb between 300 and 400 nm.

The strong absorption of ultraviolet light by lignin results in preferential lignin degradation. The process is initiated by the formation of free radicals, and begins with the oxidation of phenolic hydroxyls. Methoxyl and lignin content decrease, while acidity and carboxyl content increase. The products of decomposition, in addition to gases and water, are mainly organic acids, vanillin, syringaldehyde, and higher molecular weight, but water soluble, compounds.

The color of wood exposed to light changes rapidly. Woods rich in extractives may become bleached before photooxidation of lignin results in a loss in brightness. The general change in color in all woods is toward a yellow to brown as degradation proceeds. The yellowing of newsprint after brief exposure to light is typical behavior. The final gray color seen in wood exposed to light for long periods of time represents residual cellulose after degradation and removal of most of the lignin.

Ionizing Radiation

High energy radiation can depolymerize the wood components by creating free radicals along the C–C backbone. If two free radicals are formed on separate chains in close proximity, crosslinking can take place. If the free radicals are created near a reactive or functional group other types of reactions can occur. When the free radical is on a tertiary carbon, disproportionation with chain scission can take place.

Surprisingly, lignin is more resistant to gamma-radiation than cellulose, even though it is more susceptible to the lower energy ultraviolet radiation. Irradiated cellulose is degraded by the cleavage of glycosidic bonds. But the radical sites created on the cellulose at lower levels of irradiation have been used for initiation of grafting on the cellulose and copolymerization in the presence of vinyl monomers.

High-energy radiation in the form of gamma-rays and X-rays can penetrate wood readily, whereas photoirradiation is only a surface phenomenon from ultraviolet penetration of up to 75 μm and visible light penetration of up to 200 μm. Thus extended high-energy radiation can be very destructive. White oak wood irradiated to 1900 Mrad with gamma-rays had an increase in extractives from 9% to 69% showing extensive solubilization. Holocellulose was reduced from 58% to 4%, while lignin showed only a slight loss from 33% to 27%.

Wood Quality

J Barbour, US Department of Agriculture Forest Service, Portland, OR, USA

Published by Elsevier Ltd., 2004

Wood Product Streams

The classical definition of wood quality is the suitability of a given piece of wood for a specific end use, and, accordingly, individual wood characteristics are not usually seen as universally good or bad. The exact set of characteristics that constitute high or low quality varies depending on the specific use. Some characteristics are, however, almost always desirable and others are almost always undesirable. Some examples of desirable characteristics are soundness (lack of decay), straight grain, small scattered knots or the complete absence of knots, and dimensional stability (a tendency to dry without warping and to remain straight in use). Some examples of undesirable characteristics are decay, large or unsound knots, lack of dimensional stability, and poor mechanical properties. Some wood products are very forgiving of variation in wood characteristics. Others require raw material with a narrow range of wood characteristics. Consequently, it makes sense to begin a discussion of wood quality by thinking about the broad categories of wood products and the characteristics that are important for each group. A convenient way to do this is to divide all possible wood utilization options into a small number of 'end product streams' with similar raw material requirements, for example (1) heat and chemicals, (2) fibers and particles, and (3) solid products.

Heat and Chemicals

The energy production stream is the least demanding in terms of wood characteristics. Raw materials with lower moisture contents and higher specific gravities are more desirable but fuelwood can include a variety of low-quality raw materials. These could come from small stems, crooked stems, stems with large numbers of knots, or stems with high proportions of defects such as cross grain, rot, reaction wood (wood associated with leaning or deformed stems), etc.

Many chemicals used every day are derived from wood, bark, extractives, or foliage. Raw materials used for their production must be cleaner than for energy and, although some species work better than others because of their chemical composition, fiber characteristics or other wood properties are relatively unimportant.

Fiber and Particles

Composite wood products such as oriented strandboard (OSB), parallel-strand lumber (PSL), waferboard, particleboard, medium-density fiberboard (MDF), hardboard, wood–plastic composites, wood–cement composites, and pulp for paper and paperboard are included in the fiber and particle product stream. Manufacture of these products requires cleaner raw material than energy production, although perhaps not more so than chemical production. In most cases, bark is seen as detrimental, so ease of bark removal from roundwood is an important feature. Manufacture of fiber- and particle-based products is also less tolerant of decay, reaction wood, pitch pockets, or other irregularities. It is, however, technically feasible to make these products from small stems or stems with substantial grain deviation as long as it is not associated with reaction wood and does not interfere with debarking or primary processing such as waferizing.

Solid Products

This stream is divided into structural products and appearance products. Solid products include roundwood, such as posts and poles, sawn lumber, and veneer. In some ways, the structural product stream is the most demanding. Products in this stream must meet engineering standards, such as specified mechanical requirements and they are intolerant of grain deviations or decay. On the other hand, they can contain some knots and discoloration without adversely affecting their performance.

The raw material requirements for structural products have changed greatly during the twentieth century. Technological improvements now allow sawing of logs as small as 9 cm in diameter on the small end, although economic constraints often preclude processing logs quite so small. Techniques were also developed to use weaker or less stiff lumber in parts of engineered products where mechanical properties were less important and abundant fast-growing species such as aspen (*Populus* spp.) replaced slower-growing softwood species for structural panel products. Not long ago, the only way to make a large beam was to saw it from a large log, but now it is possible to manufacture glulam beams, wood I-beams, or parallel strand lumber (PSL) from small logs. This means that as forest managers plan new plantations they have to take potential changes in technology very seriously. Raw material requirements for structural products still favor trees with fewer and smaller knots, straight grain, and less taper but tree size is not nearly as important as it was less than a rotation ago in many timber-growing regions.

Appearance products are similar to structural products except that they contain characteristics that people consider beautiful. Some examples are dark- or light-colored heartwood, various grain patterns, and lack of knots. In some cases, appearance products perform a structural function, such as in furniture, architectural beams, or posts, but in many applications such as fascia and molding they have no structural role. This means that for many applications the mechanical properties of appearance products are relatively unimportant. A high level of dimensional stability is, however, always important for these products.

Appearance products are typically the highest-priced wood products, although certain specialty structural products such as very long power transmission poles or large structural beams can rival them in price per unit volume. Even with high prices, it is not normally economically feasible to grow trees suitable for appearance products to replace traditional hardwood and 'old-growth' softwood supplies. Pruning trees to grow clear lumber and veneer is an exception, but profitable pruning requires shortening rotations by combing pruning with intensive thinning. The wood from these fast-growing trees looks quite different from clear wood sawn from trees grown more slowly. An alternative is to extend the supply products that look like old-growth by covering wood or non-wood substrates with thin veneers sliced from slow-growing hardwoods or softwoods.

Growth Conditions Influence Tree and Wood Characteristics

Foresters began to formalize theories about how growing conditions influence tree form, branch size, and other factors that control wood characteristics as long ago as the late nineteenth century. They observed that the size and vigor of the crown was important in determining both the morphological, or externally visible, characteristics and the basic wood properties (chemical, anatomical, and physical properties) of softwood trees. Since then, wood scientists have built on these early observations by using a combination of structured experiments and retrospective studies to develop an understanding of how silvicultural manipulation of stand conditions can influence tree characteristics and, consequently, wood products manufactured from them. Field foresters now routinely use this knowledge, but their understanding of all aspects of how to manipulate wood properties is far from complete. Some general inferences that apply to most softwoods are, however, possible.

Most silvicultural treatments that influence wood quality modify the size and vigor of the crown. Treatments that increase crown length or vigor create trees more like open-grown trees with deeper crowns, larger branches, and more conically shaped stems (taper) (**Figure 1**). Treatments that reduce crown length or vigor produce trees with characteristics more like those observed in trees from dense stands with short crowns, small branches, and more cylindrical stems. Understanding these simple relations between growing space, crown length, branch size, and stem shape is important in understanding how growing conditions influence the suitability of the wood from a tree for a specific end use.

A fairly well-developed theory involving the production of growth hormones and nutrients has arisen to explain why this happens. Simply stated, trees with larger crowns produce more growth hormones and more nutrients. Growth hormones encourage cell division and radial expansion of longitudinal wood cells (tracheids) as they mature. Nutrients contribute to the growth and thickening of cell walls. Growth hormones are mainly produced in actively growing branch tips, and nutrients are mainly produced by vigorous foliage. Trees with deeper, more vigorous crowns have both more foliage and a greater number of buds, so they produce higher hormone concentrations and larger quantities of nutrients than trees with short, suppressed crowns. The change in concentration of hormones and nutrients from the apical meristem (topmost bud) to the base of the tree has been suggested as an explanation for the changes in various wood properties from the center of the tree (pith) to the bark. This inner zone of changing wood properties is generally used to differentiate juvenile, or crown-formed, wood from mature, or stem-formed, wood.

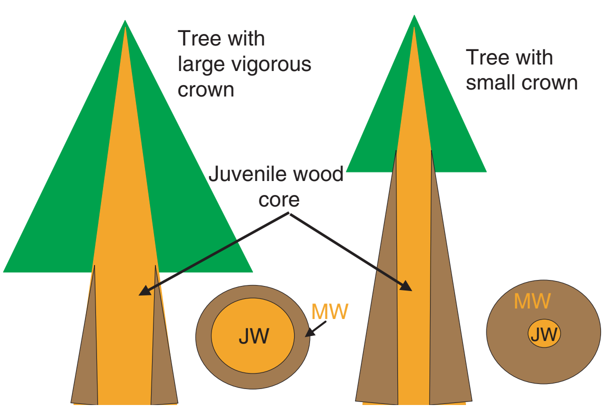

Figure 1 Relation of juvenile wood core size with crown size and vigor. With larger more vigorous crowns grow more quickly and therefore produce more juvenile wood (JW) and less mature wood (MW) than trees of the same diameter with smaller crowns.

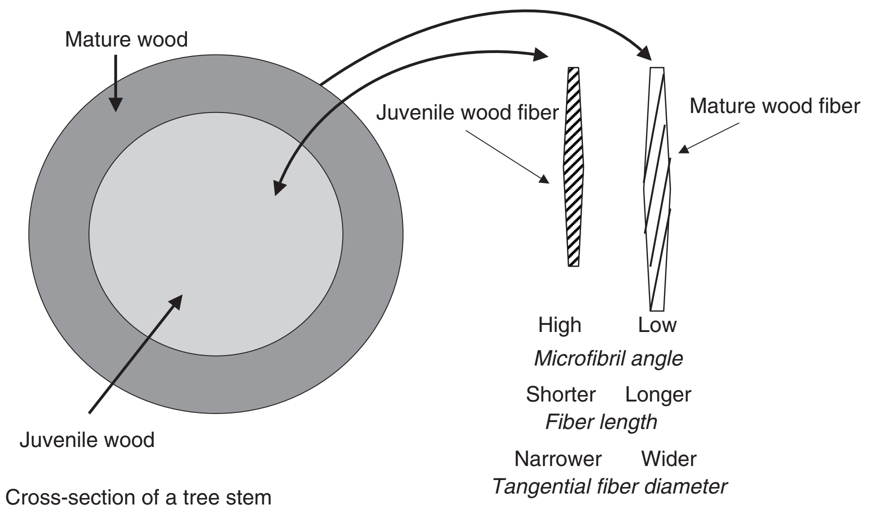

Figure 2 Variation in fiber characteristics in juvenile wood and mature wood. Juvenile wood tends to have shorter, narrower fibers with higher microfibril angles than mature wood.

For practical purposes, the transition from juvenile wood to mature wood is often thought to begin at the base of the live crown.

Another theory explains the changes in basic wood properties from the pith to the bark as the expression of aging by the cambial initials (actively dividing cells) in the vascular cambium. This theory holds that each time a cambial initial divides, it changes slightly (lengthens, grows wider, alters its cell wall structure, etc.) and as a result, wood properties change over time (**Figure 2**). This theory has been used to develop a plausible explanation of why some trees develop spiral grain as they age.

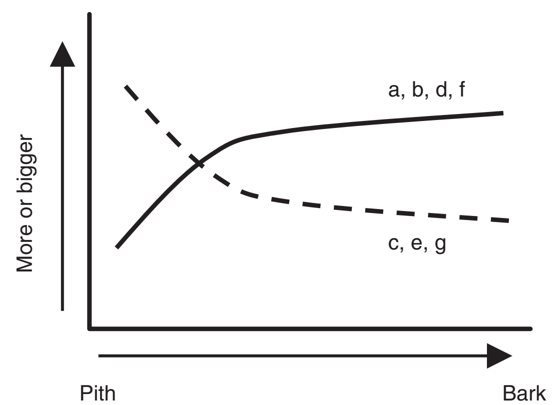

Figure 3 Pith to bark relation of various wood properties. The way some wood characteristics change from the pith to the bark is more or less universal among species. Example wood characteristics: (a) fiber length, (b) tangential cell diameter, (c) microfibril angle, (d) extractive content, (e) branch number, (f) branch size, (g) longitudinal shrinkage.

The Importance of Juvenile Wood

Juvenile wood often has different properties than mature wood. The duration of the period when juvenile wood is produced, the rate of transition from juvenile wood to mature wood, and the differences in properties between juvenile wood and mature wood are all important in determining the suitability of wood for specific end uses. There are always more knots in juvenile wood because it is formed when the crown is alive. Differences in chemical, physical, anatomical, and visual characteristics have all been reported for various species, and the importance of each depends on the wood product being manufactured (**Figures 3** and **4**). For example, differences in cell wall thickness and cell wall mechanical properties that are undesirable for lumber and veneer might actually result in fibers with excellent pulp and papermaking properties. Problems generally arise when solid products contain both juvenile wood and mature wood, but papermakers can use blends of juvenile and mature wood to obtain desired characteristics.

Variation within Growth Rings

Intraring variation of basic wood properties, or changes within individual annual rings, is another important factor in determining the suitability of wood for specific uses. The annual fluctuation in hormone and nutrient levels has been used to explain some of this variation. In the spring, when buds are most active, they produce high hormone concentrations. This promotes rapid radial expansion of new xylem cells, but the foliage has not yet fully matured so there are insufficient nutrients for substantial cell wall thickening. Large-diameter thin-walled

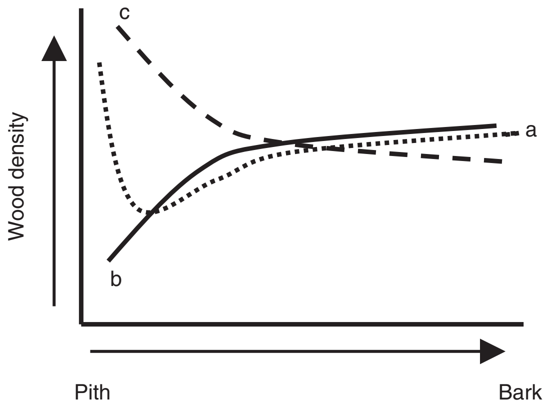

Figure 4 Different species tend to have different pith to bark wood density profiles. Pith to bark trends also tend to change with tree height so that the pattern is not always the same within a single tree. Typical patterns by species: (a) Douglas-fir and hemlock, (b) most pines, (c) most spruces.

earlywood tracheids are produced during this period. Later in the growing season, as expansion of growing tips is completed and the foliage is fully expanded, the situation is reversed; the concentration of hormones available for cell expansion is minimal, but there are plenty of nutrients to promote rapid thickening of the cell walls. As a result, thick-walled latewood cells are produced. A related theory suggests that the size of various cells is controlled by the need to move water through the stem to the foliage.

Factors such as soil nutrients, moisture availability, and temperature also are thought to influence the initiation of radial growth in the spring and cessation of radial growth in the fall. The time when growth begins or when it ends can influence the characteristics of individual growth rings. If growth starts late in the spring, perhaps owing to a late thaw, less earlywood is laid down before the transition occurs; if growth stops early in the autumn, perhaps because of a drought, less latewood is produced.

The Importance of Basic Wood Properties

Intraring characteristics are important because they play a role in determining the suitability of wood for specific uses. The proportion of earlywood and latewood and whether the transition between them is gradual or abrupt influences mechanical properties, machining, nailing and fastening, penetration of treating chemicals, and appearance of solid products. For some products, such as fine papers, an abundance of long, stiff, thick-walled fibers is seen as detrimental because they interfere with sheet formation in papermaking.

It is important to recognize that the influence of growth conditions on tree and wood characteristics is complicated by the interactions of many different factors. The interactions described here are complicated by other relations that control the orientation of cellulose microfibrils in the cell walls, cell length, and the proportions of cell wall components (cellulose, hemicelluloses, and lignin). Each of these basic wood properties varies within growth rings, from pith to bark, and from the base to the top of the stem according to a different relation with growth conditions, so it is often difficult to understand precisely why physical properties of larger pieces of wood change in the ways that they do.

The Importance of Morphological Characteristics

Morphological characteristics such as branching and grain orientation are equally or perhaps even more important in determining the suitability of a given piece of wood for a specific end use than are basic wood properties. More and larger knots are almost universally considered detrimental whether wood is used for lumber, veneer, composites, or fiber products. Notable exceptions are knotty-pine paneling and certain grades of lumber used in furniture manufacture, but these account for a tiny fraction of all wood products.

Knots are a primary factor used to determine lumber and veneer grade and value. In general, the more abundant and the larger knots are the lower the grade. Knots interfere with adhesives and reduce the mechanical properties of composite products like OSB, laminated-veneer lumber (LVL), and PSL, but they are generally not recognized in pricing raw materials for these products. This is probably because no reliable models exist to relate knot size, knot condition, and knot abundance to performance of these products or to waste during their manufacture. The effect of knots is better understood for fiber products like paper because they tend to interfere with the pulping, grinding, and refining processes used to turn raw wood into fibers. Knots are usually detrimental in composite products, but their high wood density produces more heat per unit volume when they are burnt for energy. They also contain high levels of extractives, which is desirable for manufacturing certain solvents.

Knot shape is also important. Shape comes partly from the morphology of branching and partly from manufacturing processes. Branches that join the stem at right angles to its long axis are known as low-angle branches. Low-angle branches produce the smallest knots for a given branch diameter. Branches that leave the stem at an angle result in larger oval knots and are, therefore, less desirable.

Trees with deeper, broader crowns produce larger, more persistent branches. They also tend to have more branches. One way this happens is when trees 'flush' or initiate height growth more than one time during a season (**Figure 5**). Trees with plenty of growing space located on good sites also tend to retain their branches longer and can produce more knots per whorl than those in denser stands or on poor sites. Depending on the species, more vigorous trees produce and retain more internodal branches (branches that grow between branch whorls). Taken together, these factors tend to cause the largest, fastest-growing trees to have more and larger knots.

The quality of knots also changes along the length of the stem. Live knots typically have the lowest impact on structural wood products and are even seen as desirable for some appearance products. Knots resulting from dead branches are generally more of a wood quality problem than those derived from live branches. When branches die, the vascular cambium loses its connection to the branch. This creates 'tight' or 'sound' knots which act like plugged holes in solidwood products. Dead branches begin to rot, and further below the live crown (down the stem) they become black or unsound knots. Unsound knots often fall out of products during the manufacturing process and leave holes. Unsound knots and holes are much less desirable than sound knots for most wood products. Finally, the branch is shed and eventually clear wood is produced but the process can take many decades in naturally grown stands.

A major challenge to forest managers is to design silvicultural prescriptions that maximize growth without producing trees with numerous large branches. One way to do this is to limit growing space early in the rotation then thin stands once there is sufficient height growth to allow crowns to recede above the top of the first log, typically about 10.5 to 12 m. The problem with this strategy is that it results in smaller trees but technological change is making this less important than it once was. Another option is to prune trees to shorten crown length, but this is an expensive process that is only appropriate in special cases where 'clear,' or knot-free, wood is desired. The high costs and uncertain markets for clear wood make foresters hesitant to prune unless they are confident that they can sell pruned logs for a much higher price than unpruned logs.

Branch initiation and branch growth are well enough understood that there are fairly reliable simulation models available for many of the important commercial conifer species. These models connect to individual tree growth and yield models used by forest managers to estimate the growth of stands under different conditions and evaluate whether branch size will exceed predetermined specifications related to wood product requirements. Financial analysis tools are available to help foresters evaluate the influence of branch size and pruning on the potential financial return from stands. These types of models help forest managers think about whether it makes sense to manage for small groups of end products or even specific products.

Designer Trees

If trees could be grown with particular sets of characteristics then they might be tailored for

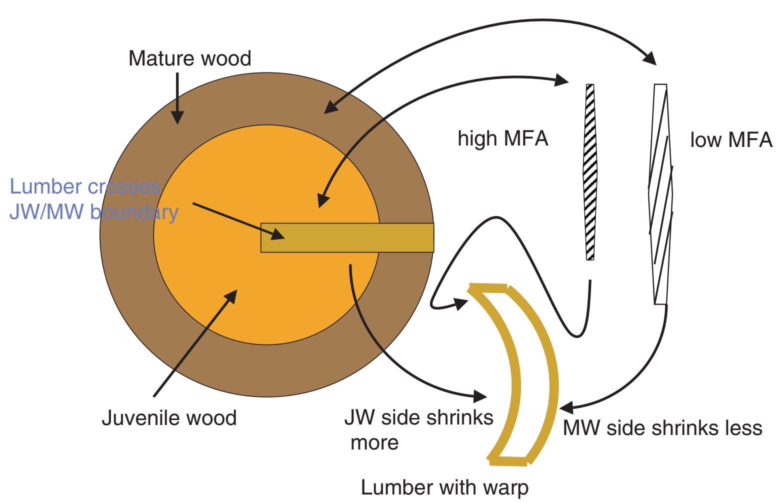

Figure 5 Effect of juvenile wood on warp. Higher longitudinal shrinkage of juvenile wood (JW) caused by high microfibril angles of cellulose fibrils can result in warp in lumber that contains both juvenile wood and mature wood (MW). MFA, Myofibril angle.

specific end products. Until recently, the length of time it took to grow a crop of trees always made this goal somewhat unrealistic and open to criticism. The uncertainty associated with predicting future demand for particular wood properties many decades in the future often seems too high. On the other hand, there have been a few situations where the economic value of large crops of trees was adversely affected by failure to consider the potential quality of the final crop. Two prominent examples are the extensive plantings of chir pine (*Pinus roxburghii*) established in South Africa early in the twentieth century for harvest in the 1930s and 1940s and the 'old-crop' radiata pine (*Pinus radiata*) that was planted during the 1930s and 1940s in New Zealand. The seed source of chir pine used in South Africa tended to produce severe spiral grain, which made the trees virtually unusable for anything other than pulp. This material was even unsuitable for roundwood applications such as posts and poles because they tended to twist as they dried and then to move with cyclic changes in moisture content. This movement loosened or broke power lines, fence wires, and fence boards attached to the posts and poles. The old-crop radiata pine was planted with 'wild' unimproved seed at relatively narrow spacings and left untended. Under such conditions radiata pine produces particularly poor stem form and variable branches. This made lumber sawn from these trees unsuitable for many uses. The size and frequency of the branches also made this wood less desirable for pulp chips. Given these experiences, foresters began to pay more attention to producing trees with good form and fewer, smaller, branches but it was still impractical to commit to specific plans for the use of trees scheduled for harvest three or four decades in the future. Today it is becoming more common for foresters in regions where trees can be grown in less than about 25 or 30 years to think seriously about the specific use or at least the product stream expected for a crop of trees.

There is also considerable interest in screening seed sources, genetic improvement, and clonal forestry to increase growth rates and improve wood quality. Combined with simulation models for planning silvicultural systems, these techniques reduce the likelihood of undesirable characteristics such as large or frequent branches or low wood density and increase the feasibility of growing trees quickly enough to fill specific market niches. For example, some of the hardwood species grown for pulp in tropical regions mature in as little as 5–10 years and rotations of conifers in temperate regions of 25 years or less are now common.

Economics and Wood Quality

Wood utilization is often more a question of what is economically feasible than what is technically possible so a discussion about wood quality is not particularly meaningful unless economics is considered. Every wood product requires some minimum set of wood characteristics in order to perform satisfactorily. There is also a maximum price above which consumers will look for a substitute material, will find another way to fill the need, or go without the product altogether. The interaction between performance and price is not particularly easy to quantify but it unquestionably influences whether individual trees or stands of trees are harvested for wood products. The idea of 'cull' trees and logs has been a part of forestry practices for many decades. Cull trees and logs do not have sufficient value to justify their harvest or processing. Often they contain too much defect (juvenile wood, rot, stain, spiral, grain, etc.) or they may be crooked or have too many or too large knots, or in some cases they are simply the wrong species. Size is often an important factor. In almost all wood-producing regions, precommercial thinning, or cutting small trees and leaving them in the forest, is a practice commonly used to accelerate growth of the trees remaining in the stand so they will reach merchantable size quickly enough to make forestry profitable. In remote areas, larger trees and logs are often treated as cull regardless of their quality. In some parts of the USA minimum merchantable log size is 23–25 cm on the small end, even though sawmilling and veneer peeling technology makes it feasible to use logs as small as 9 cm on the small end and most energy, chemical, fiber, and particle process can use even smaller logs. Even so, there are simply no markets for logs smaller than 23 cm in these places.

Topography and location frequently tip the balance between performance and price. Trees on flat ground are generally more easily harvested and therefore more profitable than those growing on steep slopes. In the past, when new areas were opened up for logging, the valley bottoms were almost always harvested first. Even today, there are vast tracts of old-growth timber with excellent wood characteristics that have not been harvested largely for economic reasons. The Russian Far East and much of Alaska are two examples where costs and accessibility kept these forests from being harvested over the past half-century. Social concerns about preservation of old-growth forests are now more important than costs in preventing harvest in Alaska, even though these forests contain some of the best-quality softwood timber remaining in the world today.

As the timber industry moves away from harvesting unmanaged stands to more intensive management systems of either naturally regenerated or planted stands, the interaction between price and performance will continue to determine whether individual trees or stands are harvested and the way they are grown. Managed stands that grow too slowly or are in places difficult to reach, far from transportation routes, or even in places where there are insufficient commercial forests, are less likely to be profitable. In some countries, agricultural land (which may originally have been forest) is being converted to plantations in preference to cheaper land located on steeper ground, because of the lower costs of land preparation, higher growth rates, and lower harvesting costs.

Most of the advances in manufacturing technology that eliminated the need for large trees were brought about by a desire to find ways to continue to use wood for structural products without having to grow trees for so long. The increased manufacturing costs required for these products is more than offset by the lower costs of holding investments in stands of trees for one-third to one-half as long as under unmanaged conditions. In fact, it is quite likely that without peeling (plywood and LVL), gluelam, engineered fasteners, and composites technology it would not be possible for wood to compete with alternative materials.

Biological Deterioration of Wood

T L Highley, Henderson, NV, USA

Introduction

Wood does not degrade as a result of aging alone. Under proper conditions, wood will give centuries of service. The service life of forest products depends on their being protected from a variety of degrading agents. Given the appropriate conditions, degradation encountered will fall into one of three categories: (1) biological; (2) physical; or (3) chemical. This article concerns only biological degradation of wood, which is the most damaging of the causal agents.

Biological degradation of wood is caused primarily by fungi, bacteria, insects, and marine borers. Wood degradation by these organisms has been studied extensively, and many preventive measures are available. By taking ordinary precautions with the finished products, the user can contribute substantially to ensuring a long service life.

Fungus Damage

Fungus damage to wood is caused by decay, molds, and fungus stains. Fungi are microscopic, thread-like microorganisms that obtain their nutrients from wood or other organic materials. The growing stage of fungi consists of microscopic threads called hyphae which in mass form cottony or feltlike growths (mycelium). Hyphae penetrate and ramify within wood, causing decay or other damage. The growth of fungi depends on suitably mild temperatures, moisture, and oxygen.

Decay

Decay is the most serious kind of fungal damage because it causes structural failure, sometimes very rapidly. Because widespread damage to wood from decay is seldom spectacular, the tremendous economic and resource loss resulting from decay is often overlooked.

Conditions for decay Most decay can progress at temperatures that favor plant life in general. Decay is usually relatively slow at temperatures below 10°C and above 35°C. Decay essentially stops when the temperature drops as low as 2°C or rises as high as 38°C.

Serious decay occurs only when the moisture content of wood is above the fiber saturation point (average 30%). The fiber saturation point in previously dried wood will be reached only when contacted by water, such as provided by rain, condensation, or contact with wet ground. By itself, the water vapor in humid air will not wet wood sufficiently to support significant decay, but it will permit development of some mold fungi. Fully air-dried wood will usually have a moisture content less than 20% and should provide a reasonable margin of safety against fungus damage. Thus, wood will not decay if it is kept dry, and decay already present from prior infection will not progress.

Wood can be too wet for decay as well as too dry. If wood is water-soaked, the supply of air to the interior may not be adequate to support development of typical decay fungi. This is why fungal decay will not occur in foundation piles buried beneath the water table and in logs stored in a pond or under a suitable system of water sprays.

Decay usually results in abnormal coloration of the wood. Abnormal mottling of the wood color, with either unnatural brown or bleached areas, is often evidence of decay infection. As wood approaches advanced stages of decay, it loses luster and may exhibit pronounced changes in color depending on the organism and the substance it removes. Advanced decay is also easy to recognize from changes in the physical appearance of the wood, such as localized depressions or sunken areas over decay pockets, and cracking in cubical patterns.

Classification of decay The most important and potent wood-destroying fungi are white- and brown-rot fungi, which utilize various components of the wood cell wall. Most white-rot fungi utilize cellulose and hemicelluloses at approximately the same rate relative to the original amounts present, whereas lignin is usually utilized at a somewhat faster relative rate. A few white-rot fungi remove lignin and hemicelluloses preferentially, but ultimately they degrade all wood cell wall components. White-rot fungi cause the wood to lose color, eventually reducing it to a fibrous, whitish mass. It does not crack across the grain, and, until severely degraded, it retains its outward dimensions, does not shrink or collapse, and often feels spongy. Brown-rot fungi utilize cell wall hemicelluloses and cellulose, leaving the lignin essentially undigested. However, brown-rot fungi do modify lignin, as indicated by demethylation and accumulation of oxidized polymeric lignin degradation products. These fungi cause the wood to darken, shrink, and break into pieces that crumble easily into a brown powder. Brown-rot fungi commonly colonize softwoods, and white-rot fungi commonly occur on hardwoods, but both brown- and white-rot fungi occasionally colonize both types of wood.

Brown, crumbly rot, in the dry condition, is sometimes called dry rot, but the term is incorrect because wood must be damp to decay, although it may become dry later. A few fungi, however, have water-conducting strands; such fungi are capable of carrying water (usually from the soil) into buildings or lumber piles, where they moisten and rot wood that would otherwise be dry. They are sometimes referred to technically as dry-rot fungi or water-conducting fungi. The latter term describes the true situation better because these fungi, like the others, must have water.

A third and generally less important kind of decay is known as soft rot. Soft rot is caused by fungi related to the molds rather than those responsible for brown and white rot. Soft rot typically is relatively shallow; the affected wood is greatly degraded and often soft when wet, but immediately beneath the zone of rot, the wood may be firm. Because soft rot is usually rather shallow, it is most likely to damage relatively thin pieces of wood such as slats in cooling towers.

Soft rot similar to other types of microbial wood decay occurs in certain ecological niches where the fungi can be active mainly due to lack of competition from other microorganisms. This is why soft rot is favored by wet situations where the more aggressive white- and brown-rot fungi are less competitive. However, it is also prevalent on surfaces that have been alternately wet and dry over a substantial period. Heavily fissured surfaces, familiar to many as weathered wood, have generally been quite degraded by soft-rot fungi.

Mold and Fungus Stains

Molds and fungus stains are confined to a great extent to sapwood and are of various colors. The principal fungus stains are usually referred to as sapstain or blue stain. The distinction between molding and staining is made primarily on the basis of the depth of discoloration. With some molds and the lesser fungus stains, there is no clear-cut differentiation. Typical sapstain or blue stain penetrates into the sapwood and cannot be removed by surfacing. Also, the discoloration as seen on a cross-section of the wood often appears as pie-shaped wedges oriented radially, corresponding to the direction of the wood rays. The discoloration may completely cover the sapwood or may occur as specks, spots, streaks, or patches of various intensities of color. The so-called blue stains, which vary from bluish to bluish-black and gray to brown, are the most common, although various shades of yellow, orange, purple, and red are sometimes encountered. The exact color of the stain depends on the infecting organisms and the species and moisture condition of the wood.

Mold discolorations usually become noticeable as fuzzy or powdery surface growths, with colors ranging from light shades to black. Among the brighter colors, green and yellowish hues are common. On softwoods, although the fungi may penetrate deeply, the discoloring surface growth can often easily be brushed or surfaced off. However, on large-porous hardwoods (for example, oaks), the wood beneath the surface growth is commonly stained too deeply to be surfaced off. The staining tends to occur in spots of varying concentrations and size, depending on the kind and pattern of the superficial growth.

Under favorable moisture and temperature conditions staining and molding fungi may become established and develop rapidly in the sapwood of logs shortly after they are cut. In addition, lumber and such products as veneer, furniture stock, and millwork may become infected at any stage of manufacture or use if they become sufficiently moist. Fresh cut or unseasoned stock that is piled during warm humid weather may be noticeably discolored within 5 or 6 days.

Mold growth in the indoor environment is not new, but in recent years the issue of toxic molds has generated national media attention. However, the scientific and medical literature contains differing opinion regarding the potential health impacts of exposure to mold. There are few case reports that molds producing mycotoxins inside homes can cause unique health conditions such as pulmonary hemorrhage or memory loss. Certain individuals with allergies may be more sensitive to molds. Individuals with immune suppression or underlying lung disease are at increased risk for infection from molds.

Ordinarily, stain and mold fungi affect the strength of the wood only slightly; their greatest effect is usually confined to strength properties that determine shock resistance or toughness. They increase the absorbency of wood, and this can cause over-absorption of glue, paint, or wood preservative during subsequent processing. Increased porosity also makes wood more wettable, which can lead to colonization by typical wood-decay fungi.

Bacteria

Most wood that has been wet for a considerable length of time will probably contain bacteria. The sour smell of logs that have been held under water for several months, or of lumber cut from them, manifests bacterial action. It has been known for a long time that bacteria cause selective degradation of nonlignified wood cells (for example, parenchyma cells of wood rays and resin ducts) and pit membranes. The major effect of this type of bacterial attack on wood is an increase in the wood's capacity to absorb liquid. This can result in excessive pick-up of moisture, adhesive, paint, or preservative treatment in use. This effect has been a problem in the sapwood of millwork cut from pine logs that have been stored in ponds. There is also evidence that bacteria developing in pine veneer bolts held under water or sprayed with water may cause noticeable changes in the physical character of the veneer, including some strength loss.

In the last 25 years or so evidence has been obtained that bacteria can degrade lignified cell walls. Currently only two major forms of wood-degrading bacteria have been recognized – tunnelling and erosion bacterial decay. These two forms are recognized from the micromorphological decay patterns they cause during degradation of wood cells and do not represent any form of taxonomic classification. Wood-degrading bacteria apparently cannot compete with fungal decay and thus will degrade wood where fungal decay is suppressed. For example, bacterial degradation will occur under conditions of oxygen limitation for fungi that usually exist in piling supporting piers, buried shipwrecks, or lumber exposed to very wet conditions such as air-conditioner water slats or mine props. Furthermore, wood made more resistant to fungal attack by high loading of wood preservatives or extractive content provides a niche in which fungi are suppressed, allowing for successful bacterial decay. The ability of researchers to identify bacterial decay patterns better has generated greater interest in bacterial degradation wood in recent years, and it is being more frequently reported in the literature.

Insect Damage

Of the insects that damage wood, termites and beetles cause the most serious damage. Carpenter ants and bees cause occasional damage to wood but do not use it as food; they hollow it out for nesting. Termites are the most destructive insects that attack wood.

Termites superficially resemble ants in size, general appearance, and habit of living in colonies. From the standpoint of their methods of attack on wood, termites can be grouped into two main classes: (1) ground-inhabiting or subterranean termites; and (2) wood-inhabiting or nonsubterranean termites.

Subterranean Termites

Subterranean termites are responsible for most of the damage to wood structures in the USA. This damage can be prevented. Subterranean termites are more prevalent in the southern than in the northern states, where low temperatures do not favor their development. The hazard of infestation is greatest first, beneath buildings without basements that were erected on a concrete slab foundation or were built over a crawl space that is poorly drained and ventilated, and second, in any substructure wood component close to the ground or an earth fill (for example, an earth-filled porch).

The subterranean termites develop their colonies and maintain their headquarters in the ground. They build their tunnels through earth and around obstructions to reach the wood they need for food. They must also have a constant source of moisture, whether from the wood on which they are feeding or the soil where they nest. The worker members of the colony cause destruction of wood. At certain seasons of the year, usually spring, male and female winged forms swarm from the colony, fly a short time, lose their wings, mate and, if successful in locating a suitable home, start new colonies. The appearance of 'flying ants' or their shed wings is an indication that a termite colony may be near and causing serious damage. Not all 'flying ants' are termites; therefore, suspicious insects should be identified before investing in eradication.

Subterranean termites normally do not establish themselves in buildings by being carried there in lumber; they primarily enter from ground nests after the building has been constructed. An introduced species, the Formosan termite, is adept at initiating aboveground infestations and nests in structures where wood remains wet for a prolonged period, such as from roof leaks. Telltale signs of subterranean termite presence are the earthen tubes or runways built by these insects over the surfaces of the foundation or other exposed areas to reach the wood above. Another sign is the swarming of winged adults early in the spring or fall. In the wood itself, the termites make galleries that generally follow the grain, leaving a shell of sound wood to conceal their activities. Because the galleries seldom show on the wood surfaces, probing with a pick or knife is advisable if the presence of termites is suspected.

The best protection for wood in areas where subterranean termites are prevalent is to prevent the termites from gaining hidden access to a building. The foundations should be of concrete, pressure-treated wood, or other material through which the termite cannot penetrate. With brick, stone, or concrete block, cement mortar should be used because termites can work through some other kinds of mortar. Also, it is a good precaution to cap the foundation with 100 mm of reinforced concrete. Posts supporting floor girders should, if they bear directly on the ground, be of concrete. If there is a basement, it should be floored with concrete. Untreated posts in such a basement should rest on concrete piers extending several centimeters above the basement floor. However, pressure-treated posts can rest directly on the basement floor. With the crawl space type of foundation, wood floor joists should be kept at least 460 mm and girders 300 mm from the earth and good ventilation should be provided beneath the floor. A rule of thumb is to have a minimum of 1 unit area of ventilation for every 150 units of crawl space.

Moisture condensation on the floor joists and subflooring, which may cause conditions favorable to decay and contribute to infestation by termites, can be avoided by covering the soil below with a moisture barrier, maintaining adequate ventilation, and assuming proper drainage of rainwater away from all sides of a structure. All concrete forms, stakes, stumps, and wastewood should be removed from the building site because they are possible sources of infestation. Generally, the precautions effective against subterranean termites are also helpful against decay.

The principal method of protecting buildings in high termite areas is to treat the soil adjacent to the foundation walls and piers beneath the building thoroughly with a soil insecticide. When concrete slab floors are laid directly on the ground, all soil under the slab should be treated with an approved insecticide before the concrete is poured. Furthermore, insulation containing cellulose that is used as a filter in expansion joints should be impregnated with an approved chemical toxic to termites. Sealing the top 13 mm of the expansion joint with roofing-grade coal-tar pitch also provides effective protection from ground-nesting termites. New modifications in soil treatment and an insecticidal bait control method appear promising. Current references should be consulted to take advantage of the new developments in termite control.

To control termites already in a building, contact between the termite colony in the soil and the woodwork must be broken. This can be done by blocking the runways from soil to wood, treating the soil, repairing leaks that keep wood within the structure wet (for example, plumbing leaks), or some combination of these techniques. Possible reinfestations can be guarded against by frequent inspections for signs of termites.

Nonsubterranean Termites

In the USA, nonsubterranean termites have only been found in a narrow strip of territory extending from central California around the southern edge of the continental USA to Virginia and in the West Indies and Hawaii. Their principal damage is confined to an area in southern California, to parts of southern Florida, notably Key West, and to the islands of Hawaii. They are a localized problem in Arizona and New Mexico.

The nonsubterranean termites, especially the dry-wood type, do not multiply as rapidly as the subterranean termites and have somewhat different colony life and habits. The total amount of destruction they cause in the USA is much less than that caused by the subterranean termites. The ability of dry-wood termites to live in dry wood without outside moisture or contact with the ground, however, makes them a definite menace in the regions where they occur. Their depredations are not rapid, but they can thoroughly riddle timbers with their tunnellings if allowed to work undisturbed for many years. Nonsubterranean termites are moved from structure to structure in infested items such as furniture.

Marine Borer Damage

Damage by marine-boring organisms to wood structures in salt or brackish waters is practically a worldwide problem. Evidence of attack is sometimes found in rivers even above the region of brackishness. The rapidity of attack depends upon local conditions and the kinds of borers present. Along the Pacific, Gulf, and South Atlantic coasts of the USA, attack is rapid, and untreated pilings may be completely destroyed in a year or less. Along the coast of the New England states, the rate of attack is slower because of cold water temperatures but is still sufficiently rapid to require protection of wood where long life is desired. The principal marine borers from the standpoint of wood damage in the USA are described here.

Mollusks

Wood-degrading mollusks include species of the shipworms *Teredo* and *Bankia* and of the pholad *Martesia* and *Xylophaga*. Shipworms are the most destructive of the marine borers. They are mollusks of various species that superficially are worm-like in form. In the early stages of their life, they are minute, free-swimming organisms. Upon finding suitable lodgement on wood, they quickly develop into a new form and bury themselves in the wood. A pair of boring shells on the head grows rapidly in size as the boring progresses, while the tail part or siphon remains at the original entrance. Thus, the animal grows in length and diameter within the wood but remains a prisoner in its burrow, which it lines with a shell-like deposit. It lives on the wood borings and the organic matter extracted from the sea water that is continuously being pumped through its system. The entrance holes never grow large, and the interior of wood may be completely honeycombed and ruined while the surface shows only slight perforations. When present in great numbers, shipworms grow only a few centimeters before the wood is so completely occupied that growth is stopped. However, when not crowded, they can grow to lengths of 0.3–1.2 m depending on the species.

Another group of wood-boring mollusks is the pholads, which clearly resemble clams and therefore are not included with the shipworms. They are entirely encased in their double shells. The *Martesia* are the best-known species, but another well-known group is the *Xylophaga*. Like the shipworms, the *Martesia* enter the wood when they are very small, leaving a small entrance hole, and grow larger as they burrow into the wood. They generally do not exceed 64 mm and 25 mm in diameter but are capable of doing considerable damage. Their activities in the USA appear to be confined to the Gulf coast, San Diego, and Hawaii.

Crustaceans

Another distinct group of marine borers are crustaceans, which are related to lobsters and shrimp. The principal borers in this group are species of *Limnoria* and *Sphaeroma*. Their attack differs from that of the shipworms and the *Martesa* in that the bore hole is quite shallow; the result is that the wood is gradually thinned from the surface inward through erosion by the combined action of the borers and water erosion. Also, the *Limnoria* and *Sphaeroma* do not become imprisoned in the wood but may move freely from place to place.

Limnoria are small, 3–4 mm long, and bore small burrows in the surface of wood. Although they can change their location, they usually continue to bore in one place. When great numbers of *Limnoria* are present, their burrows are separated by very thin walls of wood that are easily eroded by the motion of the water or damaged by objects floating upon it. This erosion causes the *Limnoria* to burrow continually deeper; otherwise, the burrows would probably not become greater than 51 mm long or 13 mm deep. Because erosion is greatest between tide levels, piles heavily attacked by *Limnoria* characteristically wear within this zone to an hourglass shape. In heavily infested harbors, untreated piling can be destroyed by *Limnoria* within a year.

Sphaeroma are somewhat larger, sometimes reaching a length of 13 mm and a width of 6 mm. *Sphaeroma* are widely distributed but are not as plentiful as *Limnoria* and cause much less damage. Nevertheless, piles in some structures have been ruined by them. Occasionally, they have been found working in fresh water. In types of damage, *Sphaeroma* action resembles that of *Limnoria*. It has been reported that *Sphaeroma* attack salt-treated wood in Florida.

The average life of well-creosoted structures is many times the average life obtained from untreated structures. However, even thorough creosote treatment will not always stop *Martesia*, *Sphaeroma*, and especially *Limnoria*; shallow or erratic creosote penetration affords only slight protection. The spots with poor protection are attacked first, and from there the borers spread inward and destroy the untreated interior of the pile.

When wood is to be used in salt water, avoidance of cutting or injuring the surface after treatment is ever more important than when wood is to be used on land. Not cutting or injury of any kind for any purpose would be permitted in the underwater part of the pile. Where piles are cut to grade above the waterline, the exposed surfaces should be protected from decay. This may be accomplished by in-place application of a wood preservative followed by a suitable capping compound.

WOOD USE AND TRADE

Contents

History and Overview of Wood Use

R L Youngs, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Introduction

Wood is a natural product of the growth of trees. It is primarily composed of hollow, elongated, spindle-shaped cells that are arranged more or less parallel to each other in the direction of the tree trunk. This makes wood basically fibrous in nature. The characteristics of these fibrous cells and their arrangement in the tree strongly affect wood's physical and mechanical properties, as well as its grain patterns and workability. In its thousands of years of use, these properties have become familiar, but not well understood. They are becoming understood as a result of research during the past century.

Humans throughout history have used wood. The *International Book of Wood* records that "Man has no older or deeper debt than that owed to trees and their wood." The Bible notes that Noah built the ark from gopher wood, the first Ark of the Covenant was made from acacia wood, and the cedars of Lebanon formed Solomon's temple. Today wood is still a primary building material and fills many specialized needs in industrial and consumer use as well as in scientific and military applications.

Historical Overview

Wood has been one of humankind's most important raw materials for at least a hundred thousand years, for building and manufacture of tools, weapons, furniture, and other commodities of daily life. Wood was used early in human existence because it was available, had many useful properties, and no elaborate tools were needed to work it. However, in the early days the characteristics of the wood, rather than the tools available, were primarily responsible for the quality of products made from it. By 5000 BC copper tools began to be available and made possible improved craftsmanship, which is evident in some surviving relics of the time. By about 2600 BC wood was being used for coffers and chests for storage of precious possessions. The first coopering to make barrels was evident in records from about 2800 BC. Wood use and wood craftsmanship continued to develop over the years. Where wood was readily available, it was used widely for materials of industry, war, transportation, construction, and daily life.

Through the eighteenth century in Europe, wood was the principal material for construction of buildings and for tools, machines, vehicles, buckets, furniture, and barrels, plus many other articles of defense, transportation, and daily life. Wood was a basic material of the Industrial Revolution. The first printing press was made with wooden type in Germany in about 1450, although the Chinese are reported to have used woodblock printing about 700 years earlier than that. From its initiation in Germany, the printing press spread rapidly through Europe and continued to use wooden type for a hundred years. Most of the machines and inventions essential to establishing the machine age were developed in wood. Wood played a dominant role in industrial operations. About the sixteenth century in Europe, ready availability of wood began to diminish due to heavy demand for both fuel and materials and expansion of agriculture to feed the increasing population, which removed much of the land base for growing wood. In North America, wood use reached a plateau during the middle to late nineteenth century. Seemingly inexhaustible forests and other material resources were exploited to feed rapidly growing economic needs. Railroads, telegraph lines, steel mills, and other industries consumed wood at a rapidly increasing rate.

Wood in Construction

Wood has been, and still is, a particularly versatile and useful building material in its many forms and adaptations. Until the relatively recent development of metallic and plastic structural materials, it was the only material from which complete structural frameworks could be built. Wood structures built at various times and places have reflected the kind and quality of timber available and the culture and way of life of the people concerned. In earliest times, pole structures were built from small trees growing along the rivers. The techniques used by these early humans have been carried down over the ages and are very similar to those used by nomadic peoples today. However, the ability to erect permanent structures has been basic to most significant developments in the use of wood building materials. In zones that were well forested with plentiful timber, structures were built using solid walls of tree trunks or heavy planks. In other areas, wood has been used in more refined ways using careful design and engineering.

Europe

In Neolithic Europe walls of timber houses were frequently made of split trunks set vertically in or on the ground or on a bottom sill plate. Examples excavated from moor settlements in Germany demonstrated this type of construction. The mortise-and-tenon type of construction using heavy beams began early in history and continued through the Iron Age up to Norman times. A Viking fortress built in Denmark in about AD 1000 had this kind of construction, as did stave churches built during that century. Later construction used similar principles but employed vertical squared lumbers or sawed planks. Early French settlers along the Mississippi River brought this palisade type of house construction to North America. Construction in wood during the eleventh to the fourteenth centuries in Europe took advantage of Gothic construction, a concept in which the roof timbers formed an integral part of the frame and the principal framing members were typically large and heavy. This type of construction persisted until the seventeenth century in Europe but variations of it were used in America even into the nineteenth century.

North America

Wood construction has had an interesting evolution in North America because of the relatively abundant timber resource and the scattered development of much of the country. Native Indians in the forested areas of eastern and northwestern America built homes and community houses from indigenous woods. In the eastern United States these structures were commonly made of poles covered with bark and palisades of vertical logs were used for protection. The Indians along the northern Pacific Coast built houses from planks of split cedar or redwood and even had gabled roofs and decorative carving. In some of the sparsely forested areas of the Great Plains and western mountains, Indians built frames of timber and covered them with earth to make strong, permanent dwellings. The architectural designs used by early American colonists were based very much on those of their homelands adapted to the climatic and cultural differences of the colonies. The log cabin, which had been used for almost 3000 years in Europe, was introduced into North America by Scandinavian immigrants in the seventeenth century and was adopted in the eighteenth century by Scottish–Irish immigrants. In the far northwest, explorers and settlers from Russia moved south from Alaska and built houses, forts, and churches of log cabin type construction.

New England immigrants from England during the seventeenth and eighteenth centuries built their dwellings by following the pattern of the English timber-frame house with wattle daub or brick between the framing members. The classical ‘salt box’ type of house evolved from adaptations of that pattern to provide more protection against the severe weather. Exteriors of brick or stone were more likely to be used on houses in the middle Atlantic and southern states, but they had elaborately decorated interiors. The fact that in the colonial days timber was readily available for building led to the preference for detached or free-standing homes, as compared with the typical row house in much of Europe and other parts of the world.

Public buildings of North America followed similar trends in the eighteenth century. Churches were made, simply or ornately, of wood using many of these types of construction. Many of the public buildings in eastern America were made of both wood and brick in ways that took advantage of the good features of both materials. Wood is still the principal construction material for housing in North America and in Scandinavia and other parts of the world where timber supplies are plentiful and the tradition of wood construction remains strong. Until well into the nineteenth century, this was true also of building construction other than housing. Problems of fire and the need for high-rise buildings to conserve land space have contributed to the demise of wood frame construction in the centers of large cities.

A concept gaining increased attention is reuse of construction wood as buildings are removed or reconstructed. Under some social and economic conditions, this may provide an additional source of wood materials. Research is providing information on properties of such wood. That is being carried forward into grading systems that provide information on the suitability of reuse of deconstruction wood under specified conditions.

Wood for Weapons and Tools

Wood was a key material for building the weapons, equipment, and tools needed for military, industrial, and domestic use from ancient well through medieval times. Military devices, such as the battering ram, the scaling ladder, and the catapult were made of wood and much attention was given to their effective design. The reason for this widespread use of wood was its high strength to weight ratio, which made it valuable for many structural applications just as it is now. One of the oldest weapons recovered is the pointed end of a spear made of yew from the Lower Paleolithic era found waterlogged in an English bog. New techniques for working wood led to much more efficient use of wood in a variety of materials for tools and military supplies as well as for daily living. In the Neolithic era, about 2000 BC, improved tools were developed and have been found in the records of those times. The lathe was used from the Mediterranean area to northern Europe by about 1500 BC. By about 700 BC the plow made of wood was in common use. Early efforts to make weapons and tools from wood began the concept of selecting particular woods for specific uses depending on their properties and performance characteristics. Early selection was based on experience but observation of performance led to more effective use of wood for both weapons and tools of many kinds.

Wood for Transport

Wood has played an important role in the transportation of people and products for thousands of years. This has been both as a material for constructing vehicles and as a fuel for driving them.

Land Vehicles

In northern Europe as far back as 7000 BC sledges made of wood were used for transport. These were for heavy loads such as stones; archeologists believe that the massive stones of Stonehenge must have been moved on wood sledges placed on rollers. From the roller developed the concept of wheels. Pictures of wheels date from 3500 BC and wheeled vehicles have been found in tombs dating from 3000 to 2000 BC. The spoked wheel is a development of medieval times and in classical Greece both the spoked wooden wheel and a three-part solid wooden wheel were in common use. Solid wheels of plank were used on farm carts, and wheels with 10 to 14 spokes have been found in Roman forts of northern England of that period. Inserting rods of wood into grooves and placing them so that they would turn between the hub and the axle made the first roller bearings.

Railroads and Roads

Railroads well into the nineteenth century, the early twentieth century, and to some extent even today use wood for tracks, sleepers, bridges, trestles, tunnel linings, sheds, and stations. Through the nineteenth century wood was also heavily used for fuel. Nineteenth-century public transport in cities was mostly of wood vehicles including horse cars, electric trolleys, cable cars, carriages, and buggies. During the period from about 1820 to 1860 in America, roads made of planks laid across parallel rows of timbers imbedded in the earth were widely used. When they were in good condition, these were the best roads in the country and more than 3000 km of such roads were built in the middle years of the century. However, they were excessively expensive to maintain and they gradually disappeared from use.

Bridges

Before effective wood preservation systems were developed, wood bridges were built with advanced design concepts, and covered bridges were common in North America and parts of Europe. Walls and roofs were designed to protect the wood framework of the bridge from deterioration. Covered bridges were gradually replaced as new techniques of wood preservation provided more economical means of protection and as iron, steel, and concrete became more common materials for bridge construction. A resurgence of timber use in bridge construction occurred in late twentieth century and continues as the technology of bridge design and protection is developed and as the economy and environmental soundness of such structures is recognized.

Water Transport

One of the first uses for wood for water transport was probably a raft or hollowed-out log. The Egyptians had made boats of reeds by about 4000 BC and the earliest wooden ships copied the form of these reed boats. As cedar was imported from Lebanon, larger ships were built in Egypt. The barge built for Queen Hatshepsut in 1500 BC to transport granite obelisks from Aswan to Thebes had a displacement of some 6800 tons and needed 30 oar-powered tugs to tow it. Theophrastus, a pupil of Aristotle, was one of the earliest students of wood and published information on wood structure and properties. He also was involved with shipbuilding woods in ancient Greece. He noted that they were silver fir, fir, and cedar – silver fir for light strong construction and fir for decay resistance and cedar in Syria and Phoenicia because of lack of fir.

The Phoenicians had large galleys with two banks of oars, called biremes. With these they dominated trade in the Mediterranean for a thousand years before the time of Christ. The Vikings had wooden ships that were at least 25 m long. Design of wooden ships evolved over the years up to the nineteenth century, by which time paddlewheel steamboats were cruising the major rivers of the United States and consuming large quantities of wood fuel in the process. American clipper ships built of wood were the fastest seagoing ships of the late nineteenth century. The sleek shape and large expanse of sail enabled them to reach speeds of over 30 km per hour. However, by the 1880s iron steamships dominated the fleets of most naval powers and the economics of the use of wooden ships became unfavorable.

Shipping Containers and Pallets

Wood has provided containers for the world's goods for hundreds of years, its economy, availability and natural strength facilitating its use for chests, boxes, and crates. The engineering design of boxes and crates was greatly accelerated by wartime needs to ship material securely. This was particularly accelerated during the two world wars of the twentieth century, in which long-distance shipping of material became essential. During World War II design of wooden containers was further advanced, but research led also to substantial improvement in the design and use of corrugated fiberboard containers. Such containers were made weather resistant and highly resistant to the rigors of shipping. The economy and convenience of such containers contributed strongly to the decline of wooden containers, a decline that still continues.

The middle of the twentieth century saw the emergence of wooden shipping pallets for transporting goods of all kinds. As the need arose for efficient bulk shipment of corrugated containers, and as forklifts became available, shippers turned to pallets as a means of consolidating containers to expedite such shipments. Many manufacturers who had been making wooden boxes turned to making pallets, and many new pallet companies emerged as the pallet industry began to grow in the latter half of the twentieth century. This growth began in the United States and by the end of the century had grown to the point where pallets were the primary use for much hardwood lumber, especially the lower grades. Pallet production in American has grown from 25 million units per year in the 1950s to over 500 million in the late 1990s. Production of new pallets is supplemented by their repair and reuse. It is estimated also that about 71% of these are made from recycled lumber or other recycled material. As the forklift truck became available around the world, use of wooden pallets has followed and international trade in pallet lumber and pallets expanded using both hardwoods and softwoods.

Aircraft

Use of wood in aircraft is a relatively modern concept, though wood has been used in aircraft construction since the beginning of aviation. This reached a peak during the early and mid twentieth century in World Wars I and II. Although many woods have been used, Sitka spruce has been favored because of its high strength to weight ratio and ready availability in large sizes as clear, straight-grained material. Aluminum alloys, steel, composites, and new materials have taken over the structural role in commercial and major military aircraft, but wood is still used extensively for light aircraft.

Wood for Furniture

Wooden furniture appears to have been developed first in Europe about 3000 BC. Its development related very closely to the development of tools for working the wood. Reeds and rushes had earlier been used for furniture and early wood furniture designs copied the style of that material. Well-refined woodworking was employed when copper tools became available. These made possible much more precise careful operation of material for furniture and much more refined furniture. Shortages of furniture wood, which was a commodity of some rarity in many parts of the world, led to the early improvements in economical wood use. Planks cut from the same log were laid side by side and carefully fitted together. Defects were cut out and replaced. Furniture and cabinet-making reached a high level of sophistication in several areas of Europe by the sixteenth century. New designs and styles were developed and executed by outstanding designers and furniture makers. New styles of furniture were developed in Italy, England, and France as the Renaissance led to the improvements available in the Middle Ages. The furniture and interior furnishings used in colonial America were first quite simple and usually homemade. However, the new world contained a rich array of woods suitable for and available for furniture and other similar uses. The highly skilled craftsmen who had served their apprenticeship came to America took advantages of the wood, and from their skills developed in Europe became designers and manufacturers of high-quality furniture in styles that were both excellent copies of the European styles and original designs conceived in America.

Wood Use Today

Wood production throughout the world has continued to increase over the years. In the latter half of the twentieth century, increasing from something over 2 billion m^3 to nearly 3.5 billion m^3 (**Figure 1**). There is a marked difference, however, in the nature of wood production in the developed world and that in the developing world (**Figures 2** and **3**). Forty-seven percent of the world's wood production is for industrial roundwood, the wood used for a wide variety of wood and paper products (**Figure 2**). Fifty-three percent is for wood fuel, primarily in the developing world (**Figure 3**).

Increasing amounts of the world's wood supply are from plantations, even though plantations occupy a very small proportion of the forest area. Forest plantations provide a critical substitute for wood supply from natural forests, for both industrial wood and fuelwood. Industrial wood plantations account for only about 3% of the world's forest area, but are estimated to supply about 35% of the world's roundwood. Furthermore, this proportion is increasing steadily, supplying increasing quantities of wood that poses new challenges by having different working characteristics and physical and mechanical properties than wood from the natural forest.

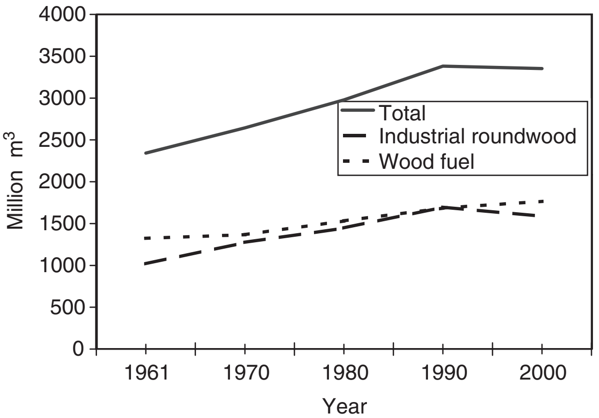

Figure 1 World wood production. Data from FAOSTAT Database 2002.

Research and its prudent application in the industry are also making possible conservation of the timber supply in the natural forest by effective and economical use of a wide range of timber previously considered unsuitable or uneconomic for use. Wood plastic composites are a new development in wood product production. They represent a new blending of the wood industry and the plastics industry. A wide variety of wood plastic composites are entering the market, especially for products like decking. This product may be encouraged by environmental pressure on, and increasing cost of, wood preservation.

Wood industries are continually adapting to changes in raw materials, particularly those due to the increased supply of plantation wood and to the introduction of additional species into the supply chain. These adaptations are leading to increased emphasis on engineered wood products and new composites, some of which are taking markets formerly served by plywood and lumber. Improved technology and the reduced availability of some traditional forest-based raw materials have encouraged innovative ways of expanding the wood supply and effective use of residues and waste.

Assumptions of continued economic growth and its effect on wood use indicate that consumption of industrial wood products will continue to increase in the future. Economic studies forecast continuing expansion of gross domestic product and increased demand for wood products at national, regional, and global levels. Increased demand for wood fuel is not related in the same way to economic growth, but may be expected by the rapid increase in population of regions of the world where it is most common.

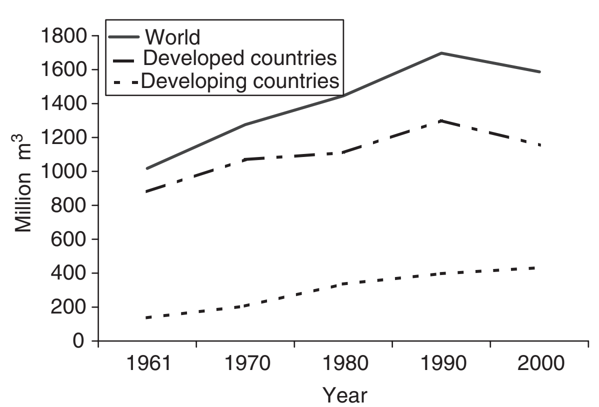

Figure 2 World industrial roundwood production. Data from FAOSTAT Database 2002.

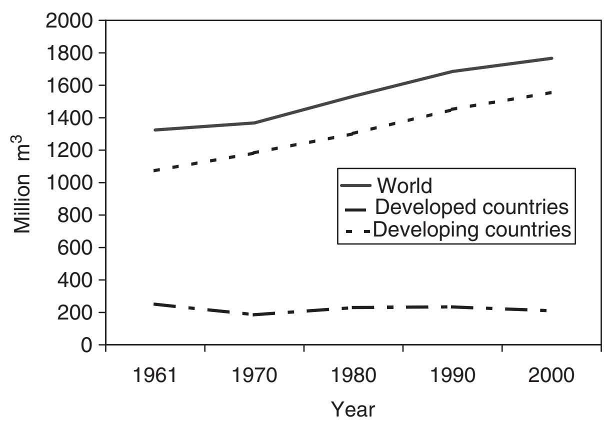

Figure 3 World wood fuel production. Data from FAOSTAT Database 2002.

Articles that follow in this section describe the current situation in wood use over a wide range of applications and employing much modern science and technology. New technologies have been developed to use the wood resource prudently to meet an increasing variety of consumer needs and provide dependable long-term service.

International Trade in Wood Products

R A Sedjo, Resources for the Future, Washington, DC, USA

Global Forest Resources

The *Forest Resources Assessment* (2000 Summary Report) of the Food and Agricultural Organization (FAO) of the United Nations indicates that the world's forests total 3.867 billion ha in 2000, or 29% of the world's land area. Of this, 47% are tropical forests, 9% subtropical, 11% temperate, and 33% boreal. Over the past half century the area of temperate and boreal forest has remained relatively stable, even modestly expanding in recent decades, while net deforestation occurred at a rate of 9 million ha annually during the 1990s, almost entirely in the tropical and subtropical forests.

Production and Consumption

The world requires approximately 1.5 billion m^3 of harvested wood annually to produce the manufactured wood and paper products it consumes. The developed countries account for over 70% of industrial roundwood (log) production and nearly 75% of the wood and paper production consumed. The global value of primary forest products (wood, pulp, and paper) in 1999 are estimated by the FAO at approximately US$750 billion, with about US$350 billion for pulp, paper, and paperboard products and $400 billion for solid wood products. Developed countries of the Organization for Economic Co-operation and Development (OECD) account for over 80% of this production. Tropical solid wood products, coming primarily from the developing world, are estimated at about US$28 billion. Total international trade in forest products was estimated at about US$135 billion in 1996 or roughly 18% of the total value of production.

The United States and Canada account for approximately 35% of global demand for wood and paper products and the European countries of the OECD account for about 25%. All developed countries account for about 75% of world consumption, while 25% is consumed by developing countries.

Table 1 presents the volume of timber harvest by major regions in a recent year while **Table 2** provides information on the value of exports, imports, and net forest product trade in a similar year. The high-harvest countries are almost all major forest-product exporters, although some, most notably the United States, are net importers due to very high demand levels. Thus, while we focus on the value of net forest products exports, this figure is also a good proxy for harvest levels.

Why Trade?

In general, forest products trade flows from countries with abundant forest resources to countries with more modest forest resources. However, raw forest resources are often transported to an intervening regional location for initial or subsequent processing.

Trade occurs because some raw materials or products are less expensive in one region than in another, even when considering transport costs. This may be because the raw material is cheaper or because the processing is less expensive. It may also reflect differences in regional demand due to population and income differences. If the costs are sufficiently higher in one region so that the wood and transport costs can be covered, well functioning wood markets would be expected to promote wood trade from low-cost to high-cost regions, if trade barriers do not offset the inherent cost advantages.

Table 1 World industrial roundwood production (volume), 1997

Country	*Volume (m^3)*	*Percent total*
USA	416 092	27.32

Trade occurs at various stages of the production process. Roundwood is usually the raw material in the production process. Processed wood, e.g., sawnwood, wood panels and pulp, is typically an intermediate input in production that is used in the production of other products such as furniture, construction, and paper products. The basis of trade is found in differences in the location of the raw material (roundwood) from the locations of processing and the locations of final product markets. Often, but not always, the first stage of processing is done near the location of the raw wood, while subsequent processing is commonly done in another location, often near the final market. However, there are major trade flows of raw logs, which may involve processing in locations far from the origins of the raw wood.

Wood-producing countries may trade raw logs, process the logs to wood products and paper, or both. This is seen in the flows of sawlogs from North America to Asia for processing to lumber for Asian markets and pulpwood imported from South America into the United States for processing to pulp and paper. Trade constitutes about 7% of world consumption of logs (roundwood), 30% of wood products, and 29% of paper products. Major forest products exporters include Canada, the United States, Russia, Finland, Sweden, New Zealand, Chile, Indonesia, Malaysia, and Brazil.

Table 2 Major global exporters and importers of forest products (value), 1996

Traded Products

Forest products trade runs the spectrum from raw wood materials, such as logs and wood chips, to highly processed products such as furniture and fine papers. Within the wood products sector some countries specialize in the production of the raw wood, others specialize in various facets of the processing, while still others produce both raw wood and processed value added. Thus, the value of wood products appears to be only a crude proxy of the amount of raw wood harvested, both domestic and imported. Nevertheless, since there are often advantages in processing located near the source of the raw material, most of the countries with large dollar values of production and exports also have large volumes of forest resources.

Sawnwood, wood milled in a sawmill and commonly referred to as lumber, is the most prevalent produce produced in the solidwood side of the forest industry and the most intensively traded globally. Sawnwood is typically used for structural purposes in construction, as well as in furniture, flooring, and woodwork. Wood panels, such as plywood, are the second most traded wood product. Plywood is manufactured from wood veneer sheets that are glued and pressed. The United States is the largest producer of conifer plywood while Indonesia is the world's largest producer of nonconifer plywood, using tropical hardwoods in its construction. Europe is a major producer and consumer of plywood, most of it being produced from hardwoods. In addition, panels, such as particleboard and oriented strandboard, made from wood fibers that are compacted and glued, are increasing in use for a variety of purposes.

Global and Regional Production and Trade Flows

As noted, international trade in forest products was estimated at about US$135 billion in 1996. Traditionally, most of the trade occurs in the northern hemisphere between industrial countries. About 75% of industrial wood comes from temperate forests. Tropical timbers are produced and consumed largely in the tropical world, with modest international exports to the temperate developed countries from Africa and South America. The Asia–Pacific region is the only really large regional exporter of tropical wood, with large volumes of wood exports flowing from Malaysia and Indonesia, largely to the Asian countries, including Japan and China, and also to the United States and Europe. Smaller tropical wood flows originate in South America and Africa.

Industrial wood is produced throughout the northern hemisphere. In the Soviet era Russia was a major producer of industrial wood, primarily for its own consumption. Today Russia continues to be an exporter of industrial wood to parts of Europe, e.g., pulpwood to Finland, and to Asia, e.g., logs to Japan. Also, wood flows from Russia to the former centrally planned economies of Europe have decreased as these countries have been using more of their domestic wood resources directly and also exporting some of their raw wood to other European countries.

North America continues to be the world's major producer and exporter of industrial wood, producing over one-third of the world's production. This overall situation has not changed substantially from that of the 1970s. The United States continues to be the world's major wood producer and also its number one consumer market for industrial wood and wood products. Within the United States wood is produced in the South, which is the dominant producing region, as well as the West, the Lake States and the Northeast. In general, North American markets draw upon regional wood resources with supplies provided from these various wood-producing regions within the United States supplemented by huge exports from Canada. Canada, with it vast wood resources and its relatively small population, is the world leader in wood products exports with the major portion of these filling the gap between production and consumption in the United States. While log exports from Canada are generally restricted, for many years over 30% of the United States consumption of softwood lumber has been imported from Canada, as well as large amounts of other wood products. The volumes of wood products imported from outside North America are relatively small, but have been growing in recent years.

Europe is a huge wood market. Most of the total wood consumed in Europe is produced within Europe, including the Nordic countries. The Nordic countries of Europe also have historically provided large volumes of wood products to continental countries. Sweden and Finland are large producers and exporters of forest products, with most of the exports going to other countries within Europe, in the form of pulp and paper and some wood products. In recent years the Nordic raw wood supply is being supplemented by imports of raw wood from Russia and Estonia. As elsewhere, in recent years the amount of processing in the Nordic countries has increased and more processed products, including large volumes of paper, are exported. In addition to imports from Nordic countries, there is a great deal of forest-products trading within the broad European setting, with France, Germany, Austria, and Poland being the primary wood-producing continental countries. Western and central Europe also import large volumes of wood products from eastern Europe and Russia and North and South America, with more modest volumes from Africa and Asia. Overall, however, Europe is a wood-deficit region with the wood deficits provided from a variety of suppliers throughout the world including, importantly, North America and Russia.

Asia is the most rapidly growing of the major global wood markets and Japan has been the dominant consuming country in Asia and indeed, Japan is the world's largest net importer of forest products and has the world's largest wood deficit (**Table 2**). Japan draws the vast majority of its wood resources and products from a host of producing countries in the Pacific Basin. In the post-World War II period the Pacific Basin has been a vast arena of wood products trade with Japan as the hub of a huge trade inflow. Traditionally, Japan has imported large volumes of logs, which were subsequently processed to meet Japanese unique sizes and standards. Log flows into Japan have come from many sources, both tropical and temperate and include log exports from Malaysia, Indonesia, Russia, and the United States. In recent years the log flows have declined and have been replaced by wood product imports. For example, logs from Indonesia have declined, being replaced by processed wood like plywood and lumber, and log flows from North American have also declined in recent years, having been replaced by North American lumber and by increased logs flows from New Zealand and Australia.

In recent decades other Asian countries have been or are becoming major wood importers, including Korea and Taiwan. China particularly has become an important importer for forest products, with its imports largely being unprocessed wood. Other countries in Asia, such as India, consume substantial volumes of wood products. However, South Asian wood consumption is mostly produced domestically.

Finally, Africa and Asia tend to supply largely tropical wood, while South America supplies growing volumes of wood pulp, primarily to Europe but increasingly to other regions too, produced by plantations, and also some tropical woods.

Traditionally, most of the raw wood used by the world global forest industry has been obtained by harvesting natural forests. Thus, the wood is obtained through an essentially foraging operation with the location of the forest resource determined by natural processes. Forest raw material trade thus began in the natural forest and made its way to the final market with various processing activities along the way. In this situation the productive advantage goes to forests with large volumes of healthy desired species. In recent years, however, the source of raw wood production has been undergoing substantial changes. Wood fiber from natural forests is being replaced by wood fiber from planted forests. In some cases these forests simply replaced earlier natural forests on the same sites, as in much of Europe. Increasingly, however, planted forests are being established on sites not recently in forest, as in planted forests established on lands on which agriculture has been abandoned, e.g., in the South of the United States. However, in other areas forest plantations are being established on lands that may never have been forested, as in grasslands of parts of Latin America or regions of Australia not previously forested.

Sources of Changing Trade Patterns

The advent of planted forests has resulted in important new supplies of industrial wood that are reflected in new patterns of wood products trading. Countries such as New Zealand, Chile, and Australia have, in recent decades, become important exporters of wood products, particularly to the growing markets of Asia. Brazil, too, has become an important producer of forest products and the nature of its product mix has changed. In the case of Brazil, its tropical hardwood exports, drawn from its vast Amazonian forests, are now dwarfed by the export of wood pulp, which uses plantation forests as its raw material.

Another factor influencing the pattern of forest products trade is growing environmental concerns. The establishment of protected forests, free from commercial timber harvests, together with the institution of new forest practices requirements, is influencing harvest levels and harvesting costs and thereby influencing wood trade flows. The dramatic reduction in timber harvests from US National Forests undoubtedly has resulted in increased lumber imports from Canada as well as increased production from the US South. Higher costs of harvesting in the coastal forest of British Columbia, due to a more stringent forest practices code enacted in the 1990s, likely is an important contributor to reduced wood trade flows from coastal British Columbia to Japan.

Trade Barriers

Trade barriers are often inserted to reduce or preclude trade. Trade barriers can consist of prohibitions of exports or imports of certain products, e.g., log export prohibitions; import taxes (tariffs), which place a tax on the imported product; export taxes, which place a tax on the product when it is exported; and quantitative restrictions, which place limits on the amount of a product that can be imported (or exported). Trade barriers have the effect of reducing the volume of imports (or exports) and thus influencing supply or prices within a country.

Quantitative restrictions in trade are common with forest products. **Table 3** provides an estimate of wood products' import tariff averages in selected countries. Note that this average does not include consideration of trade prohibitions and quotas. Trade barriers are usually introduced to achieve certain policy or political objectives and typically are designed to protect a product, industry, or other group. A restriction of lumber imports, for example, increases the price of lumber in the importing country thereby benefiting domestic producers of lumber (both firms and perhaps lumber workers). The common rationale for an export restriction, as on logs, is that the raw material be processed within the country where the log is found, thereby generating increased employment and value added. An export restriction, for example logs, has the effect of making log prices lower in the exporting country and encouraging domestic wood processing. Canada has used this rationale for decades to support a policy decision to insure that logs would be available for domestic processors at low prices. The United States restricted the export of logs from national forests in the West to insure an adequate log supply to western mills. Some countries place restrictions on processed imports for a similar reason. Japan placed an import tariff on certain types of processed wood in order to protect the domestic processing industry.

Table 3 Average of forest products tariffs in selected countries

Country	*Tariff % (Most Favored Nation average)*
Australia	2.88
Canada	3.88
Chile	11
China	20.86
Taiwan	3.22
Hong Kong and China	0
Indonesia	9.7

Mexico	11.32
New Zealand	6.06
Singapore	0
Thailand	20.04
USA	1.4
European Union	5.26

Source: FAOSTAT website (1998).

In general, forest product tariffs tend to be low. An analysis carried out in 1999 estimated that the effects of the Uruguay Round of the General Agreement on Tariffs and Trade (GATT) reduced tariffs of 33% on most forest products and increased total forest products world trade by US$460–593 million. This is an increase of only a very small fraction of global trade in forest products. Modest levels of change in trade suggest only modest levels of change in production. In the specific markets analyzed in this study, which included products with relatively modest amounts of processing valued added (logs, sawnwood, veneer, particleboard, fiberboard, plywood, wood pulp, and newsprint), trade increases constituted an increase of 1.6–2.0%. The largest trade increase was 5% for plywood, a product where tariffs have tended to be relatively high, in the 10–15% range. The lowest trade effect was a 1% export increase for wood pulp, a product which in most countries has little or no tariff. This study also found that the trade effects of tariff reductions would generally increase the exports of developed countries while reducing exports of developing countries.

Trade Liberalization

Trade liberalization has generally been regarded as a socially desirable activity in that production efficiency is increased thereby lowering costs and providing benefits to consumers. The last several decades have seen a series of trade negotiations to rationalize the global trading system with the general objective of liberalizing trade, e.g., reducing tariffs and other restrictions. An extension and further reduction of the scheduled tariff reductions associated with the Uruguay Round was proposed to the World Trade Organization (WTO), the international organization charged with overseeing the international trade process. The 1999 proposal would have accelerated scheduled tariff reductions on both solid wood products and on pulp and paper. Concerns have been raised, however, that trade liberalization could have an adverse influence on the environment.

In forestry, for example, the conflict between freer trade and concerns regarding the implications of freer trade on forest sustainability were raised in response to the proposal to accelerate the Uruguay Round agreement to decrease tariffs on forest products. This proposal, which was raised at the G7 meeting of finance ministers in Seattle in late 1999, was met with street protests that derailed the effort. The concerns raised suggested that tariff reduction would increase timber harvests thereby accelerating pressures on forests to increase the rates of harvesting. This was viewed as undermining forest sustainability and promoting deforestation. One can view this concern as a variant of the 'race to the bottom,' often cited by environmentalists, whereby countries with lax environmental standards have a cost advantage in production and trade. Here, freer trade is viewed as imparting an additional competitive advantage to countries with lax logging standards thereby leading to excessive rates of logging and the associated forest damage and destruction.

Another 1999 study estimated the trade effects on global harvests and deforestation and found them to be very modest. It was estimated that the effects generate an increase in harvest of 6–10 million $m^3 year^{-1}$ or about a 0.4–0.7% increase in the global industrial wood harvest. Further, it was suggested that the effects would be confined largely to the northern hemisphere countries which are likely to be able to facilitate additional harvests with minimal effects on the forest environment. This is due to the modest nature of the impact, new laws on forest practices, new forest set-asides, and movement toward improved practices designed to achieve multifaceted sustainable forestry. Nevertheless, the negotiations held by WTO countries in Seattle in 1999 did not result in an acceleration of wood products tariff reductions.

Trade and Forest Environmental Issues

The years since the 1992 United Nations Conference on the Environment and Development (UNCED) Earth Summit in Rio have seen significant changes in our perceptions of forest issues. Although Rio was not primarily about forests, a number of important international forest initiatives, many involving trade, emerged from Rio. In the dialogue leading up to UNCED in 1992, concerns had been expressed about forest sustainability, the loss of biodiversity, and the overall rate of deforestation, especially in the tropics.

A total of 178 governments were represented at UNCED, and a contentious debate revolved around forest issues. UNCED ultimately produced four documents related in whole or in part to forests:

- *Agenda 21*, a global environmental action plan
- a framework convention on global climate change
- a convention on biological diversity
- a *Statement of Principles on Forests*.

The *Statement of Principles on Forests* reflects a global consensus on a set of nonbinding principles of management, conservation, and sustainable development of all types of forests. One of the major outcomes of the Earth Summit was the industrial world's nonbinding agreement that sustainable forestry should be practiced by all countries, both tropical and temperate. The discussion and documents coming out of the Earth Summit also broached some specific management issues, such as the issue of forest certification and ecolabeling. For example, *Agenda 21* encourages

> expansion of environmental labeling and other environmentally related product information programs designed to assist consumers to make informed choices.

In response to international and domestic concerns, many major wood-producing countries have made changes to their domestic laws and policies concerning forests. These include changes to improve water quality, protect biological diversity, and implement less intensive silvicultural treatments. Some of these policies are regulatory in nature while others rely on taxation or other incentives. In many temperate forested countries significant revisions have been made in the legal and institutional framework dealing with forest matters.

Additionally, perhaps the most impressive changes have been the activities leading to the certification of forest practices and the movement to use certified wood in ecolabeled products. Over the past decade a number of forest certifying organizations have emerged. There are currently a number of alternative approaches to auditing and certification of forestry management under consideration and there are a host of different organizations that can act to set standards, oversee monitoring, undertake auditing and award certification of forest management. These approaches were led by the World Wildlife Fund (WWF) Forest Stewardship Council (FSC), which has initiated an aggressive forest certification campaign over the past decade.

In addition to the FSC, there have been a number of other similar efforts. In some countries and regions the forest industry has taken the initiative to create organizations similar to but strongly competitive with the FSC, sometimes in cooperation with governments. These include country and regional organizations such as the Sustainable Forestry Initiative (SFI) of the American Forest and Paper Association, a forest industry associated in the United States; the Canadian Standards Association in Canada, and, more recently, the Pan European Forest Council (PEFC) in much of Europe. Additionally, there are local and regional certification systems such as the Nordic Forest Certification System and the Finnish Forest Certification System (FFCS).

Changes in domestic forest practices regulation and the introduction of the certification to forest management are designed to address concerns of poor logging practices and excessive harvest rates, while promoting forest sustainability. However, changes in domestic forest policies and movement toward certification can have differential impacts on the underlying production cost structure of various countries thereby influencing the comparative production and trading capacities and costs. Thus, trading patterns would be expected to respond to these changes and countries are seen to strive to modify rules and practices so as to advantage their forestry production sector in relation to its competitors.

Environmental Benefits of Wood as a Building Material

J L Bowyer, University of Minnesota, St Paul, MN, USA

Introduction

The management of forests to obtain wood for use in the production of houses and a host of manufactured products is often criticized based on environmental concerns. Such concerns have led some to conclude that periodic harvesting of forests and the use of wood should be minimized, or even halted altogether. However, careful consideration of global environmental concerns in the context of the realities of today's world leads to a much different conclusion: to protect the environment, forests and the wood they produce should be utilized to the maximum extent possible within sustainable limits.

It is essential that forests be managed in a manner that sustains a myriad of forest values over the long term. At the same time, it is vitally important that forests be managed in such a way as to minimize impacts on the global ecosystem, of which forests are one part. Thus, there are a number of things to consider when contemplating the proper role of forests. One of these is the fact that growing populations worldwide consume vast quantities of raw materials, including wood. Another is that wood is the only widely available industrial raw material that is renewable. Yet another, and very important consideration, is that the environmental impacts associated with the manufacture and use of wood products are less, and in many cases substantially less, than those associated with the manufacture and use of products made of non-wood materials.

Assessing Environmental Impacts of Industrial Activity

An effective means of assessing the relative environmental impacts of a product is to examine them over the life cycle of the product from raw materials extraction, through processing and conversion, and ultimate use. Examination of energy use is particularly revealing, since a number of serious environmental problems are related to consumption of energy including acid deposition, oil spills, air pollution (SO_2, NO_x), and increasing concentrations of atmospheric carbon dioxide.

Research involving systematic examination of the environmental impacts of a product over its life is commonly referred to as life cycle assessment or simply LCA. An LCA typically begins with a careful accounting of all the measurable raw material inputs (including energy), product and coproduct outputs, and emissions to air, water, and land; this part of an LCA is called a life cycle inventory, or LCI. The LCI can be set up to deal with raw material extraction and product manufacture only, or the boundaries of an inventory may be defined more broadly to include product use, maintenance, and disposal. A full LCA seeks to assign values to factors that are currently not precisely measurable, such as impacts of an industrial activity on the landscape, flora, fauna, air, or water. Most life cycle assessment studies to date have focused primarily on the life cycle inventory.

Environmental Impacts of Wood Products Manufacturing

Energy Consumed in Manufacturing

One of the first comprehensive life cycle assessments of wood products was completed in the United States in the mid-1970s. Commissioned by the National Academy of Sciences, the study examined the energy required to build wall systems for residential homes. Energy use associated with raw material gathering (harvesting or mining), transport, manufacturing, and building construction was considered. Wood-frame construction was found to require the use of only one-half to one-seventh the energy needed for construction using steel, aluminum, concrete block, or brick (**Table 1**).

Although technologies in all industries, as well as protocols governing the conduct of LCA/LCI studies, have changed significantly since the mid-1970s, a growing number of studies have confirmed the energy advantages of wood. Dramatic differences have been shown in the quantities of energy needed to manufacture primary materials used in construction or in the manufacture of secondary products. Researchers at the University of Tokyo in the early 1990s determined, for example, that the energy needed to manufacture 1 cubic meter of steel, aluminum, and concrete was 191 times, 791 times, and 3.5 times greater, respectively, than that needed to manufacture 1 cubic meter of kiln dried lumber (**Table 2**). Energy calculations were based on production of virgin materials in all cases. When comparisons were made on a mass basis, the manufacturing energy ratios in comparison to wood became 12.5, 155, and 0.7, again for steel, aluminum, and concrete. Although these figures suggest the very large impact that materials choice can have on energy consumption, such numbers are difficult to compare, since equal volumes or masses of materials are almost never used for a given application.

The most meaningful comparisons of materials are made when comparing products that have the same function. For instance, a comparison of energy requirements for producing wood and steel siding products for structures can be very informative as long as care is taken to ensure that the same boundaries are used in defining the scope of analysis. The same is true of analysis of entire buildings. Though more complicated than examination of single products, analysis of complete structures is often favored by LCA researchers since a large segment of industrial wood globally is used in building construction.

Substantial differences in the quantity of energy needed for building construction have been shown for a wide range of building types. For example, a 1992 Canadian assessment of alternative materials for use in constructing a large research laboratory building showed all-wood construction on a concrete foundation to require only 35% as much energy as steel construction on a concrete foundation (**Table 3**). A New Zealand study in the same year found wood-frame construction of residential buildings with wood-framed windows and wood fiberboard cladding to require only 42% as much energy as

Table 1 Relative quantity of energy (oil equivalent) needed to manufacture various wall systems using construction practices common to the United States

	GJ of energy needed to manufacture 100 m^2 of wall (#2 = 1.000)
1. Plywood siding, no sheathing, 2 × 4 wood frame	0.782
2. MDF siding, plywood sheathing, 2 × 4 wood frame	1.000
3. Concrete building block, no insulation	6.725
4. Aluminum siding, plywood, insulation board, 2 × 4 wood frame	1.949
5. MDF siding, plywood sheathing, steel studs	2.009
6. Brick veneer over sheathing	7.039

MDF, medium density fiberboard.

Table 2 Energy consumption and carbon dioxide emissions in the production of various materials

Material	*MJ kg^{-1}*	*MJ m^{-3}*	*Carbon emission during production (kg m^{-3})*	*CO_2 storage*	*Net CO_2 emissions*
Lumber (air dry, SG 0.55)	1.5	750	15 (16)[a]	250	– 235 (– 234)[b]
Lumber (kiln dry, SG 0.55)	2.8	1 390	28 (100)[a]	250	– 222 (– 150)[b]
Plywood (SG 0.55)	12	6 000	120 (156)[a]	248	– 128 (– 92)[b]
Particleboard (SG 0.65)	20	10 000	200 (224)[a]	260	– 60 (– 36)[b]
Steel	35	266 000	5 320	0	5 320
Aluminum	435	1 100 000	22 000	0	22 000
Concrete	2.0	4 800	120	0	120

[a] Values in parentheses indicate total carbon emissions during production assuming fossil fuels used to supply all manufacturing energy. Values outside of parentheses indicate typical carbon emissions from fossil fuels during manufacturing assuming that wood residues generated in manufacturing are used to produce process energy. Although burning of wood liberates carbon, the process is carbon neutral if it is assumed that trees are replanted following harvest.

[b] Negative values result from the fact that wood is 49% carbon by weight and that the quantity of carbon released in generating process energy is less than the carbon stored in the finished wood product. For explanation of values within and outside of parentheses see footnote above.

SG, specific gravity.

brick-clad, steel-framed dwellings built on a concrete slab and fitted with aluminum-framed windows. When office and industrial buildings were considered, those constructed of timber were found to require only 55% as much energy as steel construction and approximately 66–72% as much energy as concrete construction. Another late-1990s Canadian study involving analysis of a large three-story building yielded almost identical results (**Table 4**). A 2002 study in Western Europe found significant differences in energy required to build wood and brick houses, although the differences were lower than in the studies just mentioned. In this case, the total energy needed to produce a wood timber-frame house was 83% of that needed to produce a concrete and brick house of the same design; both houses were built on concrete foundations and both had concrete shingles. Removing these and other common elements from the comparison, and focusing only on the parts of the structures built with different materials showed much larger differences in energy requirements, again favoring wood construction. In another mid-1990s comparison of wood- and steel-frame construction for light-frame commercial structures in Canada, which examined a wide range of factors in addition to energy, low environmental impacts of wood construction relative to steel were again demonstrated (**Table 5**).

Most LCA studies to date have assumed the use of virgin materials (i.e., no recycled content). One mid-1990s study that did consider incorporation of recovered material examined the use of recycled steel in wall studs. In this case, the manufacturing energy differences between wood and steel were found to narrow, but wood retained a significant advantage. As part of the wood vs. steel wall comparison, load-bearing wood and steel-framed walls, in which the steel contained 50% recycled steel content, were examined. In this case the steel-framed wall was found to be

> some four times as energy intensive, and correspondingly…at least that much more environmentally damaging, despite its recycled steel content.

Several interesting studies have examined differences in energy required to manufacture various kinds of building components. A team of Swiss researchers compared window units made of wood, aluminum, and PVC and found the manufacture of the wood-framed window to require only 75% of the energy needed for production of aluminum windows and 95% of that needed for production of PVC windows. It was noted that the wood waste generated in the process is often burned to produce energy, increasing the magnitude of difference in total energy consumption while also replacing fossil fuels in the process. In a 1995 Swedish study of linoleum, vinyl, and wood flooring, very large differences in net manufacturing energy were found for the three material types, with wood favored by a wide margin.

Table 5 Comparative energy consumed in manufacturing wood vs. steel-framed interior wall

	Energy consumption (GJ)	
	Wood-framed wall	*Steel-framed wall*
Extraction	0.7	1.2
Manufacturing	2.1	9.7
Construction	0.6	0.6
Total	3.4	11.5

Source: Meil J (1994) Environmental measures as substitution criteria for wood and nonwood building products. In *Proceedings, The Globalization of Wood: Supply, Processes, Products, and Markets*, pp. 53–60. Madison, WI: Forest Products Society.

An early 1990s study lent some perspective to the significance of the differences in processing energy associated with different kinds of building materials. While commenting on a proposal to reduce markedly timber harvesting activity in the Pacific Northwest region of the United States, Peter Koch noted that one possible outcome could be substitution of nonrenewable structural materials such as steel, aluminum, concrete, and plastics to replace the wood not harvested. He calculated that the impact on energy consumption and carbon dioxide releases, were this to occur, could be as high as 6 billion gallons of oil and 62 million tonnes of carbon dioxide annually – equivalent to operating a fleet of about 11 million automobiles.

Carbon Storage and Emissions

Recent concern about the possibility of global warming has focused attention on liberation of carbon dioxide in materials production and use. Wood is at the center of the global warming debate because of the ability of forests to store or sequester carbon. Dry wood is 49% by weight carbon, meaning that 0.5 kg of carbon is contained within each 1 kg of dry wood. Moreover, for each kilogram of wood produced, 3.7 kg of carbon dioxide is removed from the atmosphere. Thus, substantial carbon storage accompanies the growth of trees.

Findings of recent studies consistently indicate that wood has a large advantage over other materials with respect to carbon emissions resulting from manufacture and use for at least three reasons:

1. Relatively little energy is required to manufacture wood products as compared to non-wood materials. As a result, the quantity of greenhouse gases liberated through combustion of fuels is significantly lower when manufacturing wood products.
2. Wood is 49% carbon by weight, and thus wood used in structural and other long-lived products stores or sequesters carbon over extended time periods.
3. The majority of energy (65–70%) used in producing wood products is obtained from burning of wood residues such as sawdust, bark, and paper-mill waste liquors. Thus, quantities of fossil fuels used in wood products manufacture are typically vastly lower than those used in the manufacture of

Table 6 Net carbon emissions in producing 1 tonne of different materials

Material	*Net carbon emissions (kg t^{-1})*
Framing lumber	−460
Concrete	45
Concrete block	49
Brick	148
Glass	630
Steel	1 090
Aluminum	2 400
Plastic	2 810

Christchurch, New Zealand: Department of Civil Engineering, University of Canterbury.)

non-wood products; this translates to avoided carbon emissions from fossil fuels.

Many LCA/LCI studies have shown substantial differences in carbon liberation when comparing wood products manufacture and use with non-wood products. For example, the New Zealand study that examined manufacturing processes, including raw material extraction and transportation, not only revealed large differences in net carbon dioxide emissions from material to material, but a carbon emission figure for lumber that is actually negative (**Table 6**). Others (see **Table 2**) have reported similar findings. The negative values for wood are due to its carbon content.

When carbon dioxide emissions associated with constructing wood and other kinds of structures are examined, large differences favoring wood again become evident. Data presented in **Tables 3** and **4** and **Figure 1** are typical of findings from recent studies. One study, a portion of which is highlighted in **Figure 1**, involved analyses of alternative designs of structures ranging from single family homes, to an industrial building, to a large office structure. Included among the findings of the authors is the observation that

> The choice of building material has a huge effect on the carbon emissions to the atmosphere. Timber used for framing, floor, and wall components of a house compare much more favorably than other common materials.

Recognizing that the potential for global warming is related to compounds in addition to carbon dioxide, such as methane, LCA researchers have very recently begun expressing total greenhouse gas emissions in terms of a global warming potential (GWP) value. A life cycle assessment of houses built in Minneapolis and Atlanta in the United States (**Tables 7** and **8**) showed the GWP of steel-framed and concrete block structures to be 49% and 65% greater, respectively, than otherwise identical wood-framed structures. In both comparisons houses had common foundations (concrete) and roof systems (wood). Much larger differences, again favoring wood, resulted when common elements were removed from the comparisons.

The study of windows referred to earlier showed the GWP of aluminum and PVC-framed windows to be 10–20% greater than those framed in wood. Similarly, the potential for acid rain, eutrophication, and photochemical ozone was found to be 114–136%, 45–55%, and 42–65% greater when manufacturing aluminum and PVC windows than when manufacturing wood windows.

It should be noted that although it is often assumed that trees grown to offset carbon dioxide emissions need then to be preserved in order to keep the carbon dioxide from returning to the atmosphere, recent research shows that carbon storage can be significantly enhanced by periodic harvest of trees and their use in long-lived products. Several researchers recently determined the carbon storage implications of short- and long-term wood products use, low energy consumption and carbon liberation associated with wood products manufacture, and avoided fossil fuel use, and concluded that carbon accumulation in forests is more rapid when a portion of the wood is harvested and used in long-lived products (**Figure 2**). They noted that the greater the manufacturing efficiency and useful product life, the stronger the case for wood becomes.

In short, concerns regarding global warming potential point to greater use of wood as a part of the solution.

Manufacturing Effluents

Life cycle analysis involving wood was elevated to a new level in a 1994 study that examined not only energy and related emissions associated with wood- and steel-framed construction, but manufacturing effluents as well (**Table 9**). Differences can only be described as spectacular, with emission levels for steel-framed construction ranging from 1.6 times to 41 times higher than for wood-framed construction. More recent studies support these findings.

Energy Efficiency of Wood vs. Non-Wood Structures

All of the studies of building construction cited herein were based on analysis of structures built according to local building codes and practices. Recent research in the United States showed that because of thermal bridging issues, the differences as shown in **Tables 1, 3–5**, and **7–9** become even greater when exterior walls are constructed so as to achieve equal thermal insulation or *R* values. Moreover, because of differences in thermal bridging performance of wood, steel, and concrete walls at corners and around doors and windows, even when basic insulation properties of wall sections are equal, both steel-framed and concrete walls require more heating energy over the life of a structure than do wood-framed walls. Thus, energy implications of materials selection in building construction extend well beyond the construction process.

Summary

There is no question that periodic harvesting of forests to obtain wood raw materials results in environmental impacts. What is sometimes forgotten, however, is that the gathering and processing of all raw materials impacts the environment. When the harvesting and processing of wood is examined in this context, the inescapable conclusion is that the global environment would benefit from the maximum use of wood possible within sustainable limits.

Y

YIELD TABLES *see* MENSURATION: Forest Measurements; Growth and Yield; Timber and Tree Measurements; Yield Tables, Forecasting, Modeling and Simulation.

GLOSSARY

2*n*: The diploid number of chromosomes found in dividing root tips, and other cells, undergoing mitosis.

3D computer models: Digital (mathematical) models representing three-dimensional forms, surfaces and spaces which can be viewed in perspective (see also Geometric modeling).

A horizon: Dark colored horizon in surface mineral soil high in organic matter.

Abiotic: Aspects of the environment that are nonliving.

Aboveground biomass: All living biomass above the soil, including stems, stumps, branches, bark, seeds, and foliage of trees.

Abundance surveys: Studies undertaken to determine the number of given species in an area.

Access: The ability to use land or another resource.

Accessibility: Refers to distance, need of transportation, safety, and tranquillity of route to a forest site (for recreation or harvesting).

Accuracy of measurement: Freedom from error or the closeness of a measurement or estimate to the true value. More broadly, it is the degree to which a statement or quantitative result approaches the truth. Note that

$$\text{Accuracy} = \sqrt{\text{Precision}^2 + \text{Bias}^2}$$

using these statistical definitions. Thus, if bias is eliminated, Accuracy = Precision.

Accuracy of visualization: The similarity in appearance between the simulated scene and the real scene as it would look in the circumstances being simulated. Accuracy can be expressed in terms of color matches between real and visualized scenes, difference in size and location of observed/represented objects, and presence or absence of key visible features.

Acervulus, acervular: A disc-like asexual fruiting structure characterized by a thin spore-bearing layer covered either by a thick layer of fungal tissue or host epidermis that peels back at maturity to allow spore release. Usually 2 mm or less in diameter and typically formed on foliage.

Acid rain: Rain contaminated with industrially derived pollutants such that pH has been reduced.

Acidic papermaking: Values of pH between 3.5 and 6 before paper is formed.

Actinomorphic: Radially symmetrical and capable of being divided in more than one plane into two equal parts that are mirror images of one another, e.g., the flowers of *Gustavia*.

Actinomycete: A group of minute organisms (order Actinomycetales), commonly considered to be filamentous bacteria.

Actinorrhiza: A symbiotic association between plant roots and strains of *Frankia* bacteria that form specialized root nodules within which nitrogen fixation occurs.

Acute pollution effects: Changes to forest health and structure that are the result of very high pollutant loads, often of relatively short duration.

Adaptability: The ability of populations to adapt to a selective force.

Adaptation: A general measure of the ability of an organism to change and cope with the physical and biotic elements of a particular environment enabling it to reach its potential for growth and reproduction. For seed orchards, adaptation refers to the degree to which seedlings derived from orchard seed will cope with the environment of the target plantation zone.

Adaptive genetic variation: Genetic variation that is related to the general fitness of the plant, particularly as it relates to growth and reproductive capabilities. These traits are typically affected by many genes, each of relatively small effect.

Adaptive trait: A trait under some degree of genetic control that affects fitness (survival and reproduction) in a given environment.

Adaptive variation: See Adaptive genetic variation.

Additive gene effects: Average effects of allele substitutions; in practice, effects whereby offspring tend to be intermediate between their parents.

Additive: Any material other than fibers and water that is added to paper.

Adhesion: The process of joining dissimilar materials with an adhesive to form a bond having structural integrity. Adhesion involves chemical and physical interactions between the adhesive and the joined substrates.

Adhesive: A substance capable of holding materials together by surface attachment. It is a general term and includes cement, glue, mucilage, and paste.

Adsorption: The process of forming intermolecular associations, or secondary bonds, as when a liquid contacts a solid surface. This is similar to wetting, but it also refers to the intermolecular forces between different materials as in the case of adhesion.

Advance reproduction: Seedlings and saplings existing under the canopy of mature trees.

Advanced regeneration: Immature individuals including seedlings, saplings, and pole-sized individuals of commercial species under a mature canopy.

Adventitious: Roots arising at the nodes of rhizomes and culms and not from the initial (primordial) root.

Aerobic organism: Any organism that requires oxygen gas for respiration.

Aesthetic quality: Aesthetics refers to the human response to landscapes which result from the perceptual characteristics of the environment and the observer's sensory experience. Aesthetic qualities are capable of inducing or influencing human emotions, mood, and levels of satisfaction with the environment, and can be pleasurable or otherwise.

Afforestation: The planting of trees on previously unforested land.

AFLPs: Amplified fragment length polymorphisms; codominant genetic markers for polymorphic base sequences similar to those involved in RFLPs, but studied using the polymerase chain reaction rather than radionuclides.

After-effects: The effect of parental environment on progeny performance.

Age: The age, t, of an individual tree is calculated from the time of germination, budding, or planting, or from the year in which the tree reached a certain reference height. Stand age, T, generally refers to some sample average and is relevant mainly for more-or-less even-aged forest types. The scale of resolution for age is often one year.

Agroforestry: The practice of combining agricultural crops or animal husbandry with the maintenance and cultivation of trees on the same patch of land.

Agrosilviculture: Agroforestry practice predominantly involving trees and crops; also known as silvoarable.

Agrosilvopastoral system: Land-use system in which woody perennials are used on the same land as agricultural crops and animals, in some form of spatial arrangement or temporal sequence. In fire management agrosilvopastoral systems are planned as fuelbreaks (particularly shaded fuelbreaks) to reduce fire risk by modifying understory vegetation and soil cover (cf. fuelbreak).

Air vesicles: Air sacs in the pollen grain of some species that improve its distribution by wind.

Alfisol: See Brown forest soil.

Alkaline papermaking: Values of pH above 7 before paper is formed.

Alkyd resin: Synthetic paints and varnish resins formed by the condensation of polyhydric alcohols with polybasic acids.

Allele: One of two or more possible variants of a gene at a locus (site on a specific chromosome).

Allele frequency: The frequency of an allele in a population. The combined frequency of all the alleles at a locus in a population equals 1.

Allochthonous: Material derived from external sources.

Allogamy: The mating system in which species are outcrossing, i.e., as a rule only pollen from another individual of the same species can fertilize the ovules and produce viable seed.

Allohexaploid: An allopolyploid with six sets of chromosomes.

Allopatric: Occurring in disjunct geographic areas.

Allopatry: The situation in which species are closely related members of the same genus but growing in geographically separate regions, e.g., Europe and North America.

Allopolyploidy: A polyploid where chromosome sets are derived from more than one species.

Allozyme: One of several forms of an enzyme coded by different alleles at a locus.

Alpine: The altitudinal belt between the subalpine belt (above the montane belt) and the nival belt, which in the tropics is generally situated between 3500 and 4500 m elevation.

Alternate hosts: Two different plant species that are the host for different stages of the life cycle of rust fungi.

Amchi: This is the Tibetan system of medicine which has a rich heritage and is mostly practised in the Himalayan region of Bhutan, China, India, and Nepal. In this system the practitioners use a variety of natural products like plants, animals and minerals for healing purposes.

Amenity: The quality of being pleasant or attractive, associated with value of the environment.

Amictic: Involving no mixing.

Anaerobic organism: Any organism that grows only in the absence of oxygen.

Anamorph, asexual states, conidia: Many ascomycetes and basidiomycetes can reproduce by production of asexual spores called conidia. Structures associated with the production of conidia are termed the asexual state or anamorph, and these states are usually given a separate Latin name, even if they are known to be connected to a certain sexual state (teleomorph). Thus the same fungus species can actually have several different names for the sexual state and different asexual states. Often the sexual state is absent or rare, and the organism is more commonly known by the name of its asexual state.

Androecium: The collective term for the staminate structures of the flower; the stamens as a unit.

Andromonoecy: Having male and hermaphrodite flowers on the same plant.

Anemophilous: Plant pollinated by wind.

Aneuploid: A cell or organism that does not have an exact multiple of the haploid number of chromosomes.

Angiosperms: Flowering plants, distinguished from the gymnosperms by producing seeds that are enclosed by material tissue as a fruit or nut.

Anoxic: A low-oxygen environment caused by long-term inundation by water.

ANPP: Aboveground net primary productivity: the amount of biomass added to the shoots of a plant in a year.

Anther gland: Glands associated with the anthers and commonly found in mimosoid legumes.

Anthesis: The period or stage of full expansion of the flower structures, or (in the case of conifers) strobili. Bud burst is the anthesis of the seed cone (female strobili), and pollen shedding is the anthesis of the pollen cone (male strobili).

Anthophilous: Living among, or feeding upon flowers, usually pollen and/or nectar.

Anthracnose: A foliage disease characterized by sunken, brown necrotic spots and patches. Usually caused by ascomycete pathogens having acervular asexual states, for example *Colletotrichum gloeosporioides*.

Anthropogenic: Landscapes and ecosystems created by human activity.

Antibiosis: Resistance to an insect herbivore in which compounds produced by the plant affect the biology of the insect adversely.

Antioxidant: A chemical compound that prevents or retards oxidation. It acts by scavenging free radicals generated in oxidation processes.

Antixenosis: The ability of a plant to repel an insect and thus reduce or prevent oviposition and/or feeding.

Anuran: Of or pertaining to frogs and toads.

***Aphelenchoides xylophilus*:** A nomenclatural synonym to *Bursaphelenchus xylophilus*.

Apical placentation: Form of placentation found in ovaries with only one ovule, where the placenta forms at the top of the ovary.

Apomictic: Term describing seed originating from any kind of asexual modifications of sexual reproduction. Apomictic seed is genetically identical to its seed parent.

Apomixis: Asexual reproduction by seed without benefit of fertilization or meiosis, deriving from somatic cells of the nucellus or integument.

Apophysis: The subterminal structure of the cone scale.

Apoplast: The cell walls collectively of a tissue or a complete plant.

Application rate: This can refer to any substance but in the case of wastewater, the amount of wastewater applied per unit time of an operational cycle; usually expressed as inches or millimetres per hour.

Arboriculture: The art, science, and technology of planting and care of individual trees and other woody vegetation.

Archegonial polyembryony: A feature of gymnosperms whereby several embryo genotypes can be produced from different pollen grains within the seed structure where only one embryo can normally survive.

Areolate: Divided into small, distinct spaces by intersecting lines.

Aril: An often fleshy and brightly colored appendage growing at or near the hilum, often forming a covering around the seed as in the Myristicaceae.

Arillate: Possessing an aril.

Aromatic rings: Hydrocarbons characterized by the presence of one of more ring structures and having strong odor.

Arsenicals: Class of waterborne preservatives which contain arsenic and other metallic biocides. The principal arsenical is CCA (copper-chrome arsenate).

Ascoma (pl. ascomata): The sexual fruiting structure of an ascomycete. This structure can be a disc or saucer shape, with the fertile layer bearing the asci and ascopores exposed (cup fungi, discomycetes), or with the asci and ascopores surrounded by a wall of sterile fungal tissue in a small flask-shaped structure (a perithecium). Ascomata are usually minute but sometimes aggregated and embedded in sterile tissue, called a stroma, which can be more than 1 cm in diameter, typically black and crust like.

Ascomycete: Fungi in the phylum Ascomycota. Characterized by sexual spores (ascospores) produced in a characteristic sac like cell called an ascus. Some ascomycetes can also reproduce asexually (see anamorph, asexual states, ascoma, conidia).

Ascomycotina: See Ascomycete.

Asexual (vegetative) multiplication (bulking): When seeds of desired families or populations are in short supply, embryos or seedlings are clonally reproduced by rooting cuttings, tissue culture, grafting, or somatic embryogenesis.

Assimilation: Incorporation of elements and compounds, building up substances vitally necessary for plant structure and function.

Asteraceous: Belonging to the daisy family (Asteraceae).

ATLAS: Aggregate Timber Land Assessment System.

Autochthonous: Term to describe a species that is native to the locality and naturally adapted to its circumstances. An autochthonous population, in the strict sense, is expected to arise from natural regeneration *in situ*, in contrast to cultivated *ex situ* material. (syn indigenous).

Autocorrelation: This is a term referring to the degree of relationship that exists between two or more spatial variables, such that when one changes, the other(s) also change. This change can either be in the same direction, which is a positive autocorrelation, or in the opposite direction, which is a negative autocorrelation. For example, soil type and vegetation may be highly correlated, either positively or negatively depending upon the type of soil and vegetation under examination.

Autogamy: The mating system in which plants are self-fertile and pollen grains of the same individual produce viable seed.

Autotrophic respiration: The term given to respiration by plant tissues.

Autotrophs: All photosynthesizing green organisms (green plants, trees, algae).

Ayurveda: The term Ayurveda has a Sanskrit root, ‘Ayu’ meaning life, and ‘Veda’ meaning pure knowledge. Ayurveda can thus be translated as the knowledge of the span of life, which deals elaborately with measures for healthful living including Ayurvedic medicine.

Backcrossing: Crossing a hybrid to one of its parental types.

Backfire: A fire spreading, or set to spread, into or against the wind: (1) As used in **fire suppression:** A fire set along the inner edge of a control line to consume the fuel in the path of a forest fire and/or change the direction force of the fire’s convection column (Note: doing this on a small scale and with closer control, in order to consume patches of unburned fuel and aid control-line construction (as in mopping-up) is distinguished as ‘burning out, firing out, clean burning’); (2) As used in **prescribed burning:** designation of fire movement in relation to wind.

Backhaul: Coordination of two (or more) transports in order to minimize empty travel.

Bamboo brakes: Distinct pure stands of bamboos.

Banyan-like habit: Form of large spreading tree with multiple stems grown from aerial roots.

Bark: The outer covering of the branches, roots and stems of woody plants. Measurement of bark thickness or bark volume may be needed to quantify bark for harvesting or to convert from over bark to under bark dimensions. Mensurationally, the bark comprises all tissues outside of the xylem, including the cambium. Bark thickness is generally defined as the difference in radius of two concentric circles, one defined by the bark surface, the other by the interior wood surface. Bark volume may be derived from thickness or measured directly.

Barriers: Features in the landscape which stop organisms dispersing such as water, treeline, or road.

Basal area: Basal area, g, is the stem cross sectional area at breast height. Stand basal area, G, i.e. total basal area per unit area of land, is a specific characteristic of stand density. Usually expressed in $m^2 ha^{-1}$ ($ft^2 ac^{-1}$ in the USA).

Basidiomycete: Fungi in the phylum Basidiomycota. Characterized by sexual spores (basidiospores) produced on a characteristic cell called a basidium. Some basidiomycetes can also reproduce asexually (see anamorph, asexual states, conidia).

Basidiomycotina: Fungi characterized by basidia formed in a fruit body from an external fertile layer called a hymenium. Hyphae sometimes with clamp connections at septations. See Basidiomycete.

Battering ram: A heavy timber used to batter down walls, gates, doors, etc.

Beam: A structural member supporting a load applied transversely to it.

Belowground biomass: All living biomass of live roots.

Beltian body: Protein-rich structure produced by *Acacia* species that have mutualistic associations with ants and used as a food source.

Bending stiffness: Essentially the force required to bend a given length of paper.

Benthos: Organisms associated with the bed of a water body.

Beta distribution: A probability distribution with density function $f(x) = (x)^{\alpha}(1-x)^{\beta}/B(\alpha, \beta)$ where α and β are parameters and B denotes beta function.

Beverages: Artificial drinks usually prepared from decoctions of plant parts.

Bias: A systematic error introduced into sampling, measurement or estimation by selecting or favoring, possibly unintentionally, one outcome or answer over others.

Bifurcate: To separate into two parts or branches; fork.

Biocide: The active ingredient(s) in a wood preservative system which will control one or more of the many different organisms which can degrade wood.

Bioclimatic zone: Vegetation characteristic of a particular set of climatic conditions.

Biodegradation: Destruction of organic contaminants through microbial activity.

Biodiversity: The variability among living organisms from all sources, including land-based and aquatic ecosystems. These include diversity within species, between species, and of ecosystems. Diversity is the key to ensuring the continuance of life on Earth. It is also a fundamental requirement for adaptation and survival and continued evolution of species.

Bioindicator: Species or species groups that can be sampled to provide accurate information about the health of an environment or ecosystem.

Biological diversity: (See Biodiversity)

Biological resources: This includes genetic resources, organisms, or parts thereof, populations, or any other biotic component of ecosystems with actual or potential use or value for humanity.

Biomass: (1) The amount of living matter in a given habitat, expressed either as the weight of organisms per unit area or as the volume of organisms per unit volume of habitat. (2) Organic matter that can be converted to fuel and is therefore regarded as a potential energy source. Note: Organisms include plant biomass (phytomass) and animal biomass (zoomass). (3) In fire science the term biomass is often used synonymously with the term 'fuel' and includes both living and dead phytomass (necromass); the zoomass is usually excluded.

Biome: A major regional or global biotic community, such as a grassland or desert, characterized chiefly by the dominant forms of plant life and the prevailing climate.

Biometrics: The application of statistical methods to the measurement of biological objects.

Biotemperature: A measure of the heat effective for plant growth. Mean annual biotemperature averages daily temperature for one year with all values less than 0°C as 0 and all values greater than 30°C as 30.

Bipinnate: Arrangement in which both the primary and secondary rachises of a leaf have leaflets set along them.

Bleachable pulp: Pulp which has the capability of being purified or whitened by chemical treatment to remove or change coloring matter so that it will achieve a higher brightness characteristic.

Bleed flow: The oncoming flow which filters through the shelterbelt.

Bluestain (sapstain): A blue, brown or black stain of the sapwood that is caused by deeply penetrating fungi that do not cause decay. The appearance of the wood may greatly reduce its value.

BLUP: Best linear unbiased prediction.

Board: Solid-sawn lumber less than 38 mm (2 in.) in nominal thickness.

Bond paper: Originally a cotton-content writing or printing paper designed for the printing of bonds and legal documents, and distinguished by superior strength, performance, and durability. The term is now also applied to paper for less demanding applications such as letterheads, business forms, and social correspondence papers.

Boreal: Northern.

Bound water: Water adsorbed onto the cell wall substance.

Box beam: A built-up beam with solid wood flanges and plywood or wood-based panel product webs.

Brash: Portions of trees (stems or branches) with diameter below the minimum set for utilization (ca. 70 mm).

Breast height: Breast height is the most widely used reference level for measurements of diameter and basal area. In countries that use the SI system breast height is generally located at 1.30 meter above ground level. Other points are 1.4 m and 4′6″.

Breed: A set of genotypes distinguished by having been selected for a common breeding goal.

Breeding: The science or art of changing the genetic constitution of a population of plants or animals through sexual reproduction. Used in a narrow sense it means crossing of parents through controlled pollination to create offspring. Used in a broad sense it means all the activities of a tree improvement program.

Brightness: The reflectivity of a sheet of pulp, paper, or paperboard for specified light (usually 457 nm) measured under standardized conditions on a particular instrument designed and calibrated specifically for the purpose.

Broadleaf (or broadleaved): Tree belonging to the botanical group Angiospermae. Synonym hardwood.

Brown forest soil: A neutral to moderately acid soil of temperate forest regions, with a mull humus, without free $CaCO_3$ at the surface and with no horizon in which sesquioxides accumulate.

Bucking: Cross-cutting a tree stem into logs of predetermined length.

Buffering: The process of resisting changes in the pH. Wood sometimes buffers an adhesive which requires a low or high pH for optimal curing; this may interfere with curing and bonding.

Bulb: Fleshy stem, formed by layers of tissue, which can be planted and which will produce flowers and seed.

Bundle of rights: The several rights that constitute a tenure; all the rights belonging to various persons or groups in a piece of property.

Bushmeat: Meat of wild animals hunted and gathered from African Savannahs.

C_3 photosynthesis: Mode of photosynthesis used in trees where CO_2 is fixed into 3-carbon sugars. Of the three types of photosynthesis (C_3, C_4, and CAM), C_3 is the least efficient at using carbon and conserving water.

C_4 photosynthesis: Mode of photosynthesis in which CO_2 is fixed into 4-carbon sugars.

Caatinga: A Portuguese term referring to a dry, thorn-scrub, deciduous vegetation of northeastern Brazil.

Calcining or calcination: Incineration of a mineral, driving off CO_2 or H_2O.

Calendering: The process of passing a web through a pressurized nip (or multiplicity of nips) for the purpose of leveling the normal profile variations in the web while compacting and smoothing the substrate in paper making.

Caliper (forestry): The forestry caliper is used to measure the diameter of stems, branches, stumps and roots. The most widely used calipers are for direct measurement. Calipers for indirect measurement rely on the geometry of instrument and stem or wood segment, often based on caliper arms forming tangents to the stem periphery. Based on sighting lines, similar principles are used for remote, optical measurement of diameter.

Caliper (paper use): The thickness of a sheet of paper measured under specified conditions.

CAM: Crassulacean acid metabolism. A form of photosynthesis in which CO_2 is taken up at night and fixed into malic acid which is then released to the Calvin cycle during the day when stomata are closed.

Canopy: The combined leafy crowns of (generally) the dominant plants.

Canopy architecture: The sizes, shapes, angles, distribution and development of tree crown elements, such as leaves, twigs and branches.

Canopy closure: Stage at which leaves on trees come to cover the entire site.

Canopy conductance: Average stomatal conductance for all leaves in the canopy.

Carbon allocation: The amount and distribution of organic carbon that is assimilated and translocated into different plant structures, such as foliage, reproductive structures, stems and roots.

Carbon pool: The reservoir containing carbon.

Carbon stock: The quantity of carbon in a pool.

Carrier: The solvent in which the biocide(s) and other inactive ingredients in a wood preservative are dissolved or suspended and which is used to 'carry' the preservative system into the wood.

Typical carriers are water (i.e., waterborne), light and heavy oils (oilborne), and oil-in-water emulsions.

Casehardening: A condition in which the wood is in tension on the inside and the surface is in compression.

Catapult: A military device for throwing stones, spears, etc.

Catena: Connected series.

Catkin: A unisexual inflorescence, consisting of rows of flowers ranged in circles along a slender stalk.

Cauliflorous: Flowers arising directly from the stem.

Cauliflory: Production of flowers on the main trunk or old woody branches.

Causation: If y and x are two events such that y would not have occurred without x, then x is the cause of y. If x, y, z are a finite series of events such that y depends causally on x, and z on y, then this is a causal chain. One event is the cause of another if – and only if – there exists a causal chain leading from the first to the second.

Cavitation: Development of air bubbles in xylem resulting in failure of xylem to transport water.

Cavity Zone: A region of recirculating very low velocity air behind a shelterbelt. Exists when the porosity is low and is absent when the porosity is above 40%.

Cellulose: A linear polysaccharide made up of glucose residues joined by β, 1,4 linkages.

CentiMorgan: A unit of length in a chromosome corresponding to a 1% marginal probability of recombination.

Centromere: The primary constriction, which divides a chromosome into two arms, often long and short. It contains the kinetochore, which attaches to the spindle during nuclear division.

Cerrado: A Portuguese term referring to a savanna-like vegetation best developed in central Brazil but also found in patches in the Brazilian Amazon.

CFS: CFS refers to coated wood-free papers.

CGTM: CINTRAFOR GTM.

Charcoal: Carbon-rich combustible solids that result from pyrolysis of wood in the early stages of combustion and that can be converted to combustible gases under certain conditions, or burned directly on grates.

Chemical woodpulp: Pulp obtained by using both chemical and heat energy to dissolve the lignin bond between fibers in wood. The primary chemical processes are the sulfate (kraft), sulfite, and soda.

Chemoautotroph: Any organism deriving energy from the oxidation of inorganic compounds and using CO_2 as the principal carbon source.

Chemoheterotroph: Any organism utilizing organic compounds as both energy and carbon sources.

Chemotaxonomy: The use of chemical characteristics as a basis for, or an aid to, classifying species or populations.

Chiasma: The point of crossing-over between homologous chromosomes.

Chlorosis: Breakdown of chlorophyll resulting in a white to yellow discoloration of the affected tissues.

Chromated copper arsenate (CCA): An arsenical preservative which also contains copper and chromium compounds and, until recently, was a major wood preservative.

Chromosomes: Stainable microscopic bodies in the nucleus that contain most of the genes. A chromosome is a linear arrangement with its genes linked together in consistent sequence. The size, morphology, and number of chromosomes (karyotype) is characteristic of each species. Extranuclear chromosomes (B chromosomes) also exist, but they are small, few in number, and of obscure function.

Chronic pollution effects: Changes to forest health and structure that are the result of many years of exposure to pollutant loads at relatively low intensities.

CINTRAFOR: Center for International Trade in Forest Products.

Circumpolar: Arctic; north.

CITES: Convention on International Trade in Endangered Species, an international treaty that controls trading and the import and export of endangered species of plants and animals. (International trade in Appendix II species is prohibited without an export permit, which can only be granted if supplies are obtained legally and without detriment to surviving populations.)

Cladoptosis: Vegetative regeneration arising from abscised twigs and branches that root and form new ramets under natural conditions.

Cleaning: In silviculture/management, a release treatment made in an age class not past the sapling stage to free favoured trees from less desirable individuals of the same age.

Clear felling: In silviculture/management, the removal of all the mature trees on an area at one time. Young regeneration trees have to be established without the protection of the older trees. Note that at very small scales (<0.25 ha), the distinction between clearfelling and continuous cover forestry can be difficult.

Cleistogamy: The extreme type of **autogamy**. Self-pollination takes place inside the flower bud.

Climate change: Changes in atmospheric gases "greenhouse gases" are thought to be causing global warming, more severe weather events, and droughts.

Climax/late successional stadium: Hypothetic final stadium of succession according to site conditions and competitive characteristics of the tree species that are able to settle there. Late successional stadia can be reached only on sites where several species have the chance to grow.

Climber: Plant that grows with the help of natural (e.g., tree) or mechanical support (e.g., string).

Cline: The phenomenon of a population mean shows a smooth geographic trend for one or more traits, typically tracking an environmental gradient.

Clonal forestry: Operational deployment of a few (5–50) proven superior clones for reforestation.

Clone: A group of plants derived from a single individual (ortet) by asexual reproduction such as rooting, grafting or tissue culture. All members (ramets) of a clone have the same genotype and consequently tend to be uniform.

Cloud stripping: Direct forest canopy interception of cloud water, i.e., the stripping of wind-blown fog.

Clumping bamboo: Sympodial bamboo. The culms are clustered together into a grove.

Cluster sampling: Monitoring of a plant species through a systematic group of subplots in a fixed pattern within a large defined area.

cM: centiMorgan, unit of genetic distance between two markers that do not segregate independently.

CMP: Chemical mechanical pulping.

Coagulant: Multivalent positive ion or a highly cationic polymer of moderate mass.

Coating formulation: In paper making, the aqueous mix of one or more pigments combined with one or more binders with a number of other components in much smaller percentages.

Codominant (crown class): See crown class.

Co-firing wood: Utilization of wood energy feedstocks as a supplementary energy source with another fuel such as coal or natural gas in combustors.

Cognition: The mental process of knowing, including aspects such as awareness, perception, reasoning, and judgment.

Cohort: A group of trees that establish following a disturbance. Analogous to age class.

Collaboration: Involvement of representatives of the public in an active process to develop solutions and influence decisions, working together with others which may include government staff, industry representatives, and technical experts.

Collaborative forest management: A forest management strategy in which professional forestry organizations and local community organizations cooperate in the planning and implementation of multifunctional management systems aimed at fulfilling the amalgamated forest related needs of all partners.

Colporate: A compound aperture in the pollen comprising a groove and one or more holes.

Combined heat and power (CHP): The simultaneous production of heat and mechanical work or electricity from a single fuel.

Combustion: Consumption of fuels by oxidation, evolving heat and generally flame (neither necessarily sensible) and/or incandescence. Combustion can be divided into four phases: preignition (or preheating), flaming, smouldering, and glowing.

Comminution: The process of breaking into smaller pieces.

Common property: A commons from which a community/designated group of users can exclude nonmembers and over which the community/designated group of users controls use.

Common property management: Use of a resource by a group of users, with powers to define membership of the group, to exclude those who are not members, and to set rules governing use of the resource.

Common-pool resource: Resource available to more than one person and subject to degradation as a result of overuse.

Commons: Land or another natural resource used simultaneously or serially by the members of a community.

Community: Naturally occurring group of different organisms inhabiting a common environment and interacting with each other.

Community forestry: The art, science, and technology of planning and managing forests and tree resources for the benefit of and together with local communities as part of their rural livelihood strategies.

Compartment: A portion of a forest under one ownership, usually contiguous and composed of one or more forest stand types, defined for purposes of locational reference and as a basis for forest management.

Complete cultivation: General term for ploughing (tillage) of all soil on a site. Sometimes used to describe a method of soil (or soil-forming material) loosening using the bucket of an excavator to dig out and drop material in a manner which emulates loose tipping.

Composite products: Fabricated materials consisting of wood used in combination with non-wood components such as various types of gypsum, Portland cement, plastics and resins.

Compost: A mixture that consists largely of decayed organic matter that is used for fertilizing and conditioning soils.

Compression resistance: The resistance of wood, paper and paperboard to compressive stresses.

Computer animation: Computer animation is the creation and compilation of a series of still images to represent movement, either between viewpoints, or in image elements (e.g. animation of different weather conditions, or simulation of tree growth over time). Individual images are created (rendered) by the computer visualization software and then strung together to create the animation.

Conductivity: Within the context of pollen viability testing, this is a technique that relates viability with the conductivity of an aqueous solution of pollen leachate.

Cone induction: Bringing about seed cone development by manipulating the environment, cultural practices or specific plant hormones (i.e., gibberellins).

Conidiophore: A specialized fertile hypha which bears a conidiogenous cell, that produces asexual spores (conidia).

Conifer/coniferous: Needle-leaved or scale-leaved trees; usually cone-bearing, and usually evergreen. (e.g., pines, cypresses, podocarps).

Conservation: The wise management of human use of natural resources and the environment including their preservation and protection.

Consistence: The attributes of soil material as expressed in degree of cohesion and adhesion or in resistance to deformation or rupture.

Construction log: A profiled log or timber used for the walls of log buildings.

Consultation: Where information is provided to the public and public opinions are sought for consideration in expert or managerial decision-making.

Contact angle: In the case of a liquid resting upon a solid surface, this is the angle drawn from the tangent of the liquid/solid/air intersection and measured from this tangent to the liquid/solid interface. The contact angle represents the balance of liquid and solid surface energies; it reveals the quality of wetting, be it favorable ($<90°$) or unfavorable ($>90°$).

Containerboard: Any type of single- and multi-ply, solid and corrugated boards used to make up boxes and other containers for shipping materials, and the type of paperboard used to make them up.

Contamination: In tree improvement, the incorporation of pollen external to orchard sources and generally considered to be deleterious to genetic worth either as poor growth performance and/or introducing poorly adapted genes into a production population.

Contingent evaluation: Placing a value on conditions or occurrences not yet established.

Continuous cover forestry: An approach to forest management characterized by the avoidance of clear felling. Young trees are established under the cover of and in the protection of the mature trees (hence 'continuous cover').

Continuous variable: A variable expressed in a numerical scale of measurement, where any interval of the scale can be subdivided into an infinite number of values.

Controlled pollination (CP): The transfer of pollen from a known source to known seed-cone parents while excluding all other pollen sources.

Coordinated inventories: Data collection efforts by different entities but designed to do so effectively. Collecting information needed by a number of resource functions coordinated either spatially or temporally, or both.

Copal: A hard translucent resin obtained from various tropical trees; may be semifossilized.

Coppice: 1. The production of new stems from the stump or roots. 2. To cut the main stem (particularly of broadleaved species) at the base to stimulate the production of new shoots for regeneration. 3. A plant derived by coppicing. 4. Any shoot arising from an adventitious or dormant bud near the base of a woody plant that has been cut back.

Coppice forest: Forest originating from coppice shoots, root suckers or both, i.e. by vegetative means.

Coppice-with-standards: A coppice system in which selected stems are retained as standards at each felling to form an uneven-aged overstory which is removed selectively on a rotation constituting some multiple of the coppice rotation; a crop partly of vegetative and partly of seedling origin.

Cordillera: Mountain chain (Spanish term).

Core area: Habitat area with relatively stable conditions, e.g., forest interior.

Coriaceous: Leathery.

Corm: Bottom part of the stem of a plant which, like a bulb, can be preserved and from which the plant sprouts again in spring.

Correlogram: A measure of the continuity of spatial phenomena expressed as an average correlation between measured quantities at different locations.

Corridors: Relatively narrow strips of habitat linking different forest fragments; natural or man-devised conduits in a landscape, intended to be used by dispersing organisms.

Corrugated board: (1) A pasted, single- or double-faced, multi-layered type of board in which the bottom or middle layer is fluted. (2) The fluted paperboard after it has gone through the corrugating operation and before it is pasted to the flat facing board sheets. It is used as a protecting, separating, or support medium in packaging fragile items.

Corrugated fiberboard: A type of paperboard made with strong paper faces separated by a corrugated paper core.

Corrugating medium: Paperboard that is made from chemical and semichemical pulps sometimes mixed with straw or recycled paper stock that is to be converted to a corrugated board by passing it through a corrugating machine.

Cotyledon: The primary leaf in the embryo of higher plants; the seed-leaf. The number varies between species of conifers and is typically two in the Dicotyledons.

Covalent bonding, primary forces: Strong and relatively permanent attraction between atoms, holding atoms together in the form of molecules.

Covariance: A variance or measure of association between paired measurements of two variables.

Covariate: A quantitative explanatory variable in a model such as a regression model. Covariates are often important in improving estimation.

Creosote: A thick, black oil from the fractional distillation of coal tar, mainly composed of polyaromatic hydrocarbons and used as a wood preservative for over 150 years.

Crepe angle: In paper making the angle the crepe blade makes with the Yankee dryer at the point of contact with the dryer.

Creping: A paper-manufacturing process in which the paper product is foreshortened scraping it from the Yankee dryer and then winding it at a slower velocity than that at which it is made.

Criteria and indicators: A monitoring system for the assessment of the economic, social, or ecological data about land management practices as an aid to improving sustainability.

Criterion: An aspect that is considered important and by which success or failure will be judged. The role of criteria is to characterize or define the essential elements or sets of conditions or processes by which sustainable forest management may be assessed.

Critically endangered species: Species whose populations are very small (usually smaller than 50). Such species are said to have an inviable population size.

Crop: In silviculture/management, the standing crop; the vegetation growing on a forest area, more particularly the major woody growth.

Crossdating: Matching different tree-ring series to identify their overlap.

Crossing-over: A process during meiosis that causes structural recombination of maternal and paternal segments of homologous chromosomes.

Crosstie: See Rail road tie.

Crown class: A category of tree based on its crown position relative to those of adjacent trees. Types of crown class are: **dominant** upper canopy trees with largely free-growing crowns exposed in entire vertical plan but usually in contact with others laterally; **codominant** upper canopy trees, similar to and often difficult to distinguish from dominants but crowns somewhat less free and more in contact with others; **subdominant** middle or lower canopy trees, partly exposed and partly shaded vertically by crowns but leading shoots free. Also known as intermediate or dominated trees; **suppressed** lower canopy trees entirely shaded vertically by other crowns. Also known as subordinate or overtopped trees.

Crown closure: Canopy closure.

Crown cover: A measure of stand density.

Crown management: Controlling the size and shape of a tree's crown while maintaining or increasing seed cone and pollen cone development.

Crown thinning: See thinning.

Cryogenic storage: Use of ultralow temperatures (e.g., of liquid nitrogen) for long-term storage of genetic material.

CTI: Central tire inflation

CTMP: Chemithermomechanical pulp.

Culm: Segmented aerial axis that emerges from the rhizome and forms the aboveground stem.

Cultivar: A clone or set of genotypes, representing a common breed and level of improvement, that is a unit for genetic deployment.

Cultural: Denoting deriving from, or distinctive of, the ways of living built up by a group of people.

Current annual increment (CAI): The growth observed in a tree or stand in a specific one-year period.

Cytogenetics: The science that deals with the material basis of heredity and genetic control at the cell level. It was initiated with microscopic studies on the morphology and behavior of chromosomes. It has later developed to include detailed analyses at the molecular level, such as gene mapping and transmission of genetic information.

Data element: A basic unit of information built on standard structures having a unique meaning and distinct units or values.

Data visualization/scientific visualization: Data visualization refers to the graphical representation of numerical information. Data visualization can take many forms, from simplistic representations such as tables and graphs, to more complex representations such as multi-dimensional computer simulations. Scientific visualization usually refers to data visualization of information that has a spatial component (geographic mapping can be thought of as a form of scientific visualization). Information visualization is the term used for data visualization of information that does not have any inherent spatial organization (e.g. a family tree can be thought of as a form of information visualization).

Dbh: See Diameter at breast height.

Decay: Wood degradation caused by wood-decaying (white rot, brown rot, or soft rot) fungi. Incipient decay describes the early stages of colonization and degradation with some loss in wood strength properties but little or no visual changes, followed by advanced decay where the wood has little or no strength and is obviously decayed.

Deciduous: Of perennial plants that are normally more or less leafless for some time during the year (e.g., temperature hardwood species).

Decking: Lumber used as the upper surface of an extended horizontal structure attached to a building.

Decomposition: 1. Integrated process of physical reduction in particle size combined with biochemical degradation of organic matter. 2. The breakdown of complex organic compounds into simpler compounds that may ultimately result in the return of CO_2 to the atmosphere and the release of energy stored during photosynthesis.

Defoliation: A term often misused to identify trees with thin, transparent crown. More correctly, it means the actual loss of foliage on a tree.

Deforestation: The complete or almost complete removal of tree cover and conversion of forested land to other uses as a result of human activities.

Degraded forest: A forest that has lost structure, productivity, and species richness. A degraded forest might still contain trees (i.e., a degraded site is not necessarily deforested) but it will have lost ecological integrity and its capacity to maintain the original ecological functions and processes.

Degree days: A measure of temperature implying heat energy available for plantgrowth. Degree days accumulated = [(maximum + minimum daily temperature)/2] − base temperature (usually 5°C).

Dehiscent fruit: A type of fruit that opens at maturity.

Delimbing: Removing the branches from the stem of a felled tree.

Deliquescent: Having a shape that branches out into numerous subdivisions that lack a main axis, such as the stem of an elm.

Demographic stochasticity: Temporal variation in population growth driven by chance variation in the fates of individuals; its magnitude is strongly dependent on population size.

Dendrochronology: The science of using tree rings and their characteristics to understand tree ages and past climate or management conditions.

Denitrification: The microbial reduction of nitrate to nitrous oxide and di-nitrogen gas.

Density (stand): An ecological measurement that provides an indication of how many individuals of a species are found in a forest, usually measured as the number of individuals per hectare.

Density (wood): Weight per unit volume. In USCS units it is expressed as pounds per cubic foot, and in ISO units it is expressed as kilograms per cubic meter.

Density-dependence: Population processes that are a function of the number of individuals (density) within a population. Extrinsic forces that act on populations irrespective of its size are density-independent.

Depithing: The process of removal of pith.

Deployment: The planting of improved genotypes for reforestation and all of the decisions of which genotypes to plant and how to propagate them. Clonal forestry and using seedlings from seed orchards are two examples of deployment schemes.

Deposit: Undesired material building up on process equipment at any point.

Desertification: The development of desert conditions as a result of human activity, frequently by overuse of trees and overgrazing, or climate change.

Destination: Aims to minimize the loaded transport distance between all forest supply nodes (active landings) and demand nodes (mills).

Detackifier: Talc or one or various organic polymers that reduce tackiness.

Detritus: Organically derived material of small particle size.

Deuteromycetes: A diverse assortment of fungi whose common feature is the lack of a sexual stage.

Development pathway: The sequence of structures through which a forest stand moves over time.

Devolution in forest management: The transfer of (part of) the decision-making authority over forest resources from state bureaucracies to local communities.

Diagnosis: Determination of the nature of an abnormal condition (e.g., a disease) from observation of symptoms.

Diagnostic horizons: Combinations of specific soil characteristics that are indicative of certain classes of soils. Those which occur at the soil surface are called epipedons, those below the surface, are diagnostic subsurface horizons.

Diallel: A scheme to artificially cross genotypes by assigning them to a small group and have the genotypes act as either male or females contributors to the diallel table. This design was commonly used with lines in maize but has been widely adopted to tree breeding.

Diameter: Diameter, girth or cross-sectional area of the stem or other woody parts of the tree is frequently used as an indicator of size, to calculate wood volume or as a predictor of other tree and stand properties. For standing trees, the most widely used tree and stand characteristic is stem diameter, d, measured outside of the bark at breast height, often referred to as diameter at breast height (dbh). In countries that use the SI system breast height is generally located at 1.30 meter above ground level. Commonly used stand variables includes arithmetic mean diameter, D, and quadratic mean diameter, D_g. In forestry terms, the quadratic mean is often considered more meaningful because of its direct relation to stand basal area and, in turn, stand volume.

Diameter at breast height (dbh): The diameter of the stem as measured at a common reference height. The reference height, usually known as breast height is set at a constant value, usually around 1 to 1.5 m. Different countries may adopt different reference heights from within this range as a national standard. A common example is 1.3 m (4.5 ft in the USA). The diameter is usually measured directly with callipers, or from tree girth by calibrated tape, assuming a circular cross section. Dbh is used to estimate basal area.

Dichogamy: Different timing of functionality of female and male flower parts.

Dicotyledons: One of the two great divisions of flowering plants in which the embryo usually has two cotyledons or seed leaves and the nervation is generally reticulate (cf. Monocotyledons).

Dieback: A term often used to mean 'death.' More correctly, it means a progressive death of a tree or a branch from its extremities towards the roots. In certain situations, dieback in individual trees should be seen as an adaptation to changed environmental condition (e.g. lower water table). Dieback can be reversible.

Digester: A pressure vessel used for pulping.

Dimension lumber: Solid-sawn lumber 38 mm (2 in.) to, but not including, 127 mm (5 in.) in nominal thickness.

Dimensional stability: A property of a sheet of paper that reflects the constancy of its dimensions that may occur with changes in moisture content, with applications of compressive or tensile stresses, or with time under stable ambient conditions.

Dioecious: Plant species in which male and female reproductive organs occur separately on different, unisexual, individuals.

Dioecy: The system in which plants of a species have separate sexes, each individual carrying either only female flowers or only male flowers. Dioecy guarantees cross-pollination.

Diploid: Term to describe cells or plants that have a double set of chromosomes (commonly shown as $2n$), one set coming from the seed parent and the other set from the pollen parent.

Diploxyon pines: Members of the subgenus *Pinus* of pines, characterized by having two fibrovascular bundles in each needle.

Dipterocarp: Member of the plant family Dipterocarpaceae.

Directive participation: Where information is exchanged but primarily in one direction, e.g. from government to the public.

Discrete variables: Qualitative variables or those represented by integral values or ratios of integral values.

Disease: A harmful and persistent deviation from normal physiological processes, caused by enviornmental or biotic factors.

Displacement Zone: The area ahead of and above the shelterbelt in which the flow is displaced upwards.

Distributions from the exponential family: binomial, Poisson, or gamma: Probability distributions with particular features. For example, the Poisson distribution relates to a variable where only integer outcomes are possible, and the mean is exactly equal to the variance.

Disturbance: A relatively discrete event that disrupts stand structure and/or changes resource availability, or the physical environment, or the function of an ecosystem.

Diversity: Variation at ecosystem, species and genetic levels measured by various indices; number of species in an ecological unit.

DNA content (1C): The amount of DNA in the haploid set of chromosomes.

DNA polymorphism: Genetic differences that can be detected with laboratory tests.

DNA primer: A short single-stranded DNA fragment used to initiate synthesis of new DNA.

Dominance: 1. An ecological measurement that provides an indication of how much basal area is occupied by a given species in a forest, usually measured as the number of square meters per hectare. 2. Inter-allele interaction at one locus on a chromosome.

Dominant (crown class): See crown class.

Dominant dbh: The average diameter of the dominant trees in the stand, sometimes used in the assessment of top height.

Dominant use silviculture: Silvicultural practices which seek to maximize the yield of a single output (e.g. timber, habitat for game birds) from a stand.

Dormancy: Absence of germination despite optimal conditions; may be due to several causes.

Double fertilization: Fusion of the egg with one sperm and the fusion of the polar nuclei with the second sperm; a process unique to flowering plants.

Down wood: Dead woody material on the ground, such as logs or branches. Also called ‘coarse woody debris’.

Draw: The tension applied to the paper between sections of a paper machine, such as the press section or drier section.

Drupe: Fleshy indehiscent fruit where the seed or seeds are surrounded by a hardened endocarp.

Dry deposition: The transfer of atmospheric pollutants from the air to terrestrial ecosystems by gravitational, physical, and chemical processes.

Dry strength: Ability of dry paper to resist tensile failure, tear, or delamination.

Dry strength agents: An ingredient added to paper stock that will improve the strength of dry paper. Starch is commonly used.

Drying oil: An oil that chemically reacts with oxygen from the air changing to a relatively hard, tough, insoluble, elastic substance after application to a surface as a thin layer.

DTRAN: An extension of the DUALPLAN (Dual formulation of the Linear Programming formulation for forest management scheduling) with transport considerations.

Duff mull: Forest humus type transitional between mor and mull.

Durability: A general term for permanence or resistance to deterioration. Frequently used to refer to the degree of resistance of wood or finished wood to weathering. Also to the degree of attack by wood-destroying fungi under conditions that favor such attack. In this connection the term ‘decay resistance’ is more specific.

E horizon: Light-colored mineral horizon resulting from removal of humus and sesquioxides by leaching with organic acids.

Early burning: Prescribed burning early in the dry season, before the leaves and undergrowth are completely dry or before the leaves are shed; carried out as a precaution against more severe fire damage later in the fire season.

Earthscraper: Engineering plant designed to strip soil materials at the beginning of mineral extraction, and often used to replace soils during site reclamation. Soil compaction is often induced using this machinery.

Ecological balance: A state of dynamic equilibrium within a community of organisms in which genetic, species and ecosystem diversity remain relatively stable.

Ecological carrying capacity: A measure of how much recreational use an area can stand without a permanent disturbance to the processes of its ecosystem.

Ecological services: Benefits provided by forests such the protection of biologicaldiversity, the protection of hill slope stability, the maintenance of soil fertility, or the maintenance and protection of hydrological functioning.

Ecophysiology: The study of cellular and biochemical processes within organisms that affect how and where organisms live in their environment.

Ecosystem: The complex of a unique community of organisms and its environment functioning as an ecological unit.

Ecotone: Transition zone between plant communities.

Eco-tourism: Ecologically sustainable tourism focused on human experience in natural areas.

Edaphic: Pertaining to the soil and its capacity as a media for plant and animal growth.

Edaphic climax: A later successional stage of vegetation which persists for long periods as a result of soil based limiting factors.

Eddy covariance: Covariance in vertical air movements and exchange rates of CO_2, water vapor and other gases to the atmosphere.

Edge effects: Biotic and abiotic changes along edges of forest fragments and the junction of different habitat patches.

Edge systems: Modifications of the shelterwood or clear cutting systems in which regeneration is encouraged along the edge of a crop or stand, and therefore growing under conditions of light and exposure different from those prevailing within the crop or stand, or in the open.

Edible: Any product that can be consumed safely.

Effect: The conscious subjective aspect of feeling or emotion.

Effective population breeding number: The average number of individuals contributing gametes to the next generation.

Efficient design: Selection of a particular experimental design that results in the highest power for a given level of cost, or, conversely results in the lowest cost for a given level of power.

EFISCEN: European Forest Information Scenario Model.

Egg gallery: A tunnel, often linear, created by a female bark beetle within the host tissue along which eggs are laid.

Eigenvalue: Value λ_r corresponding to eigenvector $\mathbf{x}_r$.

Eigenvector: Vectors $\mathbf{x}_r$ satisfying the equation $(\mathbf{A} - \lambda_r\mathbf{I})\mathbf{x}_r$ where $\mathbf{A}$ is the matrix considered, $\mathbf{I}$ is identity matrix and λ_r is the corresponding eigenvalue.

Elaiosome: Plant tissue attached to a seed that is offered as a reward to ants that in turn disperse the seed.

Elasticity: The property of a material which enables it to undergo deformation and to recover its original dimensions after removal of the deforming stress.

Eluviation: Removal of soil material in suspension or solution from one layer in the soil to another. Akin to leaching by solution.

Embryogenesis: 1. The natural process of creating embryos. 2. A laboratory technique utilizing specific cultures to produce many embryos from a single seed. These are developed into seedlings that are genetically identical to the original parent seed. Seedlings derived by this process are called emblings.

Embryonic lethals: Recessive genes that cause the abortion of homozygotic embryo (after self-fertilization). In many conifers embryonic lethals effectively restrict inbreeding.

Endangered: In danger of extinction or genetic erosion.

Endemic: A species confined to a particular area, and believed to have originated there.

Endocarp: The inner layer of the fruit wall.

Endosperm: The energy-rich food supply surrounding the embryo of a seed.

Engineered wood product: Any one of numerous building materials made from small pieces of wood joined with adhesives or fasteners and strategically arranged to create a structural member of designated stiffness and strength.

Enrichment planting: Planting commercially or ecologically important species in heavily logged or degraded forest to enrich the composition of that forest.

Environmental accountability: Assessment of the environmental impacts and values of a project or activity and defining responsibility of the project to the public.

Environmental stochasticity: Temporal variation in vital rates driven by changes in the environment that are inherently unpredictable.

Eocene: Geological epoch (54.8–37.7 million years ago) of Tertiary period.

Eophyll: The first leaf produced by a germinating seed.

EPA: Environmental Protection Agency.

Epidemic: Rapid spread of a disease in a population in a large geographic area over a short time.

Epilimnion: Upper (warmer) layer of thermally stratified lakes.

Epilithic: A species growing on top of a rock.

Epiphyte: A plant that lives on another plant for physical support but does not draw water or nutrition from the host.

Epiphytism: A way of growing (rooting) on the surface of trunks, branches, twigs, and leaves, commonly found among herbs (e.g., orchids, bromeliads, aroids) and certain shrubs (e.g., ericads) in tropical cloudy environments; epiphytes use other plants for support and generally do not parasitize on them, although sometimes this may be the case (e.g., in Loranthaceae and Viscaceae).

Epistasis: Interaction between alleles located on different loci on chromosomes of an individual.

Equilibrium moisture content (EMC): The moisture content wood attains when surrounded by air at a specified temperature and relative humidity.

Equity: Distribution or sharing of benefits in a manner so as to protect the interests of disadvantaged sections of the society.

Ericoid: Plants of the Health Family or Family Ericaceae. Also can be used as resembling or like a true heath (Family Ericaceae). In referring to an ecosystem may contain true heaths as well as species of similar form.

Error variance: The variance associated with the experimental error and residual unexplained variation.

Estimate: The numerical value calculated from an estimator for a sample.

Estimator: A function of the values in a sample or a formula used for estimating a parameter based on a sample.

Estuarine: Living in river mouths, joining the sea.

Ethnoagriculture: Tribal agriculture/traditional methods of raising crops.

Ethnobotany: The study of plants and their uses by humans.

Ethnoecology: The proper utilization of natural resources and maintenance of ecological balances as practised by primitive societies.

Ethnogynaecology: Medicines used by tribal peoples during childbirth and prenatal and postnatal medicine, and techniques adopted by them for family planning.

Ethnomedicobotany: Traditional knowledge and practices about herbal remedies.

Ethnomycology: The study of molds eaten by tribal peoples and their fermenting liquors since ancient times.

Ethnopharmacognosy: Traditional concepts or methods for distinguishing between various plant products, or the quality of such products from different seasons, particularly those used medically.

Ethnopharmacology: Study of the methods adopted by tribal peoples for selecting, experimenting, and administering herbal recipes in human or animal diseases.

Ethnophytotaxonomy: Traditional concepts or practices for classification, identification, and naming of plants.

Ethnotaxonomy: See Ethnophytotaxonomus.

Ethnotoxicology: The study of the plants used by tribal peoples as poisons to kill animals during hunting.

ETTS: European Timber Trend Studies.

Euchromatin: An expanded region of genetically active chromatin in the eukaryotic nuclei which stains lightly with basic dyes.

Eukaryote: An organism whose cells have a distinct nucleus (i.e., in all protists, fungi, plants, and animals) with nuclear envelopes, chromosomes, and nuclear divisions in forms of mitiosis and meiosis, in contrast to prokaryotic organisms (i.e., bacteria and blue-green algae).

Eutrophication: High levels of organic production.

Eutropic (soils): Soils rich in nutrients.

Evapotranspiration: The combination of evaporation from the soil and plant surfaces and transpiration from plant leaves.

Evergreen: Plants that do not shed all leaves at one time and hence appear green throughout the year.

Excurrent: Having a single, undivided trunk with lateral branches, as in spruce trees.

Exine: The outer layer of the pollen grain wall which is highly resistant to strong acids and bases and which is composed primarily of sporopollenin.

Exotics (Exotic species): Species or populations that are introduced from elsewhere and are not native to the site.

Expected mean-squares: The expected relationships between the mean-squares, calculated using the sample data, and the population variances.

Experimental design: A plan for establishing, measuring, and evaluating the results of an experiment.

Expressed sequence tag (EST): Sequence, usually brief, of DNA copied from messenger RNA (mRNA) that can serve for gene recognition.

***Ex-situ* conservation:** To conserve species or populations in areas other than their natural habitat.

***Ex situ* remedial technology:** Remediation that involves excavation or extraction of materials to be treated above ground or offsite, e.g., land disposal, incineration, soil washing, pump-and-treat.

Extinction: Complete loss of a population or a species.

Extirpate: Remove a species from a specified locality.

Extractant: Chemical solution used to remove nutrients from a soil sample for analysis or chemicals from wood and leaves for use (e.g., pine resin, pharmaceuticals).

Extractive reserves: A patch of forest where extraction of certain resources are allowed by a certain group of people (indigenous groups) while the rest of the resources are protected.

Extractivism: The practice of commercial harvesting of NTFPs from forests; particularly used in Latin America.

Extraporate: A pollen grain where the furrow and pores are not closely associated.

F_1: First filial generation; progeny resulting from crosses between two species or individuals (usually selected in breeding programs); in the case of interspecific hybridization it is the hybrid resulting directly from crossing two pure species.

F_1: First generation of hybrids between two populations.

F_{st} and G_{st}: Two genetic statistics used to measure differentiation between populations for molecular markers.

Factorial: A mating scheme which assigns one group of trees as only male and the other as female.

Facultative organism: Any organism that can adapt to the presence or absence of oxygen.

Fagaceous: Belonging to the beech and oak tree family.

Family: Seedling offspring from a particular tree. Half-siblings have one parent in common among family members and full-siblings have both parents in common.

Family forestry: Small-scale forestry carried out by ordinary families with the aim of enabling successive generations to enjoy the bounty of forests – both in an economic sense and as places that provide recreational value.

FAO: Food and Agriculture Organization, a Specialized Agency of the United Nations.

Farm forestry: Forestry practised by farmers and integrated into the farm business, generating revenue and environmental services to complement other enterprises on the farm.

Fascicle: The morphological unit in which pine needles are produced in clusters of 1 to 5 or more needles; this is generally, a species-specific characteristic.

FASOM: Forest and Agriculture Sector Optimization Model.

Fatty acid: Long chain carboxylic acids present in rosin or tall oil.

Fauna: Animals or a document on animals in an area.

Feller–buncher: Off-road forestry vehicle designed for felling trees and accumulating them in bunches.

Fertility potential: The potential for a particular pollen lot to fertilize an egg cell.

Fertilization: The union of the male gamete (sperm) with the female gamete (egg) to form a zygote from which a new plant will form.

Fiber: A slender, threadlike cell with tapered ends in wood, composed chiefly of cellulose. Note that fibers differ from tracheids in being more slender, having simple pits and thicker walls in relation to diameter, and often retaining protoplasm. They are separated from each other during the pulping operation in a pulp mill and reassembled into the form of a sheet during the papermaking process in the paper mill. Found in angiosperms; responsible for support and strength; includes fiber tracheids and libriform fibers.

Fillers: Materials such as china clay with particles often in the size range 0.5–4 μm added to paper to impart properties at less cost than using 100% fiber. Newsprint (the paper on which newspapers are published) is up to 33% filler.

Filmy ferns: Small, tiny ferns with thin, transparent, finely-lobed, film-like leaves, belonging to the family of Hymenophyllaceae.

Fines: 1. Small particles of wood residue that vary in size in the range common to different forms of sawdust. 2. Very short pulp fibers or fiber fragments and ray cells.

Finish: Coatings of paint, varnish, lacquer, wax, etc., applied to wood surfaces to protect and enhance their durability or appearance.

Fire behavior: The manner in which fuel ignites, flame develops, and fire spreads and exhibits other related phenomena as determined by the interaction of fuels, weather, and topography. Some common terms used to describe fire behavior include the following: ***smouldering*** A fire burning without flame and barely spreading. ***creeping*** A fire spreading slowly over the ground, generally with a low flame. ***running*** A fire rapidly spreading and with a well-defined head. ***torching*** Ignition and flare-up of foliage of a single tree or a small clump of trees, usually from bottom to top (syn. *candling*). ***spotting*** A fire producing firebrands carried by the surface wind, a fire whirl, and/or convection column that fall beyond the main fire perimeter and result in spot fires. ***crowning*** A fire ascending into the crowns of trees and spreading from crown to crown. (See: Three classes of Crown Fire under **Forest Fire**).

Fire belt: A strip, cleared or planted with trees, maintained as a firebreak or fuelbreak.

Fire break: Any natural or constructed discontinuity in a fuelbed utilized to segregate, stop, and control the spread of fire or to provide a control line from which to suppress a fire; characterized by complete lack of combustibles down to mineral soil (as distinguished from fuelbreak).

Fire control: All activities concerned with protection of vegetation from fire.

Fire cycle: The number of years required to burn over an area equal to the entire area of interest.

Fire danger: A general term used to express an assessment of both fixed and variable factors of the fire environment that determine the ease of ignition, rate of spread, difficulty of control, and fire impact; often expressed as an index.

Fire danger rating: A component of a fire management system that integrates the effects of selected fire danger factors into one or more qualitative or numerical indices of current protection needs.

Fire ecology: The study of the relationships and interactions between fire, living organisms, and the environment.

Fire exclusion: Planned (systematic) protection of an ecosystem from any wildfire, including any prescribed fire, by all means of fire prevention and suppression in order to obtain management objectives (cf. fire control).

Fire frequency: The average number of fires or regularly occurring fire events per unit time in a designated area.

Fire hazard: (1) A fuel complex, defined by volume, type, condition, arrangement, and location, that determines the degree both of ease of ignition and of fire suppression difficulty; (2) a measure of that part of the fire danger contributed by the fuels available for burning. It is worked out from their relative amount, type, and condition, particularly their moisture contents.

Fire history: The reconstruction and interpretation of the chronological record, causes and impacts of fire occurrence in an ecosystem in relation to changes of past environmental, cultural and socio-economic conditions. Fire history evidence is based on analysis of charcoal deposits in soils, sediments, and ice, dendrochronology (fire scar analysis), historical documents, and fire reports.

Fire information system: An information system designed to support fire management decisions. Advanced fire information systems integrate different sources of information required (e.g., vegetation conditions including fire history, topography, fire weather, fire behavior models, real- or near-real-time fire detection and monitoring data, fire management resources, infrastructures and pre-suppression information) on the base of a Geographic Information System (GIS) and allows real-time distribution or access via telecommunication.

Fire interval or fire-return interval: The number of years between two successive fires documented in a designated area; the size of the area must be clearly specified.

Fire management: All activities required for the protection of burnable forest and other vegetation values from fire and the use of fire to meet land management goals and objectives. It involves the strategic integration of such factors as a knowledge of fire regimes, probable fire effects, values-at-risk, level of forest protection required, cost of fire-related activities, and prescribed fire technology into multiple-use planning, decision making, and day-to-day activities to accomplish stated resource management objectives. Successful fire management depends on effective fire prevention, detection, and pre-suppression, having an adequate fire suppression capability, and consideration of fire ecology relationships.

Fire management plan: (1) A statement, for a specific area, of fire policy and prescribed action; (2) The systematic, technological, and administrative management process of determining the organization, facilities, resources, and procedures required to protect people, property, and forest areas from fire and to use fire to accomplish forest management and other land use objectives (cf. fire prevention plan or fire Campaign, pre-suppression planning, pre-attack plan, fire suppression plan, end-of-season appraisal).

Fire pre-suppression: Activities undertaken in advance of fire occurrence to help ensure more effective fire suppression; includes overall planning, recruitment and training of fire personnel, procurement and maintenance of fire fighting equipment and supplies, fuel treatment, and creating, maintaining, and improving a system of fuelbreaks, roads, water sources, and control lines.

Fire prevention: All measures in fire management, fuel management, forest management, forest utilization and concerning the land users and the general public, including law enforcement, that may result in the prevention of outbreak of fires or the reduction of fire severity and spread.

Fire protection: All actions taken to limit the adverse environmental, social, political, cultural and economical effects of wildland fire.

Fire regime: The patterns of fire occurrence, size, and severity – and sometimes, vegetation and fire effects as well – in a given area or ecosystem. It integrates various fire characteristics. A natural fire regime is the total pattern of fires over time that is characteristic of a natural region or ecosystem. The classification of fire regimes includes variations in ignition, fire intensity and behavior, typical fire size, fire return intervals, and ecological effects.

Fire risk: The chance a fire will start (be ignited) by a cause such as arson, accident, lightening or spreading from adjoining land.

Fire season: (1) Period(s) of the year during which wildland fires are likely to occur and affect resources sufficiently to warrant organized fire management activities; (2) a legally enacted time during which burning activities are regulated by State or local authority.

Fire suppression: All activities concerned with controlling and extinguishing a fire following its detection. (Syn. Fire Control, Fire Fighting). Methods of suppression are: ***direct attack*** A method whereby the fire is attacked immediately adjacent to the burning fuel. ***parallel attack*** A method whereby a fireguard is constructed as close to the fire as heat and flame permit, and burning out the fuel between the fire and the fireguard. ***indirect attack*** A method whereby the control line is strategically located to take advantage of favourable terrain and natural breaks in advance of the fire perimeter and the intervening strip is usually burned out or backfired. ***hot spotting*** A method to check the spread and intensity of a fire at those points that exhibit the most rapid spread or that otherwise pose some special threat to control of the situation. This is in contrast to systematically working all parts of the fire at the same time, or progressively, in a step-by-step manner. ***cold trailing*** A method of determining whether or not a fire is still burning, involving careful inspection and feeling with the hand, or by use of a hand-held infrared scanner, to detect any heat source. ***mop-up*** The act of extinguishing a fire after it has been brought under control.

Fire weather: Weather conditions which influence fire ignition, behavior, and suppression. Weather parameters are dry-bulb temperature, relative humidity, wind speed and direction, precipitation, atmospheric stability, winds aloft.

Fire-dependent species: Plant and animal species which require regular fire influence which triggers or facilitates regeneration mechanisms, or regulates competition. Without the influence of fire these species would become extinct.

Flammability: Relative ease of igniting and burning of a given fuel under controlled conditions, with or without a pilot flame. Flammability of a fuel is characterized quantitatively by the ignition delay of a sample of fuel exposed to a normalized radiation source.

Flat crush resistance: The maximum compressive resistance which corrugated combined board offers prior to collapse of the flute, to a force applied perpendicular to the plane of the board.

Flexographic printing: A rotary letterpress printing process in which the ink used consists of a dye or a pigment or both and generally a binder in a rapidly evaporating solvent vehicle. The printing press is much simpler than conventional machines, because only two rolls may be required, one running partially submerged in the fountain, the other transferring the ink to the plate. The rolls and plates are ordinarily made of rubber.

Floating chronology: In dendrochronology a ring-width series of unknown age that has not been associated with a particular calendar date.

Flocculant: Very-high-mass water-soluble polymer, usually having ionic groups.

Flocculation: Clumping of individual clay particles into larger aggregates.

Flora: Plants or a document on plants in an area.

Flower: The structure concerned with sexual reproduction in the angiosperms. (cf. **Strobilus** in gymnosperms)

Fluctuating asymmetry: Deviations from bilateral symmetry, often caused by genetic problems or environmental contamination.

Flute: The geometric configuration formed by one of the undulations of the corrugated medium in corrugated board. The exact dimensions of the flute will vary slightly depending on corrugating roll contour, material characteristics, converting equipment, and technique.

Flux: The movement of a substance from one compartment to another. Within the global change literature, a positive flux of carbon indicates a movement from a compartment into the atmosphere, and a negative flux indicates a movement from the atmosphere into another compartment.

Focus groups: Small groups of people, intended to represent a narrow or broad range of public interests, convened for the purpose of interactive and spontaneous discussions of a particular topic or plan.

Fodder banks: Fast-growing trees planted in blocks to provide a cut-and-carry fodder resource for livestock.

Fodder pollen: A type of pollen that cannot germinate and serves as a pollinator reward, e.g., the hood pollen of *Lecythis pisonis*.

Foliar analysis: Chemical analysis of leaves or needles of a tree to determine mineral content to provide information about nutritional state.

Foliar uptake: The ability of a pollutant to enter the interior of a leaf either through stomatal exchange or by transcuticular absorption.

Folivore: An organism that feeds primarily on the leaves of trees. Commonly used to describe foliage-feeding insects with chewing mouthparts.

Folk medicine: A culture- and ethnic community-specific, traditional healthcare system which is purely empirical in nature and exists in all rural communities throughout the world. Folk medicine practitioners generally use herbs and animal products found in the vicinity of their habitations for treating ailments.

FOLPI: Forestry-Oriented Linear Programming Interpreter.

Forb: A broadleaved herb other than grasses, sedges a especially one growing in a field, prairie, or meadow.

FORCABSIM: Forestry Development and Carbon Budget Simulation Model.

Forest: Traditionally considered an ecosystem dominated by trees and observed in multisized, multishaped landscape patches, of which at least two-thirds (66.7%) of its surface area is covered by trees. The FAO Forest Resource Assessment 2000 aims towards global standardization of the terminology: ***Forest*** Land with tree crown cover of more than 10 percent and area of more than 0.5 hectares. The trees should be able to reach a minimum height of 5 meters at maturity. ***Other wooded land*** Land either with a crown cover of 5–10 percent of trees able to reach a height of 5 meters at maturity; or a crown cover of more than 10 percent of trees not able to reach a height of 5 meters at maturity; or with shrub or bush cover of more than 10 percent. ***Other land*** Land with less crown cover, tree height, or shrub cover as defined under 'Other wooded land.'

Forest botanicals: Term used by US Congress; naturally occurring mushrooms, fungi, flowers, seeds, roots, barks, leaves, and other vegetation (or portions thereof) that grow on National Forest System lands.

Forest decline: The reduction in vigour of many trees growing together at the same site. In general, forest decline is due to a combination of biotic and abiotic factors and progresses slowly over time.

Forest degradation: Damage to forest ecosystems through human activities that does not result in the total elimination of forest cover.

Forest design plan: A type of forest planning used in the UK to plan the felling and restocking of a plantation forest and to use the process to improve the landscape quality, ecological value and recreational potential, and to diversify tree species and ages.

Forest fire: Any wildfire or prescribed fire that is burning in a forest, variously defined for legal purposes (see Forest). ***Other land fire*** Indication is desired if recurring wildfires affect 'Other land' by inhibiting regeneration to the 'Forest' and 'Other wooded land' categories. ***Ground fire*** A fire that burns **in:** the ground fuel layer (syn. Subsurface fire, *below* surface fire). ***Surface fire*** A fire that burns in the surface fuel layer, excluding the crowns of the trees, as either a head fire, flank fire, or backfire. ***Crown fire*** A fire that advances through the crown fuel layer, usually in conjunction with the surface fire. Crown fires can be classified according to the degree of dependence on the surface fire phase: ***Intermittent crown fire*** A fire in which trees discontinuously torch, but rate of spread is controlled by the surface fire phase (syn. Passive Crown Fire). ***Active crown fire*** A fire that advances with a well-defined wall of flame extending from the ground surface to above the crown fuel layer. Probably most crown fires are of this class. Development of an active crown fire requires a substantial surface fire, and thereafter the surface and crown phases spread as a linked unit (syn. Dependent Crown Fire). ***Independent crown fire*** A fire that advances in the crown fuel layer only (syn. Running Crown Fire).

Forest floor: All organic matter including litter and decomposing organic layers resting on the mineral soil surface.

Forest gardens: Often a form of multistrata agroforest, usually located close to settlements, where many useful species are grown in intimate association for a wide array of household subsistence items and some produce for sale.

Forest inventory: A system for measuring the extent, quantity, and condition of a forest cover, usually by sampling. An assessment of forest resources, including digitized maps and a database which describes the location and nature of forest cover (including tree size, age, volume, and species composition) as well as a description of other forest values such as soils, vegetation, and wildlife features.

Forest inventory non-disclosure: Procedures for safeguarding the locations of inventory plots and proprietary information obtained from them.

Forest landscape design: A branch of landscape architecture where the layout of a new forest or the felling/harvesting of an existing forest is designed to fit into the landscape while meeting a range of management objectives and taking account of practical, legal and economic constraints.

Forest landscape restoration: A planned process that aims to regain ecological integrity and enhance human well-being in degraded or deforested forest landscapes. In practice this means that any landscape will contain a mosaic of land covers including patches of original forest, areas with monoculture plantations, enriched forests and ecologically restored forests.

Forest mensuration: The art and science of locating, measuring, and calculating the length of lines, areas of planes, and volumes of solids; and the appropriate application of these calculations to trees and forest stands.

Forest protection: That section of forestry concerned with the management of biotic and non-biotic damage to forests, arising from the action of humans (particularly unauthorized use of fire, human-caused wildfires, grazing and browsing, felling), natural wildfires, pests, pathogens, and extreme climatic events (wind, frost, precipitation).

Forest recreation: Recreational activities and experiences conducted in forest and associated wildland environments that are dependent on the natural resources of these areas.

Forest sector model: Models that project market equilibria and/or forest resource conditions related to the forest-products industry.

Forest stand dynamics: The study of changes in forest stand structure over time, including responses of trees and stands to disturbances.

Forest stand: The smallest unit of forest management; a unit of land that is relatively homogeneous with respect to site conditions and tree characteristics (e.g., species composition, density, age).

Forest sustainability: Forest sustainability is a process with the objective of assuring that forest resources are and will be sufficient to satisfy present and future environmental, economic, and social needs.

Forest sustainability criteria: See criteria and indication.

Forklift: A device with projecting steel prongs mounted on a truck for lifting and moving heavy loads.

Form factor: The form factor, f, reflects the taper of a tree stem and is a reduction factor, by which the so-called reference cylinder volume ($g \cdot h$) is multiplied to obtain the volume of wood, v. Thus, $v = g \cdot h \cdot f$.

Formulation: The combination of the biocide(s), other inert ingredients, and carrier into a commercially viable system to treat wood.

FORPLAN: FORest PLANning.

FORSKA: A simulation model for the transient effects of climate change on forested landscapes.

Fortified rosin: Rosin stabilized by reaction with fumeric or maleic anhydride.

Forwarder: Off-road forestry vehicle designed for carrying logs.

Fourdrinier: A papermaking machine characterized by a horizontal forming section having a single forming fabric.

Fragmentation: The process of transforming large continuous vegetation or landscape patterns and habitats into smaller patches by disturbance. Natural agents of fragmentation are fire, landslides, windthrow, insects, erosion. Human-induced fragmentations include land use (e.g., agriculture, grazing, forestry), construction of residential areas, roads and other infrastructures. Fragmentation involves change of fire regimes due to alteration and discontinuity of fuels. It may influence forest ecology, diversity and regeneration.

Free sheet: A term denoting paper made from stock having rapid drainage on a paper machine or paper free of mechanical woodpulp.

Free water: Water in the cell lumens or capillaries not bound to cell walls.

Freehold: Full private ownership, that is, free of any obligations to the state other than payment of taxes and observance of land use controls, imposed in the public interest.

Frequency: An ecological measurement that provides an indication of how widely dispersed a species is found in a forest, usually measured as the number of times a species occurs in the sampling units.

Frost heaving: An upthrust of ground due to ice forming in the underlying soil.

FSC: Forest Stewardship Council.

F-test: A statistical test that compares variances, and is often used to test the null hypothesis of no difference among treatment means.

Fuel: All combustible organic material in forests and other vegetation types, including agricultural bio-mass such as grass, branches and wood, or infrastructure in urban interface areas, which create heat during the combustion process.

Fuel accumulation: Process or result of build-up of those elements of a vegetation complex which are not subject to biological decay, reduction by fire, animal grazing and browsing, or harvest by humans; it is used in characterizing fuel dynamics between two fires and has implications on fire behavior.

Fuel arrangement: The horizontal and vertical distribution of all combustible materials within a particular fuel type.

Fuel consumption: The amount of a specified fuel type or stratum that is removed through the fire process, often expressed as a percentage of the pre-burn fuel weight (or fuel load). It includes available fuel plus fuel consumed after the fire front passes.

Fuel management: Act or practice of controlling flammability and reducing resistance to control of wildland fuels through mechanical, chemical, biological, or manual means, or by fire, in support of land management objectives.

Fuel reduction: Manipulation, including combustion, or removal of fuels to reduce the likelihood of ignition and the potential fire intensity, and/or to lessen potential damage and resistance to control.

Fuelbreak: Generally wide (20–300 meters) strips of land on which either less flammable native vegetation is maintained and integrated into fire management planning, or vegetation has been permanently modified so that fires burning into them can be more readily controlled (as distinguished from firebreak). In some countries fuelbreaks are integrated elements of agro-silvopastoral systems in which the vegetative cover is intensively treated by crop cultivation or grazing. Some fuelbreaks contain narrow firebreaks which may be roads or narrower hand-constructed lines. During fires, these firebreaks can quickly be widened either with hand tools or by firing out. Fuelbreaks have the advantages of preventing erosion, offering a safe place for firefighters to work, low maintenance, and a pleasing appearance (cf. control line, agrosilvopastoral system, buffer strip/zone).

Fulvic acid: The portion of soil organic matter that is soluble under both alkaline and acid conditions.

Function: Processes that occur in the forest ecosystem (e.g., growth, nutrient cycling, etc.).

Functional additive: Chemical that mainly affects paper properties when used.

Fungal viruses: Viruses, commonly double stranded RNA (dsRNA), found in fungi that can result in reduced virulence – hypovirulence.

Fungi: Eukaryotic microbes having a branched, filamentous (hyphae, mycelia), or single celled (yeast) growth form. Fungi produce enzymes that degrade complex molecules, and absorb nutrients through their hyphal cell walls. The Eumycota, or true fungi, includes the phyla Ascomycota and Basidiomycota, as well as the Zygomycota and Chytridiomycota, which do not contain any pathogens of significance in forests.

Fungi imperfecti.: Ascomycetes or basidiomycetes that reproduce by asexual means only.

Funicle: The stalk by which a seed or ovule is attached to the placenta.

Furnish: The mixture of various materials that are blended in the stock suspension from which paper or board is made. The chief constituents are the fibrous material (pulp), sizing materials, wet-strength or other additives, fillers, and dyes.

Fynbos: Heath vegetation in South Africa. Derivation possibly from Dutch referring to timber too slender or fine for harvesting. It has also been suggested that the name 'fijnbosch' referred to the dominance of small- or fine-leaved shrubs.

Gall: An abnormal growth or swelling in a plant induced by attack from certain mites, nematodes and insects, or by fungal or bacterial infection.

Gamete: A mature sex cell, either male (sperm) or female (egg). For conifers, there are two sperm cells (derived from the body cell) within each pollen grain.

Gametic selection: Natural selection occurring at the gametic level.

Gametogenesis: The formation of female (eggs) and male (pollen) gametes.

Gametophytic self-incompatibility: A self-incompatibility mechanism prerenting self-fertilization in which successful fertilization is determined by the genotype of the pollen.

Gamma distribution: A probability distribution with density function

$$f(x) = \frac{(rx)^{a-1}}{\Gamma(a)} re^{-rx},$$

where a and r are parameters and Γ denotes gamma function.

Gasification: Thermal degradation process which preferentially produces gaseous products such as carbon monoxide, carbon dioxide, hydrogen, or methane.

Gasifier: A pyrolysis unit that produces combustible gas from solid wood feedstock.

GAYA-JLP: A Norwegian long-range forest management planning model.

Gender: Cultural ideas that construct images and expectations of males and females.

Gene flow: The movement of genes, via seed, pollen, or vegetative propagules, from one population to another.

Gene pool: The genetic resource of a population or species.

Genecology: Study of patterns of intraspecific variation shaped by evolutionary adaptation to environmental conditions.

Gene-for-gene system: Genetic interactions in a pathosystem in which a gene for resistance in a host is matched by a specific and complementary gene for avirulence in the pathogen.

General combining ability: The superiority (or inferiority) of a parent as measured by the relative performance of its offspring compared to the offspring of other parents in genetic tests.

General linear model: A linear model showing the relationships between the variable of interest (e.g., response or dependent variable) and the other variables, such as treatment levels, covariates, etc.

Generic guidelines: Relating to all members of genera.

Genetic diversity: The degree of variability of the genetic material of an organism. Variation of alleles at a particular gene locus, or at a number of gene loci, such that it can be detected through molecular analysis, or statistical analysis of phenotypes from pedigreed populations.

Genetic drift: The evolutionary process by which allele frequencies change due to random sampling error from generation to generation, important in small populations.

Genetic gain: The average (heritable) change from one generation to the next that results from selection.

Genetic load: Genes of deleterious effects, typically recessive in action and masked under conditions of outbreeding. Elimination of such genes is referred to as purging.

Genetic map: A diagram of the relative positions of genetic loci arranged into groups that may correspond to chromosomes.

Genetic marker: An allele with an easily recognized phenotype that can be used to follow the inheritance of genes in genetic crosses.

Genetic resistance: Inherited ability of organisms to avoid ill effects caused by a pathogen.

Genetic resource: The entirety of genes within a species that is available for tree breeding and domestication programs.

Genetic systems: The manner in which hereditary variation is regulated during transmission from the parental generation to the offspring.

Genetic testing: The process of planting pedigreed genotypes in randomized, replicated experiments for a range of purposes.

Genetic value or worth: A statistical measure based on quantitative genetic theory that indicates a level of genetic superiority of one genotype over another. The average breeding value of all seed from contributing parents weighted for the proportion of their contribution.

Genome: The DNA complement of the organism or of an organelle, which can be characterized in terms of total DNA, its organization into chromosomes, the coding and noncoding DNA, and the patterns of recombination within chromosomes. In addition to the main, nuclear genome, there are the chloroplast and mitochondrial genomes.

Genotype: The genetic constitution of an organism as distinguished from its physical appearance (phenotype). Clonal and progeny tests are used to evaluate sets of clones and seedlings (different genotypes) and furnish information on different genotypes but do not necessarily provide information on their breeding behavior.

Genus: Classificatory group containing species possessing certain common structural characteristics distinct from those of any other group.

Geographic information system: A GIS is a computer-based system that provides for the storage and representation of geographic data. GIS data are most commonly stored in a relational database format, from which they can be analyzed, combined and displayed as maps or in other data formats. The primary difference between GIS data and computer-aided design data (CAD) is that GIS data are referenced to a particular geographic location.

Geographic race: A race restricted to a geographical area. Other races may be less well adapted than the local race.

Geometric modeling: Geometric modeling is the creation of mathematical descriptions of the dimensions of real world objects, enabling these real world objects to be represented by 3D computer modeling software.

Germination: Resumption of embryo development after water imbibition and enzyme activation in the seed. 1. Normally beginning with the growth of the radix and ending with the lignification of the seedling. 2. Within the context of pollen viability testing, this is a technique that relates viability with the growth of pollen grains under controlled conditions.

Gibberellins: A class of plant hormones, which number over 100, that occur in most plants including conifers. The mixture of gibberellins A_4 and A_7 (GA4/7) are the active components for inducing flowering in western hemlock as well as most other Pinaceae species.

Girth: See diameter.

GIS: (See Geographic Information System).

Glass transition temperature: The temperature associated with the softening of amorphous polymers, macromolecules which have no crystallinity. Liquid-like flow begins to occur at the glass transition in amorphous polymers.

Glassine paper: A supercalendered, smooth, dense, transparent or semitransparent paper manufactured primarily from chemical wood pulps, which have been beaten to secure a high degree of hydration of the stock.

Gleichläufigkeit: A measure of the year-to-year congruence between the trend changes of two chronologies in dendrochronology.

Global positioning system: A satellite-based radionavigation system comprised of constellation of 24 space satellites and their supporting ground stations, used to obtain precise positions of targets on, or near, the surface of the Earth.

Global warming potential (GWP): A value based on net emissions of carbon dioxide, methane, and other gases shown to have the potential to warm the climate of earth when liberated to the atmosphere.

Gloss: That property of the surface which causes it to reflect light specularly and which is responsible for its shiny or lustrous appearance.

Glue-laminated timber or glulam: A large structural member made from multiple pieces of dimension lumber glued end-to-end and face-to-face.

Good manufacturing practices (GMPs): Standards published in the code of Federal Regulations and used by the Food and Drug Administration (FDA) to ensure the quality of marketed products and that products are produce under sanitary conditions. Any FDA-regulated product can be designated adulterated if the manufacturing methods or facilities for processing do not confirm with GMPs, which are developed through a consultative process between the FDA and the affected industry.

Good practices: To adopt appropriate procedures in order to achieve desired results.

Government land: Land legally belonging to a government at any level.

GPP: Gross primary productivity, i.e., total net photosynthesis of an entire ecosystem.

GPS: See Global positioning system

Grammage: The mass of paper measured in grams per square meter of area. Related to basis weight, which is the weight in pounds of a prescribed area measured in square feet.

Graphical user interface (GUI): A computer interface that uses visual icons and cues as the basis for navigation. GUIs are often referred to as 'point-and-click' interfaces, as they require the user to interact with them by making visual selections of buttons, menus, or slider bar positions, using a mouse or keyboard as the primary input device. Microsoft Windows and Apple Macintosh operating systems are examples of graphical user interfaces.

Gravure printing: Printing from plates in which the image is sunken below the surface, as distinguished from printing by letterpress or offset lithography.

Greenbelt: A fuelbreak maintained by the cultivation of strips of less flammable plants within a zone of high fire hazard, e.g., an irrigated, landscaped, and regularly maintained fuelbreak put to some additional use (e.g., golf course, park, playground).

Greenhouse gases: Gases such as carbon dioxide, methane, chlorofluorocarbons, nitrous oxide and tropospheric ozone that are building up in the atmosphere and that trap radiative heat near the Earth's surface causing global warming.

Gregarious flowering: Simultaneous flowering of all plants even though separate especially if from a given generation; common in bamboos.

Ground vegetation: The herbaceous or shrub species growing beneath a tree canopy.

Groundwood (GWD) pulp: A mechanical pulp produced by pressing debarked logs sideways against a rotating pulpstone in the presence of water and reducing the wood to a mass of relatively short fibers and fines.

Group systems: Modifications of the selection, shelterwood or clear cutting (clear felling) silvicultural systems in which small groups, rather than whole or sub-compartments are treated at a time.

Growing space: The net presence of the factors (light, moisture, nutrients, and physical space) required for tree growth.

Growth and yield model: Model that projects future stand or tree characteristics from a given set of initial conditions.

Growth form: The morphology and structure of a plant (e.g., grass, herb, shrub, deciduous tree).

Growth rings: Seasonal growth of wood in a ring around the central axis of a tree as seen on the cross (transverse) section; composed of two growth regions-that formed early in a season – earlywood or low density wood; and that formed later – latewood or high density wood; if one growth ring is formed annually, it is called an annual ring. (See Dendrochronology)

Growth/productivity: Changes in total volumes of plants or parts of plants.

Gt: Giga-ton (giga $= 10^9$).

GTM: Global Trade Model.

GW: Groundwood.

Gymnosperms: A subdivision of the seed plants, distinguished from angiosperms in that the ovules are not enclosed by material tissues but supported naked on the cone scales. Includes all coniferous trees.

h^2: Heritability: genetic parameter used to estimate the proportion of the phenotypic variation of a trait that is due to gene effects.

Habitat: The place or type of site where an organism or population naturally occurs.

Habitat fragmentation: See Fragmentation.

Haploid: Refers to the state of having only a single set of chromosomes, as in the pollen grains and the megagametophyte that produces the egg cells with which pollen nuclei fuse to produce zygotes.

Haploxylon pines: Members of the subgenus *Strobus* of pines, characterized by having one fibrovascular bundle in each needle.

Hardiness: The ability of plants to endure freezing temperatures without being killed.

Hardwood: 1. Tree belonging to the botanical group Angiospermae. Synonym broadleaved. 2. Common and timber tradename for broad-leaved, commonly deciduous, woody angiospermous trees. 3. Pulpwood from broad-leaved dicotyledonous deciduous trees. 4. A term applied to wood obtained from trees of the angiosperm class. The hardwoods are obtained from dicotyledonous trees such as birch, gum, maple, oak, and poplar. The leaves are broad except in rare instances and are usually deciduous in the temperate zones. The seeds are enclosed in a fruit that is either fleshy or dry at maturity. Hardwoods are also designated as porous woods.

Harvester: Off-road forestry vehicle designed for felling, delimbing and bucking trees.

Hazard reduction: Treatment of living and dead forest fuels to reduce the likelihood of a fire starting, and to lessen its damage potential and resistance to control (cf. Fuel Treatment). Activity gaining special importance in residential/wildland interface areas.

Heartwood: Physiologically inactive (dead) inner core of a tree stem or log, usually darker in color than the outer portion of the stem (sapwood); sometimes possessing odor, taste, and higher durability. The high amount of extractives and a low moisture content are features of heartwood. The wood of tree species with true heartwood is often more resistant to wood-decaying fungi than that of many other species. These include pine, larch, oak, robinia, elm, walnut, and cherry.

Heat pump: A device which alternatively compresses and expands a refrigerant and uses heat exchangers to move energy from a colder region to a warmer region.

Heat treatment: Heating wood, typically above 180°C, in an inert atmosphere to cause sufficient chemical changes to render the wood partially resistant to attack by wood-decaying fungi.

Hedgerow intercropping: An agroforestry practice in which fast-growing shrubs, that are often nitrogen fixing, are grown between strips of crops and periodically cut back to provide a nutrient rich mulch to fertilize the crop; also referred to as alley cropping. Woody parts may be retrieved for kindling fires.

Hedonic pricing: Placing cash value on pleasure.

Height: Total tree height, *h*, is defined as the shortest distance either between base and top of the tree, or between ground level and top of the tree. The first definition may be preferred because it is often compatible with the length of felled trees and a consistent measure for volume calculations, whereas the second definition may be generally more practical. Other height definitions may refer, for example, to merchantable parts of the tree. Also, see stand height.

Heliophilus: Adapted to high intensity of light.

Hemiepiphyte: Epiphytic plant which starts its development growing on the surface of trunks and branches of other plants, but later sends its roots down to the soil in order to access soil nutrients; in some cases, it may behave as a strangling plant (e.g., in *Clusia* and *Ficus*) affecting the health of its host.

Herbivory: The consumption of plant tissue by animals.

Herbs: Non-woody plants that die down at the end of the growing season.

Heritability: Degree to which a trait is transmitted from one generation to another (i.e., from the parent tree to its seed). Highly heritable traits are those under strong genetic control. Traits that are also influenced by the environment are less heritable. The proportion of total or phenotypic variation that is governed by genotypic effects. Narrow-sense heritability relates to purely additive gene effects, broad-sense to total gene effects.

Heterochromatin: Compact chromosomal segments or whole chromosomes with a dense structure which accept dyes in telophase, interphase, and early prophase, as distinct from euchromatic segments.

Heteroecious: Having certain spore forms of the life cycle on one host species and others on an unrelated host species.

Heterosis: Superiority of the F_1 generation compared with the parental generation with respect to a metric trait.

Heterozygote: An organism in a diploid state where the alleles at a given locus are different. Heterozygosity is common in allogamous plants.

Holistic management: A management approach that takes into account all relevant factors when making a decision.

Homeopathy: Homeopathy is a form of medicine system that treats the body as a whole and helps it to heal itself. It is based on the principle that substances that are poisonous in large doses can be beneficial in small doses. In this practice extremely small doses of medicines, mostly derived from herbs, are used to cure the disease.

Homozygote: An organism in a diploid state where both alleles at one locus are the same. Homozygosity is predominant in autogamous plants.

HOPSY: Houtoogst Prognose Systeem (Wood Harvest Forecast System).

Horizontal precipitation: Horizontal water influx into an ecosystem due to the condensation of small water particles originating from mist and fog, on top of the surface of the vegetation.

Hot spot: A recently coined term to draw attention to areas of both high species diversity and that are also under severe threat of destruction.

Humic acid: The portion of soil organic matter that is soluble under alkaline conditions but is acid insoluble.

Humidity or absolute humidity: Mass of water vapor contained in a unit mass of dry air.

Humin: The insoluble portion of soil organic matter.

Humus: Organic component of soil derived from dead and decaying plant and animal remains.

Hybrid breakdown: The reduction in fitness of F_2 and/or backcross generations compared to the F_1 and parental generations. This decline may involve weakness of vegetative growth, sterility, or both of these; it is over and above any loss of vigor due to the lowered heterozygosity if inbreeding is involved. Hybrid breakdown is also known, perhaps more appropriately, as advanced generation breakdown or later generation breakdown.

Hybrid geometric/photo-imaging: A combination of geometrically modeled objects (3D) and photographic elements. The combination may take the form of a photograph draped over a geometric shape (e.g. an aerial photograph placed on a landscape model, or a photograph of a building facade placed on a geometric representation of the building) or they may involve the placement of photographic elements onto a 3D terrain surface (such as 2D 'billboard' trees that turn so they always face the viewer).

Hybrid swarm: A natural population of hybrid offspring of two or more related species encompassing several generations including the backcross generation.

Hydraulic conductivity (or permeability): Property of a saturated porous medium which determines the relationship, called Darcy's law, between the specific discharge and the hydraulic gradient causing it.

Hydraulic loading: The amount of wastewater applied in a complete operational cycle; usually expressed in inches per week.

Hydrocarbons: C-H compounds, such as methane (CH_4).

Hydrogen bonds: Bonds that occur between the hydrogen of one molecule and the electronegative atom of another molecule such as oxygen.

Hydrolysis: Method by which polysaccharides from wood are depolymerized by the action of chemicals or enzymes, in preparation for fermentation to other products.

Hydroperiod: Period of time that an area is inundated.

Hygrophilous: Plants restricted to moist conditions.

Hypersensitive reaction (HR): Local necrosis of cells in response to pathogen invasion.

Hyphae: Vegetative 'threads' of growth in fungi that make up the mycelium.

Hypogeal: Of seed germination in which the cotyledons remain underground.

Hypolimnion: Lower (cooler) layer of thermally stratified lakes.

Hyporheic exchange: Interchange of streamwater with water occurring within or below the streambed.

Hyporheic zone: Area where surface water and groundwater interact.

Hypsometer: Instrument for measuring the height of standing trees. Direct height measurement may be carried out using a graduated rule, stick, pole or tape measure. Indirect height measurement is based on geometric or trigonometric principles. The geometric principle relies on the use of similar triangles, whereas the trigonometric principle makes use of trigonometric functions. Modern instruments use optical and laser methods and may be digitized for recording.

Ideotype: A set of characteristics, representing specific levels of expression of certain traits, that embody a breeding goal.

IFS: Interactive Forest Simulator.

IIASA: International Institute for Applied Systems Analysis.

Immunoassay: Use of immune reactions in animal material, in this case to evaluate plant taxonomic affinities.

Importance index: An index calculated from relative density and relative dominance of a selected plant family or species.

Imputation methods: Methods for substituting data for missing observations.

INA: Information needs assessment or analysis.

Incident Command System: A standardized on-scene emergency management concept specifically designed to allow its user(s) to adopt an integrated organizational structure equal to the complexity and demands of single or multiple incidents, without being hindered by jurisdictional boundaries (element of the Incident Command System [ICS]).

Inclusion: One or more polypedons or parts of polypedons within a delineation of a map unit that is not one of the named component soils.

Incompatibility: The state in which functional female and male organs are unable to achieve fertilization. Self-incompatibility prevents self-fertilization after self-pollination, and interspecific incompatibility blocks species hybridization.

Incompatibility system (genetic incompatibility): Inability of plants having functional gametes to set seeds when either self-pollinated or crossed with some of their genetic relatives.

Increment: The change in a particular measure of tree growth (e.g. height, diameter, basal area or volume) over a particular time period.

Indehiscent fruit: A type of fruit that does not open at maturity.

Independent, normally distributed, with equal variances: A trio of assumptions about residuals that are required for least-squares estimates to have desirable properties.

Indexing: Detrending a tree-ring curve to differentiate between short-term and long-term oscillation by dividing the measurements by a standardizing smoothing function, resulting in a time series of ring-width indices.

Indicator: A quantitative, qualitative, or descriptive measure that, when periodically measured and monitored, shows the direction of change. Indicators are species or communities that enable an evaluation of environmental conditions and detect changes. Indicator species are normally surrogates of other species in the area of interest and are usually sensitive to environmental change. Environmental variables may also be used as indicators.

Indigenous: See Autochthonous.

Indigenous knowledge: The knowledge belonging to a specific ethnic group.

Industrial roundwood: Wood to be used for manufacture of wood or paper products.

Infection: The process by which a pathogen establishes a parasitic relationship with a host organism. Infection is usually considered the initial establishment of a parasite with its host, and colonization is the expansion of the parasite in its host.

Inflorescence: The arrangement of the flowers on the flowering branch.

Information dissemination: To share information, with a purpose of raising awareness, improving skills and practices and enhancing knowledge in a given community.

Information open house: A venue where information on a project or issue is displayed or presented for a specified time period, to which the public is invited.

Infraspecific: At a lower taxonomic level than a species.

Infructescence: An aggregate fruit, with the same relation to a simple fruit that an inflorescence has to a single flower.

Inoculation: Arrival or transfer of a pathogen on to a host plant.

Inoculum: The amount of fungal, bacterial, viral, etc., propagules available and potentially capable of infecting a host plant.

Inoculum potential: A term to describe a sufficient base of energy enabling a fungal pathogen to spread.

***In-situ* conservation:** To conserve species or populations inside their natural habitat.

***In situ* remedial technology:** Remediation accomplished onsite without excavation and removal of material, e.g., bioremediation, phytoremediation, natural attenuation.

Integrated Forest Fire Management (IFFM): Designation of fire management systems which include one or both of the following concepts of integration: (1) Integration of prescribed natural or human-caused wildfires and/or planned application of fire in forestry and other land-use systems in accordance with the objectives of prescribed burning; (2) Integration of the activities and the use of the capabilities of the rural populations (communities, individual land users), government agencies, NGOs, POs to meet the overall objectives of land management, vegetation (forest) protection, and smoke management including 'community-based fire management' or CBFiM. The term IFFM is common for fire management approaches in less developed regions including forest and non-forest ecosystems. Note: In case of absence of forests in the area concerned the term *Integrated Fire Management* (IFM) is used instead (cf. prescribed burning).

Integrated inventories: Combined or coordinated data collection efforts designed to share data and to improve information flows between functions, sister units, parent units, and/or over time.

Integration: The act of combining or coordinating separate elements so as to provide a harmonious, interrelated whole.

Interactions among factors: Effects of a particular factor vary depending on the level of another factor. If there is no interaction, the two factors can be interpreted separately.

Interblock information: Information about the treatment effects that may be extracted from differences between the effects of blocking levels in incomplete block designs.

Interior spruce: Naturally occurring hybrid between white (*Picea glauca*) and Engelmann (*P. engelmannii*) spruce.

Intermolecular forces, secondary forces: The association and attraction between complementary charges (positive and negative) which occur on the surfaces of all molecules. These are called secondary forces (or bonds) because they are relatively weak and temporary, in contrast to primary forces (and bonds).

Interpolation: The computation of points or values between ones that are known using the surrounding points or values.

Intrageneric: At a lower taxonomic level than the genus but above that of the species.

Intraspecific taxonomy: Genetic or phenotypic variation within a species, i.e. varieties or subspecies.

Introgression: The progressive incorporation of genes from one population into another by hybridization events and back-crossing.

***In vitro* culture:** Propagation of plants from small pieces of tissue in enclosed sterile conditions on nutrient medium.

Inventory: Originally a commercial term consisting of the preparation of a detailed descriptive list of articles with number, quantity, and value of each item. As forest inventory: a set of techniques for collecting reliable and satisfactory information on species, volumes and values of forests.

Inverse density dependence: The effect decreases as a percentage of the population as the population increases in density.

Involucel: A whorl of bracts surrounding one of the divisions in an inflorescence.

Irregular: Of a regeneration method, characterized by variation in age structure (usually uneven-aged) or in spatial arrangement of trees.

ISO: International Standards Organization. Among many other things, it sets standards for aspects of paper manufacture, e.g., brightness.

Isozyme: Enzymes that exist in alternative forms that can be differentiated in laboratory tests and used to provide information or genetic variation.

IUCN: The World Conservation Union.

JLP: A linear programming package for management planning by Juha Lappi.

Johnson's SB distribution: A probability distribution with density function:

$$f(x) = \frac{\delta\lambda}{(x-\xi)(\xi+\lambda-x)}\frac{1}{\sqrt{2\pi}}\exp\left(-0,5z(x)^2\right)$$

where

$$z(x) = \gamma + \delta \ln\left(\frac{x-\xi}{\lambda-\xi-x}\right)$$

and γ, δ, ζ and λ are parameters.

Joint forest management: Management of forest by the State forest department and the village forest councils.

Kairomone: Chemical emitted by an organism that is detected by other species (e.g., tree kairomones detected by bark beetles).

Kappa number: A measure of residual lignin present in pulp.

Karyotype: The configuration of the chromosome complement, in terms of the number of chromosomes, relative lengths, and positions of the centromeres of individual chromosomes, plus secondary features such as constrictions, zones of heterochromatin, and banding patterns.

Keystone species: A species that has a major influence on the structure of an ecosystem.

Krummholz: A stunted growth form of trees at the upper treeline or in the alpine zone due to wind and blowing snow.

Kwongan: Western Australian Aboriginal term for heathland.

Lagged or delayed-density dependent factors: Factors of which the effect is not apparent until subsequent generations of the populations.

Laminated strand lumber (LSL): A dimension lumber-sized structural member composed of thin strands of wood glued together such that the grain of each strand is parallel to the member's length. Also parallel strand lumber.

Laminated veneer lumber (LVL): A dimension lumber-sized structural member composed of multiple sheets of veneer glued together such that the grain of each ply is parallel to the member's length.

Land limiting constituent (LLC): The waste constituent that requires the largest land area for assimilation.

Land race: Usually an introduced species which has undergone some form of natural selection to the local environment and has become well adapted after one or a few generations.

Land tenure: The terms on which land is held: the rights and obligations of the holder of the land.

Land treatment: The practice of applying partially treated liquid and/or solid wastes produced by municipalities and industries to the land for further treatment, recycling beneficial nutrients, improving site productivity, and protecting surface and ground water supplies.

Landing: Place where round timber is stored, sorted, and assembled for secondary transport, commonly with a change of transport method.

Landscape: Within the context of forests, this term holds different meanings for different types of professional. In the context of visual analysis, it refers to the overall visual appearance of a place or area together with the underlying biophysical and cultural factors which affect perception and the quality of experience of the viewer.

Landscape character: The combination of a set of physical, ecological, and visual factors which combine to give a landscape a unique sense of identity.

Landscape diversity: The spatial heterogeneity of the various land uses and ecosystems within a larger area.

Landscape (visual) sensitivity: A measure of the likely concern expressed by the public over landscape change in a given area. Usually assessed from a combination of degree of visibility, numbers of viewers, the nature of the viewing experience, and the value or quality of the landscape.

Landscape visualization/visual simulation: One or more images showing an existing, future, past, or imaginary set of conditions in perspective view, usually in the context of an actual place. These may have various levels of realism.

Larderhoarding: The collection, movement, and storage in single or few locations of resources, usually fruit or seed, by animals.

Larva: Grub-like, immature form of bark beetles and other insects.

Late burning: Prescribed burning activities towards the end of the dry season.

Latent pathogens: Pathogens, often endophytic and not associated with symptoms, that remain latent in plants until the onset of stress.

Laterite: Hard, impenetrable soil.

Latex paint: A paint containing pigments and a stable water suspension of synthetic resins (produced by emulsion polymerization) that forms an opaque film through coalescence of the resin during water evaporation and subsequent curing.

Lathe: A machine for shaping a piece of wood by holding it at its ends and rotating it rapidly against a cutting tool.

Laticifers: Latex-producing glands.

LEA proteins: Late embryogenesis abundant proteins, encoded by the *lea* genes. They appear late in embryogenesis and accumulate to a relatively high concentration.

Leaf area index: The area of foliage per unit area of ground. Leaf area is usually calculated based on the upper surface of flat leaves. It can also be the area of complex leaves projected onto a flat surface.

Least-squares analysis or techniques: Statistical methods where the objective is to find a solution that minimizes the sum of squared differences between observations and predictions.

Lentic: Associated with still water.

Leptomorph: Slender and continuous rhizome of monopodial bamboos.

Lerp: Starch shell of sedentary nymphs of psyllids, important sapsucking insects found on eucalypts.

Liana: Woody climbing plant that grows from the soil into the tree canopy; tropical woody vines.

Life cycle assessment (LCA): An evaluation of the environmental impact of a process or product including measurable inputs and outputs (as determined in an LCI), as well as impacts that are not precisely measurable (i.e., impacts on human health, landscape impacts).

Life cycle inventory (LCI): A systematic accounting of all measurable inputs and outputs to a manufacturing process, including raw materials, products and co-products, and emissions to air, water, and ground.

Light demander: See shade bearer.

Lignin: A very variable cross-linked polymer of phenyl propane units such as coniferyl alcohol (guaiacyl), sinapyl alcohol (syringyl) or hydrocinnamyl alcohol, and which stiffens the cell wall. The noncarbohydrate portion of wood that is removed to various degrees during chemical pulping.

Line-plot transects: Plots located along lines at various intervals across a central transect.

Linguistic: Of or relating to language.

Linkage disequilibrium: A nonrandom association between specific alleles at different loci, normally reflecting location on the same chromosome.

Linkage group: A group of coupled genes within a chromosomal segment.

Lipid: Any of a group of organic compounds, including the fats, oils, waxes, sterols, and triglycerides, that are insoluble in water but soluble in nonpolar organic solvents, are oily to the touch, and together with carbohydrates and proteins constitute the principal structural material of living cells.

Liquefaction: Thermal degradation process in which wood is liquefied under conditions of elevated temperature, in the presence of catalysts.

Litter: The surface layer of the forest floor that is not in an advanced stage of decomposition, usually consisting of freshly fallen, recognizable, leaves, needles, twigs, stems, bark, and fruits. It includes all nonliving biomass in various states of decomposition above the mineral or organic soil.

Litter raking: The practice of regularly gathering forest litter (leaves/needles, twigs, and branches) from beneath a forest stand for fuel, bedding for livestock and other domestic uses.

Llanos: A Spanish term referring to large expanses of plains found mostly in Colombia and Venezuela.

Loam: Soil with sand, silt, and clay in almost equal proportions.

Locus: A site on a chromosome occupied by a specific gene.

Lodging: Wind damage to crops either by uprooting or by stem/stalk breakage. Enhanced by high turbulence levels.

Log-normal distribution: A probability distribution with density function

$$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} \exp\left(-\frac{1}{2}\frac{(\ln(x)-\mu)^2}{\sigma^2}\right),$$

where μ and σ are parameters.

Long-horn beetles: Wood-boring insects belonging to the family Cerambycidae that tend to have long antennae.

Long-term productivity: Yields of forest crops over long intervals of time, especially from successive rotations.

Loose tipping: This method of ground preparation involves the use of dump trucks to transport soil or soil-forming materials to the deposition area on the reclamation site. There, it is tipped in heaps on the surface of the overburden which are spread and levelled using an excavator working from the overburden surface.

Lotic: Associated with flowing water.

Low thinning: See thinning.

Lowland: The altitudinal belt between sea-level and the montane belt, with its upper limit in the tropics generally at about 1000 m elevation.

LP: Linear programming.

Lumber: The product of the saw and planing mill for which manufacturing is limited to sawing, resawing, passing lengthwise through a standard planing machine, crosscutting to length, and matching. Lumber may be made from either softwood or hardwood.

LWC: Light-weight coated papers.

Machine glazed finish: The finish produced on a Yankee machine, where the paper is pressed against a large steam-heated, highly polished revolving cylinder, which dries the sheet and imparts a highly glazed surface on the side next to the cylinder, leaving the other side rough.

Macromolecules: This is another term for polymer. Polymers are so unusually large that they are called macromolecules, as opposed to very small molecules like water.

Macrophyte: Any aquatic plant visible to the naked eye (includes algae and higher plants).

Macropores: Soil pores through which water can move rapidly and which are mostly formed by plant roots, soil structure, and burrowing animals (e.g., earthworms). Water flow in macropores is often turbulent and driven by gravity.

Major gene resistance (MGR): Resistance conditioned by single, dominant genes (R genes).

Mallee: Low-growing, multi-stemmed eucalypts generally 2–10 m tall and with woody lignotuber.

Mangal: Vegetation in swampy or tidal areas, often called mangroves.

Map unit: A group of delineations identified by the same name in a soil survey that represent similar landscape areas comprised of the same component soils plus inclusions.

Map-based estimation: A system that combines techniques for constructing maps of forest attributes and techniques for calculating estimates from those maps that are unbiased and sufficiently precise at the required spatial scales.

Maquis: Heath vegetation in New Caledonia. (Closest to Corsican use of the term rather than French.)

Marcotting: Propagation on the intact plant by air-layering (area where bark has been removed is enclosed in propagation medium).

Marginal thinning intensity: The maximum volume of growing stock that can be removed in thinning without decreasing future cumulative production. This volume is known to be close to 70 per cent of the maximum mean annual increment over the 'normal thinning period.'

Massart model: A tree growth and architecture model, which involves a straight trunk, horizontal branches, and rhythmic growth and branching.

Massenerhebung: A mass elevation or telescope effect causing a compression of altitudinal vegetation belts on smaller tropical and temperate mountains (German term).

Mast seeding: The synchronous and massive production of fruit by trees. Irregular variation between years in seed output with high output at variable intervals. Masting shows highest seed crop variability at mid latitudes and in the southern hemisphere, which are similar to the patterns in variability of rainfall. Masting may be an adaptive reproductive trait (e.g., to allow effective pollination or to overwhelm predators) overlaid on the direct influence of weather.

Mata Atlantica: The Atlantic Coastal forest of Brazil, a hot spot that is full of endemic species and is under severe threat with only 7% of its original area remaining.

***Matsukuimushi*:** A general term which formerly covered more than 70 species of pine bark beetles and pine wood borers. At present, an administrative term which indicates Japanese pine sawyer.

Matrix habitat: Habitat surrounding forest fragments; it is often highly disturbed or distinct.

Maximum likelihood techniques: Methods where the objective is to find a solution that maximizes the probability of observing the sample data.

Maximum size-density relation: Trees growing in single-species even-aged stands do not grow beyond a specific size for a given density. When expressed as the logarithm of size versus the logarithm of density the maximum size-density relation has the slope of $-3/2$. The relation is independent of site quality and age and the intercept depends on the species.

MDS: Mobile Data System; vehicle computer linked on-line to a central company server.

Mean: The average value of a variable for all units in a population or sample.

Mean annual increment (MAI): the total increment of a tree or a stand (standing crop plus thinnings) up to a given age divided by that age.

Mean (quadratic) dbh: The dbh corresponding to the average basal area of a group or stand of trees. This is the root mean square dbh and not the same as the arithmetic mean (average) dbh.

Mechanical woodpulp: A high-yield pulp produced from wood by a variety of mechanical pulping processes. It is characterized as a woodpulp with high lignin content. It is primarily suitable for printing grade papers, but can be used in other paper grades, like tissue, board, and fluffed pulps.

Median: The value of a variable so that half of the values are larger and half are smaller than this value in a population or sample.

Megagametophyte: Female gametophyte in heterosporous plants; embryo sac within the ovule in angiosperms.

Meiosis: Nuclear divisions leading to the formation of gametes (either egg or sperm cells). The first division results in reducing the number of chromosomes in half (haploid) and the second division results in the formation of four haploid daughter nuclei.

MELA: MetsäLAskelma, a Finnish forestry model.

Melting temperature: The temperature associated with melting of crystals, and in this context, the crystals present in semicrystalline polymers. Liquid-like flow begins to occur at the melting temperature of semicrystalline polymers, as in the case of hotmelt adhesives.

Mensuration: Generally the study of the measurement of geometric magnitude. In forestry the measurement of the number, volume, dimensions and shape of trees and stands.

Meristem: An undifferentiated plant tissue, often with rapidly dividing cells, from which new tissues or organs arise. In woody plants the primary epical meristems of shoots and roots provide principally for extension growth while secondary cambil meristems initiate the production of wood and diameter growth.

Mesic habitat: Moist habitat.

Mesocarp: The middle layer of the fruit wall.

Mesophyllous: Having leaves of medium size.

Mesophytic: Sites or habitats that are neither too wet not too dry.

Mesopredators: Predators of medium size.

Metacentric: Refers to the state of a chromosome having the centromere (the attachment point for the chromosome being pulled clear towards the end of cell division) located near the middle.

Metapopulation: A group of smaller populations whose persistence is dependent on the dispersal of individuals between them.

Methanogenesis: The biological production of methane.

Microfibril: Microscopic strands in a wood cell wall composed of a core of bundled, parallel cellulose chains encased in other polysaccharide, nonglucose sugars; the cellulose chains have crystalline and amorphous regions. The angle of the microfibril to the long axis of a wood fibre influences strength and flexibility.

Microgametophyte: Male gametophyte of a heterosporous plant; pollen grain in a seed plant.

Microphyllous: Having small leaves.

Micropores: Soil pores through which water moves very slowly and can retain water against gravity. The capillary concept is valid in micropores.

Micropyle: A wide, funnel-shaped structure arising from the integument and surrounding the nucellus through which the germinating pollen tube must pass to penetrate the nucellus to reach the egg cell.

Microsatellites: A class of highly variable, codominant (both alleles at a diploid locus may be visualized) DNA marker.

Microsclerotia: Very small thick-walled survival structures in fungi.

Microspore: The male pollen grain which is mature at shedding and consists of five cells; two prothallial cells, a stalk cell, a body cell, and a tube cell

Microtubules: Tubular structures composed of subunits of the protein tubulin. They occur in large numbers in all eukaryotic cells freely in the cytoplasm or as a structural component of organelles. In addition, they form part of the structure of the mitotic spindle.

Migratory users: Resource users who are not settled where the resource is located and use it at intervals often as part of a pattern of moving from one resource location to another. (e.g., branshumance, nomadic pastoralism)

Mineral soil: Soil comprised of less than 18% (weight) organic carbon.

Mineralization: Conversion of an element from an organic form to an inorganic state as a result of microbial decomposition. Release of inorganic forms of nutrients from complex-carbon bonded forms during decomposition of organic matter.

Ministerial Conference for the Protection of Forests in Europe: The periodic Conference and its inter-sessional activities promote and reinforce cooperation among European States in the field of forest protection and sustainable development.

Miocene: Geological epoch (23.8–5.3 million years ago) of Tertiary period.

Miombo: Open, African woodland dominated by ***Brachystegia*** and related legume genera.

Mode: The value of a variable that occurs most frequently in a population or sample.

Model: Abstract representation of a system, often mathematical.

Model forest: A partnership of individuals and groups representing diverse forest stakeholders working together to develop and demonstrate approaches to SFM that are locally acceptable and nationally relevant; people with an interest in the forest participate in decisions its sustainable management and demonstrate this in operational terms. A model forest is of a size that includes the full range of forest uses and needs that are considered in the surrounding geographic region and which is representative of a broad ecosystem.

Model resolution: Level of detail, or smallest item represented.

Model scope: Breadth or area of interest.

Moisture content: Mass of water contained in a unit mass of wood, usually expressed as a percentage of its dry mass.

Moment: The k^{th} moment of x is the expected value of x to k^{th} power $E(x^k)$.

Monad: A dispersal unit comprising one pollen grain.

Monitoring: The process of taking repeated observations of the same variables in the same area over time to note changes and to predict trends. Continuous forest inventories or repeated inventories across the same area over time are a form of monitoring.

Monocotyledons: One of two great division of flowering plants in which the embryo characteristically has one cotyledon and the nervation is generally parallel. (cf. Dicotyledons).

Monoecious: Plants in which male and female reproductive organs occur separately on the same individual.

Monoecy: The system in which plants have separate female and male flowers but borne on the same individual.

Monophyletic: A group that includes all the evolutionary descendants of a taxon's common evolutionary ancestor and only those descendants.

Monopodial bamboo: Bamboo with a single and continuous rhizome, with lateral buds that grow into culms.

Monopodial: Stem developing by repeated growth of the principal buds.

Monotypic genus: A genus that contains only a single species.

Montane: 1. Living in mountains. 2. The altitudinal belt between the lowland belt and the (sub)alpine belts, which in the tropics is generally situated between 1000 and 3000 m elevation.

Monte Carlo simulation: Random values for uncertain variables are generated many times to simulate the behavior of a stochastic system.

Montreal Process: An initiative of the Government of Canada to develop forest sustainability criteria and indicators for non-tropical boreal forests. Montreal Process member countries include: Argentina, Australia, Canada, Chile, China, Japan, Republic of Korea, Mexico, New Zealand, Russian Federation, United States of America, and Uruguay.

Moran effect: The synchronization of fluctuations in population density over a wide geographic area that are driven by environmental factors such as weather.

Mor: Forest humus type characterized by accumulation of organic matter on the mineral soil surface and an abrupt boundary between the organic horizon and the underlying mineral soil.

Mortality: Number of (tree) deaths caused by, e.g., a disease.

Mortise-and-tenon: A method of joining two pieces of wood in which a projecting part of one is fitted into a hole or recess in the other.

Motivations: The underlying reasons and forces that often serve as the antecedents to a person's observed actions and behavior.

Mottle: Mottle is a patchy appearance of paper due to a nonuniform coating distribution causing density, gloss, and brightness variations.

MRI: Multiple Resource Inventory.

Mulch: Ground cover put in place to reduce evaporation, maintain even soil temperature, prevent erosion, control weeds, or enrich the soil.

Mull: Forest humus type characterized by incorporation of organic matter in the mineral A horizon without the buildup of Oa and Oe horizons.

Multilayered paperboard: A paperboard made up of two or more plies that are hydrogen bonded to each other.

Multilocus genotype: Definition of an individual's genetic structure which incorporates information from multiple loci.

Multiple comparison and contrasts, and pairwise tests: Tests comparing particular treatments, once an overall difference among factor levels is detected.

Multiple population breeding: Method of integrating gene conservation and tree improvement goals based on subdivision and management of breeding populations to increase their genetic divergence over time.

Multiple resource inventories: Data collection efforts designed to meet all or part of the needs of two or more sectors (i.e., timber and wildlife, wildlife and range management).

Multiple use silviculture: Silvicultural practices which aim to provide a wide range of outputs from a stand.

Multiseriate: Formed of many rows of cells. (e.g. some rays in wood).

Multistrata agroforests: Involves mixtures of plants that grow to different heights. They often involve plantation tree crops such as cocoa, coffee, and rubber combined with shade trees and herb crops.

Municipal solid waste (MSW): Material in the regular periodic collection stream of discards from an urban community.

Mutualism: A symbiosis in which two associated organisms contribute mutually to the well-being of each other, especially where the relationship is not necessary for the survival or reproduction of the organisms involved.

Mycelium: A matted mass of fungal hyphae that form the vegetative body of a fungus.

Mycophagy: Fungus consumption, an important part of eucalypt forest ecosystems.

Mycorrhiza: Intimate symbiotic association of tree roots and fungal mycelia that greatly increases the absorptive area of the root system.

Nanic: Dwarfed state due to arrested development.

Nanophyllous: Having very small leaves (dwarfish).

NAPAP: North American Pulp and Paper.

National parks and sanctuaries: An area of land dedicated to the protection of a focal taxon or groups of taxa (e.g., tiger reserves, wildlife sanctuaries).

Natural attenuation: Destruction and/or immobilization of organic or inorganic contaminants through microbial, chemical, and physical processes.

Natural durability: Resistance of wood to degradation by wood decay fungi and/or insects, particularly by the heartwood of many tree species, mainly due to extractive compounds accumulated in the heartwood as the tree ages.

Natural forest: An area of land which supports a minimum of 20% tree cover that has arisen as a result of natural processes of establishment and succession.

Natural selection: The differential fitness (survival and reproduction) of individuals with different genotypes producing different phenotypes for adaptive traits.

Nearest neighbor methods: Methods is that produce estimates of attributes for selected units by combining observations of the attributes obtained from units that are similar in a covariate space to the unit for which the estimate is required. Nearest neighbor methods include *k*-nearest neighbors, most similar neighbor, and gradient nearest neighbor.

Nearest neighbor tree: The tree (with a DBH higher than the minimum DBH) with the minimum distance to the tree of subject.

Necromass: Dead biomass (litter, dead plant materials).

Necrosis: Process of cell death in plants, resulting in a brown discoloration of affected tissues.

NEE: Net ecosystem exchange of CO_2; the dynamic balance between photosynthesis and respiration.

Needle blight: A foliage disease of conifers in which the foliage is killed rapidly after infection, turns brown, and typically remains attached to the branch. Foliage blights often have asexual states that can produce numerous conidia (asexual spores) under favorable conditions, leading to increased disease severity. Needle blights of conifers include *Sphaeropsis sapinea* and *Mycosphaerella pini*.

Needle cast: Premature abscission of conifer needles caused by a needle cast pathogen. The pathogens typically have a prolonged development time (at least 9 months) and symptoms are slow to develop after infection. Needle cast pathogens include fungi in the Rhytismatacaeae (e.g., *Cyclaneusma)*, Hemiphacidiaceae (e.g., *Rhabdocline, Meria)*, and Mycosphaerellaceae (e.g., *Phaeocryptopus)*.

Negative draw: A tissue-manufacturing process in which the forming section of the paper machine is operated at a higher speed than the Yankee or TAD dryer.

Nematode: A microscopic unsegmented round worm with well-developed digestive and reproductive systems.

Neo-formed leaves: Leaves initiated throughout the growing season as opposed to preformed leaves that arise from primordia that over winter in buds.

Neotropics: The tropics of the New World, tropical America.

Networking: Developing a broad list of contexts for a common goal and interacting with a large number of like-minded people through different means.

Neutral variation: Genetic variation which has no selective advantage.

Newsprint: A generic term used to describe a grade of paper of the type generally used in the publication of newspapers. The furnish is largely mechanical woodpulp, with some chemical woodpulp.

NFI: National forest inventory.

Niche: Functional position of an organism in an ecosystem; the portion of the environment, defined in terms of conditions that a species needs to survive.

NIRA: Near-infrared reflectance analysis. The technique is widely used in agriculture and is now being used to assess expensive to measure wood properties such as pulp yield and cellulose content. The wood sample is ground to produce a pulp meal, which is then measured in a spectrophotometer. A calibration is developed that relates the spectra of large number of samples to their known chemical constitution, which is then used to predict the chemical constitution of further samples from their NIR spectrum.

Nitrification: The oxidation of ammonium compounds in dead organic matter to nitrite and nitrate by soil bacteria.

Nitrogen fixation: Biological conversion of elemental nitrogen (N_2) to organic combinations or to forms readily utilized in biological processes. It is commonly achieved by Actinomycetes (**Frankia**) and bacteria (**Rhizobium**) in special structures in plants, e.g., root nodules.

Nival: The snow belt on mountaintops.

Nodulating: Capable of forming root nodules with nitrogen-fixing bacteria.

Nonendospermous: Lacking endosperm, the nutritive material enclosed with the embryo, in seeds.

Non-industrial private forestry: Forestry practiced by farmers, other individuals and corporations that do not operate wood-processing plants.

Nonnodulating: Incapable of forming root nodules with nitrogen-fixing bacteria.

Nonparametric: Tests and models that are not based on assumptions of certain distributions or model forms, such as normality and linearity.

Nonpoint source: Non-localized, diffuse source of contamination, e.g., atmospheric deposition, agricultural runoff.

Nonpolar: The state of polarity for molecules which tend to have temporary and low-magnitude surface charge, as in the case of vegetable oils. Nonpolar molecules tend to have a low surface energy. Oil and water do not mix because of the relative differences in polarity.

Non-timber forest products (NTFPs): Plants, parts of plants, extractires, fungi, and other flora that are collected or cultivated from within and on the edges of natural, manipulated, or distributed forests. Some agencies exclude animals from the concept but the FAO definition includes food and game, fibers, resins, gums, and plant and animal products used for medicinal, cosmetic, or cultural purposes.

Non-timber forest resources (NTFRs): Relates to the biological organisms that provide NTFPs while they are still in the forest, prior to being harvested; includes fungi, moss, lichens, herbs, vines, shrubs, or trees.

Normal distribution: A probability distribution with density function

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{1}{2}\frac{(x-\mu)^2}{\sigma^2}\right)$$

where μ and σ are parameters.

NPP: Net primary productivity, i.e., gross primary productivity minus total autotrophic respiration.

Nucellus: At the base of the micropylar canal, the nucellus is the first tissue mass that a pollen tube must penetrate to reach the egg cells.

Nucleolar organization region (NOR): The chromosome region which is active in nucleolus formation, where the 45S ribosomal RNA gene is tandemly clustered. Such regions are identified as secondary constrictions, often seen as a gap, located towards the end of the chromosome. Nucleoli in the interphase nucleus are associated with NORs.

NUE: Nitrogen use efficiency.

Null hypothesis: Hypothesis stated as a neutral condition. For example, a null hypothesis might be that all treatment means are equal.

Nuptial chamber: Small chamber constructed by bark beetles immediately upon entry into the host tissue where mating occurs.

Nutrient use efficiency: The ability of a plant to minimize nutrient losses, computed as mass of litter divided by mass of nutrient in litter.

Nuts: Dry one-seeded fruits surrounded by hard shells generally rich in protein, fats and fibers.

Oa: Highly decomposed amorphous organic horizon with rubbed fiber content less than 17%.

Ocular estimation: Estimation of tree or stand properties without any measurement.

Oe: Partially decomposed organic horizon with rubbed fiber content between 17% and 75%.

Offset printing: An adaptation of the principles of stone (or direct) lithography, in which the design is drawn or photographically reproduced upon a thin, flexible metal plate which is curved to fit a revolving cylinder. The design from this plate is transferred to or offset onto a rubber blanket carried upon another cylinder, which in turn transfers the design to paper, cloth, or metal.

Oi: Relatively undecomposed organic horizon with rubbed fiber content exceeding 75%.

Oil paint: A paint containing a suspension of pigments in an organic solvent and a drying oil, modified drying oil, or synthetic polymer that forms an opaque film through a combination of solvent evaporation and curing of the oil or polymer.

Old growth: The phase of forest development during which younger cohorts that established beneath an initiating cohort replace the initiating cohort in the absence of a major disturbance.

Oleoresin: A solution of resin in an essential oil that occurs in or exudes from many plants, especially softwoods. The oleoresin from pine is a solution of pine resin (rosin) in turpentine that has many uses.

Oligocene: Geological epoch (33.2–23.8 million years ago) of Tertiary period.

Oligotrophic: Having low levels of organic production.

Oligotrophic peats: Soils poor in nutrients.

Ombrotrophic: Derived from rainfall.

Omnivory: Feeding on material from a variety of sources.

Onionskin paper: A lightweight writing paper used primarily for making carbon copies of typewritten matter.

Ontogenetic: Relating to the development of an individual from conception to maturity.

Ontogenetic resistance (OGR): Resistance that changes with host development and age.

Oomycetes: Filamentous, fungus-like organisms classified in the phylum Oomycota, of the kingdom Stramenopila (or Chromista). Formerly classified together with fungi because of their similar growth form and their parasitism of plants, oomycetes are more closely related to the golden brown algae than the true fungi. Dissemination is by asexual, motile zoospores that can swim short distances in water films in soil and on plant surfaces.

Oomycotina: Fungi with infrequent septation of the hyphae and cell walls that are primarily of cellulose rather than chitin.

Opacity: The property of a sheet that obstructs the passage of light and prevents one from seeing through the sheet any objects on or in contact with the opposite side.

Open access: Unregulated use of resources when they are available to all and consequently not owned or managed by anyone.

Open access resource: A resource to which access is open to all users and uncontrolled.

Optimization models: Models that use exact mathematical solution methods to achieve specific goals.

Organic soil: Soil comprised of 18% or more organic carbon.

Oriented strand board (OSB): A structural panel composed of multiple, cross-laminated layers of long, thin strands of wood.

Orthodox seed: Seed that can be stored for long periods without loss of germination capacity.

Outbreak: An increase in an insect population generally occurring over relatively short time frames and usually spanning several orders of magnitude. Outbreak populations usually consume a substantial proportion of the foliage resource in affected forests.

Outbreeder: A species for which outcrossing or cross-pollination is the norm.

Outcrossing: Production of zygotes by cross-pollination (cf. self-pollination).

Overdominant gene action: Gene action in which heterozygous loci lead to superior performance relative to homozygous loci.

Overland flow: Water flow at the surface due to infiltration excess or saturation excess of rainfall which results in a rapid runoff generation.

Overstory: Story of trees dominating other trees.

Overwood: That portion of trees, in a forest of more than one story, forming the upper or uppermost canopy layer, e.g., in a two-storied forest, seed bearers over regeneration, or standards over coppice.

Oviposition: The depositing of eggs.

Ovule: A structure in seed plants enclosing the female gametophyte and composed of the nucellus, one or two integuments, and funiculus; differentiates into the seed.

Oxisols: Soil that is highly weathered, low cation-exchange capacity.

Ozone: A secondary air pollutant that is the product of atmospheric reactions of nitrogen oxides and volatile organic carbon catalyzed by sunlight.

Pachymorph: Short and thick rhizome of sympodial bamboos.

Pachyphyllous: Having thick leaves.

Packaging papers: All grades of paper made especially for use in wrapping and making up packages for bundling and shipping purposes.

Paclobutrazol: A plant growth regulator that inhibits the natural production of a group of plant hormones called gibberellins (GAs). In eucalypts it can reduce vegetative growth, stimulate precocious flowering in seedlings and increase the abundance of flower buds on mature trees.

Paint: Any pigmented liquid, liquefiable or mastic composition, designed for application to a substrate in a thin layer that converts by drying to an opaque solid film after application.

Pallet: A platform on which material can be stacked to facilitate handling, moving, and storage.

Pandemic: Universal spread of a disease in a relatively short period of time.

Paniculate inflorescence: A compound raceme. An indeterminate inflorescence with flowers borne on branches of the main axis or on additional orders of branching.

Paper: A homogeneous sheet of felted cellulose fibers, bound together by interweaving and by the use of bonding agents, and made in a variety of types. Paper may be bleached or unbleached, coated or uncoated, filled or not filled, and composed of virgin or recycled fibers. It is used for a multitude of purposes such as writing, printing, wrapping, clothing, industrial, domestic, and sanitary.

Paperboard: A thick, heavy-weight, rigid, single- or multi-ply type of paper which was traditionally made on multi-cylinder paper machines, but is now also made on fourdrinier-type machines, with and without dual formers. Thickness and material vary, depending on its end use. It is used for wrappings, packaging, boxes, cartons, containers, advertising, merchandising displays, and building construction. Also known simply as *board*.

Parallel strand lumber (PSL): A timber-sized structural member composed of long, narrow strips of veneer glued together such that the grain of each strip is parallel to the member's length. Also laminated strand lumber.

Parameter: A characteristic or function of the values of the units in a population, i.e., the population characteristic of interest, such as average volume per hectare or total volume of trees in a forest.

Paraphyletic: A group which contains some, but not all, of the descendants of a common ancestor.

Parenchyma: Thin-walled, brick-shaped wood cells that function primarily to store and conduct nutrients and may be vertically or horizontally arranged in characteristic patterns that are used taxonomically.

Partial resistance (PR): Mechanisms that stop, retard, or confine disease spread.

Participation rate: In recreation the number in a population who participate in one or more outdoor recreation activities during a certain time period.

Participatory democracy: Direct involvement of individuals from a broad cross-section of society in decision making.

Particulate emissions: Minute solid airborne particles that result from biomass combustion.

Particulate wood fuels: Solids of small size that are combusted or gasified to produce energy. Examples are sawdust and chips.

Partnership (for sustainable forest management): A group composed of key land users and other stakeholders of the region who volunteer to work together towards the common goal of SFM. Generally there is a core group of partners that typically include the tenure holders (forest industries), government, environmental specialists, aboriginal and other local communities, non-governmental organizations and academia.

Pathogen: An organism, virus or viroid capable of inciting disease.

Pathosystem: One or more hosts that are attacked by a single pathogen, or pathogen complex.

Peat bog forests: Inundated forests growing in peat-rich soil.

PEC cycles(production, execution and control) The basic components of the logistic system to regulate the wood flow from forest to mill.

Pedogenesis: The factors and environmental conditions influencing soil formation.

Pedon: A three-dimensional body of soil with lateral dimensions large enough to permit the study of horizon shapes and relations. Its area ranges from 1 to 10 m^2.

PELPS: Price Endogenous Linear Programming System.

Pentachlorophenol (penta, PCP): A biocide developed in the 1930s and used in many applications. Many countries have reduced or banned penta due to environmental concerns.

Percentile: A value indicating the percentage of a distribution that is equal or below it; for example, the 95th percentile is the smallest value of x that is greater than 95% of the values in the distribution of x.

Percept: The object of perception.

Perception: The process of becoming aware of sensory stimuli through any of the senses to facilitate recognition and/or interpretation.

Perhumid: Under the Holdridge life-zone classification, humidity conditions corresponding to tropical wet forest ($>$4000 mm annual precipitation).

Perhumid climate: A climate with no dry season.

Periodic Mean Annual Increment (pmai): The annualized change in a growth variable over a particular period, typically 5 to 10 years.

Periodic cyclical dynamics: Regular oscillations in the abundance of an organism around an equilibrium position.

Periphyton: Plant material associated with submerged surfaces.

Perithecium: Fruiting body produced by ascomycetous fungi, producing sexual spores (ascospores).

Peri-urban forestry: Dealing with trees and forest resources around urban community ecosystems. (cf. Urban forests).

Permeability: The ease with which a fluid can move through a porous material.

PET: Potential evapotranspiration.

Petiolar glands: Secretory structures present on the leaf stalk.

Petiolate: Having a petiolule, a leaflet stalk.

PGW: Pressurized groundwood in pulping.

Phase change: The change from juvenile vegetative growth stage to sexually mature growth stage.

Phenology: Periodicity in function or behavior of organisms in relation to local climate or environment, often seasonal.

Phenotype: The observable characteristics of an organism produced by the interaction of its genotype with the environment.

Pheromone: Chemical emitted by animals that is detected by others of the same species (e.g., aggregation/pheromones in bark beetles).

Photosimulation/photo-imaging: Photosimulation refers to a number of techniques using manipulation of physical photographs to create realistic visualizations, using for example photoretouching by hand with paint, or physical photo-montage. Photo-imaging refers to the modern digital equivalent of photosimulation, using manipulation of scanned images with appropriate software to modify pixel colors or 'paste-in' other images.

Photosynthesis: The manufacture of organic compounds, particularly carbohydrates, in the chlorophyll cells of plants from carbondioxide, water, and enzymes in the presence of light as the energy source.

Photosynthetically active radiation: Light of wavelengths between 400–700 nanometers that corresponds to the waveband absorbed by photosynthetic pigments.

Phyllode: A modified leaf stalk that has the form and function of a leaf.

Physiognomy: External features; the form or appearance of a forest.

Phytochrome: A pigment with two interconvertible forms, Pr that absorbs mainly red photons (maximum at 665 nm) and Pfr that absorbs mainly far-red photons (maximum at 730 nm). Absorbance by one form converts it to the other. Many plant processes are sensitive to the ratio of Pfr to total phytochrome.

Phytogeography: Geographic distribution of plants.

Phytophthora: A soilborne oomycete that causes root rot and consequent dieback in many host plant species including trees.

Phytotechnology: Use of plants to remediate or contain contaminants in soil, groundwater, surface water, and sediments; sometimes referred to as phytoremediation.

Phytotelmata: (singular **phytotelm**) Water-container habitat formed from plant material.

Phytotoxicity: Toxicity induced in vegetation by elevated elemental concentrations (usually heavy metals) in certain mineral spoils, and mineral waste materials contaminated by industrial processes.

Pick strength: The ability of the surface of the paper to resist the lifting of coating from the surface of the paper during printing.

Picturesque: Distinctive in forming a good or pleasing picture.

Pile: A straight, bark-free, tree-length log partially or fully driven into the ground to support the foundation of a building or bridge.

Pilodyn: An instrument used to shoot a metal pin into the tree stem with known force. A small bark window is initially removed and the depth of penetration of the pin is inversely related to the stem's wood density.

Pinnate: Arrangement in which the primary rachis of a leaf has leaflets set along it.

Pinyon pines: A distinctive group of North American pines adapted to dry conditions which comprise the subsection *Cembroides* of the section *Parrya* within the subgenus *Strobus*.

Piscivory: Feeding on fish.

Pistillate: Pertaining to a flower or inflorescence of flowers that produces pistils and seed only. Synonymous with the female gender.

Pith: Nonfibrous cells found in plant organs.

Pixel: The ground area or "picture element" corresponding to a single element of a digital image data set.

Plagiotropic: Growing horizontally.

Plagiotropic habit: A nonvertical form as typified by a branch, which is nonreversible and persists in vegetatively propagated stock.

Plant nutrient: Chemical element essential for plant growth.

Plantation: An area of land that supports planted forest, usually for commercial exploitation.

Plantation forests: Forests composed of stands of perhaps 1–2 fast-growing species, often not native to that country. These stands are generally managed primarily to produce wood. The planting of abandoned agricultural land often created such forests, hence 'plantation'.

Pleistocene: Geological epoch (1.8–0.011 million years ago) of the Quaternary period.

Pleurogram: A distinct horseshoe-shaped line occurring on either side of some legume seeds.

Pliocene: Geological epoch (5.3–1.8 million years ago) of the Tertiary period.

Plotless sampling: Sampling without the use of a measured or defined perimeter. Examples include the point-centered quarter methods and 'random forest walks'.

Plywood: An all-veneer structural panel in which the grain of each layer is perpendicular to that of adjacent layers.

Pneumatophores: A porous, woody, specialized branch growing upright into the air from the buried roots of certain swamp trees, such as the mangrove, and providing access to the atmosphere.

Podsolization: Formation of soils with a leached horizon.

Podzols (podzolized sands): Soil with high silica (sand) content, low in clay and bases and in minerals that might weather into these products.

Point source: Localized source of contamination, e.g., outfall pipe, smokestack.

Point-centered quarter method: Random numbers are used to identify points along a central transect line. The area around the point is divided into four quadrants, and the plant closest to the point in each quadrant is measured. The distance from the plant to the point is measured to calculate average spatial arrangements.

Pointer year: Rings in dendrochronology that are considerably smaller or larger than neighboring rings, formed as a reaction to exceptional unfavorable or favorable growth conditions.

Poisson-forest: A forest where the trees are randomly distributed following a Poisson distribution.

Polarity: The state of electrical charges which exist on the surfaces of all molecules. Different states of polarity arise from the variety of elements and their configuration in different molecules.

Pole: A straight, bark-free, tree-length log with one end embedded in the ground that supports power and communications wires, highway sound barriers, and similar structures.

Pollarding: Cutting back, in a more or less systematic fashion, the crown of a tree, with the object of producing a close head of shoots (a pollard) beyond the reach of browsing animals.

Pollen: The mass of microspores containing the male genetic material, produced by the anthers in flowering plants or male cones of gymnosperms.

Pollen management: The use of various pollen handling techniques to store and test pollen and to aid or control pollination. See also Controlled Pollination and Supplemental (mass) Pollination.

Pollen mix: The application of mixed sources of pollen parents either under controlled crossing or open pollinated conditions.

Pollen tube: The tube formed by germinating pollen grains down which male nuclei is transferred to the ovules.

Pollination: The transfer of pollen grains from the anther to the stigma of a flowering plant thereby facilitating contact between male and female gametes leading to fertilisation.

Polyad: A dispersal unit comprising more than four pollen grains.

Polyembryony: The formation or presence of more than one embryo in a seed.

Polygon: A map feature class used to represent areas. A polygon is defined by the arcs that make up its boundary and a point inside its boundary for identification. Polygons have attributes that describe the geographic feature they represent.

Polymerase chain reaction (PCR): A method used to create millions of copies of a particular segment of DNA by repeated amplification in order to produce enough material for detection, analysis and interpretation.

Polymers: Very large molecules which contain long sequences of repeating chemical units; they resemble chains. Polymer chains may form linear, branched, or network structures. Cellulose is a typical polymer and most adhesives contain polymers because polymers form structurally sound solids.

Polymerization: The process for the preparation of polymer.

Polymictic: Frequently mixed.

Polymorphism: The presence of two or more differing versions (or alleles) of a gene, or of a non-coding DNA-base sequence, at a specific site (locus) on a specific chromosome.

Polyploid: Having more than two entire chromosome sets.

Polysaccharide: Any carbohydrate formed from long chains of simple sugars such as cellulose.

Polyvinyl chloride (PVC): A plastic in common use for a variety of purposes.

Population: A group of interbreeding individuals, usually defined geographically. An aggregate of items each with a common characteristic or common set of characteristics. In the statistical sense, a population is an assembly of individual units formed in order to describe the population quantitatively. For example, it might be all the trees in a particular forest stand or all the users of a recreation area.

Population genetic differentiation: The proportion of the total genetic diversity that is distributed between populations.

Population genetic diversity: An estimate of the genetic variation that exists within a single population.

Porate: A pollen grain with a simple aperture.

Porosity: The property of having connected pores or minute interstices through which fluids (liquids and gases) may pass. It is dependent on the number or pores and their distribution in size, shape and orientation. The porosity of paper is commonly evaluated by measuring its air permeability.

Porosity (shelterbelt): A measure of the ease with which air may move through a shelterbelt. Optical porosity is a rough guide to the aerodynamic porosity and is the ratio of sky visible through the shelterbelt to the area occupied by the shelterbelt. An optical porosity of 0% represents a very impermeable shelterbelt which cannot be seen through, a porosity of 90% would represent an extremely open shelterbelt.

ppmv: Parts per million of volume (e.g., 350 ppmv = 350 volume parts of CO_2 per million parts of air).

pps sampling: A sampling design where sample units are selected with a probability proportional to a measure of size, usually a covariate such as dbh or basal area in the case of tree volume.

Precautionary principle: In situations where knowledge is imperfect setting harvesting or pollution levels low in order to avoid possible detrimental impacts.

Precision: Relative freedom from random variation. In sampling it is expressed as the standard error of the estimate and relates to the degree of clustering of sample values about their own average or the reproducibility of an estimate in repeated sampling. It is also used to indicate the resolving power of a measuring device. See Accuracy.

Preferential flow: The rapid and nonuniform transport of water and solutes through macropores and subsurface channels.

Prescribed burning: Controlled application of fire to vegetation in either their natural or modified state, under specified environmental conditions which allow the fire to be confined to a predetermined area and at the same time to produce the intensity of heat and rate of spread required to attain planned resource management objectives (cf. Prescribed Fire). Note: This term has replaced the earlier term 'Controlled Burning.'

Prescribed fire: A management-ignited wildland fire or a wildfire that burns within prescription, i.e. the fire is confined to a predetermined area and produces the fire behavior and fire characteristics required to attain planned fire treatment and/or resource management objectives. The act or procedure of setting a prescribed fire is called prescribed burning (cf. Prescribed Burning). A wildfire burning within prescription may result from a human-caused fire or a natural fire (cf. prescribed natural fire, integrated forest fire management, wildfire).

Prescribed natural fire: Naturally ignited fires, such as those started by lightning, which are further used to burn under specific management prescriptions without initial fire suppression and which are managed to achieve resource benefits under close supervision (cf. prescribed fire, wildfire).

Preservative: Any substance that, for a reasonable length of time, is effective in preventing the development and action of wood-rotting fungi, borers of various kinds, and harmful insects that deteriorate wood.

Pressure process: Any process of treating wood in a closed container whereby a preservative is forced into the wood under pressures greater than one atmosphere. Pressure is generally preceded or followed by vacuum.

Pressurized groundwood (PGW) pulp: A mechanical pulp produced by pressing debarked logs against a rotating pulpstone under elevated temperatures and pressures. The resultant pulp has more long fibers than in groundwood produced at atmospheric conditions.

Prickle: A rigid sharp-pointed process developed from the bark or any part of the epidermis. Botanically, a prickle differs from a spine in that it may be peeled off with the epidermis.

Primary production: A term use to denote the turnover, expressed as dry weight, in a plant community – the annual production of wood, bark, leaves, flowers, fruits, and roots, whether harvested or not. It may be expressed as: 1. Gross primary production representing total assimilation including the portion subsequently used for respiration in the dark. 2. Net primary production is the amount of assimilated organic matter remaining after the requirements of respiration and other natural losses (e.g., predation and decay) have been met.

Primary species: In bark beetles, species that are the primary cause of tree death (kill healthy trees).

Printing paper: All types of paper that have characteristics suitable for printing purposes.

Private property: Property held by private persons including property held by legal persons such as corporations or partnerships.

Probabilistic sampling: Procedures in which samples are selected such that all units and each pair of units in the population have a positive probability of selection.

Process additive: Chemical that improves process efficiency.

Progeny: The offspring of sexual reproduction.

Progeny test: Evaluation of a parent (or parents) from the performance of its (their) offspring. The progeny test is essential in determining the genetic character and value of a specific tree.

Prokaryote: A cell or organism lacking a membrane-bound, structurally discrete nucleus and other subcellular compartments.

Propagule: A plant derived from vegetative propogation including tissue culture and rooted cutting, capable of developing into an adult.

Property: Social relations between people regarding the possession and use of things; a claim to some use or benefit of something that will be enforced by society or the government.

Protandry: The release of pollen prior to the stigmas becoming receptive.

Protected area: A geographically defined area that is designated or regulated and managed to achieve specific conservation objectives.

Protogyny: Female organs of the flower mature before the male organs.

Provenance: If the source is the native origin, it is termed origin or original provenance; if the source is an exotic tree or strand, it is termed derived provenance. See also Geographic race, Seed source.

***P*-value:** The probability of observing a higher value (or higher absolute value) than that obtained for the statistical test if the null hypothesis is true and the experiment is repeated. A very low value indicates that the null hypothesis is unlikely, based on the sample data.

PVC: Polyvinyl chloride.

Pruning: Removal of branches naturally following senescence and death or artificially by stick, blade or saw to reduce knots and improve the quality of timber.

Pteridophytic: Belonging to the ferns and allies plants.

PTMP: Pressure thermomechanical pulp.

Public Advisory Group (PAG) or Citizen Advisory Committee: A group or panel of individuals representing various interests in society, which advises forest managers on issues and initiatives in an ongoing forum for public discussion.

PUE: Phosphorus use efficiency.

Pulp: A fibrous material produced by mechanically or chemically reducing woody plants into their component parts from which pulp, paper, and paperboard sheets are formed after proper slushing and treatment, or used for dissolving purposes (dissolving pulp or chemical cellulose) to make rayon, plastics, and other synthetic products. Sometimes called *wood pulp*. Pulp may include cotton or rags used to manufacture paper and other natural fiber-containing products.

Pulping: Conversion of raw material into fibers by chemical/mechanical measures.

Pulpwood: Small logs suited for the production of pulp (cellulose), measuring approximately 2–3 m in length.

Pyrolysis: Oxidation at less than stoichiometric conditions, involving the physical and chemical decomposition of solid organic matter by the action of heat in the absence of oxygen into liquids, gases, and a carbon char residue in varying proportions depending on process conditions.

Pyrolyze: To decompose with heat in an environment that lacks sufficient oxygen for complete combustion.

Q_{st}: An analog to F_{st}, used to measure differentiation between populations for a quantitative trait.

Quadrat: A usually rectangular plot used for ecological or population studies.

Quantitative trait locus (QTL): A site or narrowly defined region in the genome where a polymorphism governs a detectable portion of the phenotypic variation.

Quaternary: Most recent geological period (1.8 million years ago to present day).

Radar data: Remotely sensed data from the microwave portion of the electromagnetic spectrum, collected by aircraft or satellite.

Radiation transfer: The radiative exchange of energy with another body or the atmosphere. During the day radiation transfer from the sun heats up the ground, plant canopies and animals. During the night radiation transfer to the sky cools the ground, canopies and animals. The cooling is most rapid when the sky is clear.

Railroad tie: One of the transverse supports to which railroad rails are fastened to keep them in line. Also called cross tie and sleeper.

Rainshadow: Area on the lee side of a mountain that receives less rain because orographic uplift of air masses has caused rain to fall on the windward side.

Ramiflory: Production of flowers on branches.

Random allocation: Assigning treatments at random to the experimental unit.

Random amplified polymorphic DNA (RAPD): A PCR technique which uses short and anomalous primers. Polymorphisms arise from mutations in the priming site that cause the amplification product to be present or absent. RAPDs are cheap genetic markers, but their informativeness is limited as they are dominant rather than codominant.

Randomization: A deliberately haphazard arrangement of observations to simulate selection by chance.

RAPDs: Random amplified polymorphic DNAs.

Rare, endangered and threatened species: A species that exists only in one or a few restricted geographic areas or habitats or occurs in low numbers over a relatively broad area is a rare species. An endangered species is one that is in danger of extinction throughout all or a significant portion of its range. A threatened species, is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range.

Raster, grid, lattice: A method for the storage, processing and display of spatial data. Each given area is divided into rows and columns, which form a regular grid structure. Each cell must be rectangular in shape, although not necessarily square. Each cell within this matrix contains an attribute value as well as location co-ordinates. Groups of cells with the same value represent features.

Rate of spread: The speed at which a fire extends its horizontal dimensions, expressed in terms of distance per unit of time (m/min or km/h) (syn. fire spread, cf. rate of area growth, rate of perimeter growth).

Ray: A collection of wood cells that store and conduct nutrients radially across the grain in a tree stem; composed of parenchyma and some specialized cells in the angiosperms and parenchyma and sometimes tracheids in the gymnosperms.

Reaction wood: wood with distinctive anatomical and physical characteristics, formed typically in parts of leaning or crooked stems and in branches. It tends to restore the branch or stem to its original position. Reaction wood is known as tension wood in broadleaved trees and compression wood in conifers.

Realism: The degree to which a landscape visualization is lifelike, i.e., replicates the appearance and perceptual characteristics of a real-world setting or viewing experience. This is often interpreted as the degree of image accuracy or photorealism, though there are various dimensions of realism beyond pictorial accuracy, such as angle of view and speed of motion through a landscape. Realism can also be defined in terms of the perceptual responses the observer obtains (see Response equivalence). Apparent realism refers to the degree to which a visualization appears to be realistic, in the absence of knowledge about what the actual landscape represented would really look like, and is more a function of the medium than the image content.

Real-time interactivity: This indicates that a system reacts to user input with a very small lag time such that the user interprets their input as causing an immediate or near-immediate reaction in the system. For computer visualization systems, real-time interactivity is often reported in 'frames per second', which is the number of times per second that the image being presented to the user is changed to reflect changes in view position or image elements. In general, the more frames presented to the user per second, the more fluid and responsive the interaction will appear to them (up to a limit, at which time further increases in presentation speed are imperceptible to the human eye).

Ream: A number of sheets of paper, either 480 or 500 according to the grade.

Receptivity: The stage of phenological development of the seed cone that permits the entry and capture of pollen on exposed bracts, scales, and micropyle.

Reciprocal recurrent breeding: A method used to refine the breeding quality of two separate populations or species. Interpopulation or interspecific progeny information is used to direct the selection and mating within each population/species.

Recombination system: The way in which the release of genetic variability is controlled during sexual reproduction.

Recreation experience impact: A change in the social conditions of the recreation experience as a result of recreation use.

Recreation opportunity spectrum (ROS): A recreation planning tool for inventorying and classifying the diverse physical, social, and managerial condition of a recreation area into a spectrum of six opportunity classes.

Recreation quality: Perceived and/or objective condition of the recreation resource, recreation experience, and recreation management associated with an area.

Recreation resource impact: A change in the natural conditions of the recreation resource as a result of recreation use.

Recurrent breeding: A method of breeding in which selected parents are mated to form an improved population that in turn becomes the basis for a new cycle of selection and mating, continuing the improvement of the population.

Recurrent selection: The process of repeated cycles of selection of superior genotypes and breeding them together to induce recombination. Each cycle of selection achieves genetic gain in the few traits being selected, because the offspring selected have higher frequencies of favorable alleles.

Recycled fiber: Cellulose fiber reclaimed from recovered material and reused.

Red Data Book: The term for books that list the threatened and endangered species of a region or country and classify the degree of threat in accordance with the categories of the IUCN (The World Conservation Union).

Reel: A revolvable spool for winding and storing long lengths of flexible rope, cable, wire, or other material which may be wound.

Reforestation: the act or process of changing previously deforested lands back to forest by planting trees or other means of regeneration.

Regeneration: The act of renewing tree cover by establishing young trees naturally (natural seeding, coppice, or root suckers) or artificially (direct seeding or planting).

Regeneration rate: The amount of time needed for a population of plants to recover from harvest.

Rehabilitation: Re-establishment of the productivity and some, though not necessarily all, of the original biodiversity formerly present at a site. Rehabilitation may be done using monocultures or mixed species plantations. It includes the activities necessary to repair damage or disturbance caused by wildfire or the wildfire suppression activity (cf. restoration).

Relascope: (or angle gauge) An optical instrument used for measuring stand basal area by point sampling, rather than collecting data from sample plots. The instrument uses relative geometry to determine the number of trees included in a count; this number is then multiplied by a calibrated factor to determine stand basal area.

Relative humidity (RH): Partial pressure of the water vapor divided by the vapor pressure times 100.

Remote sensing: The science, technology and art of obtaining information about objects or phenomena from a distance, without being in physical contact with them. The practice of using data from satellites and aerial photography to infer or measure land cover.

Representation: The degree to which all interests concerned by the issue at hand or affected by the decision-making are included in or legitimately represented by other individuals or groups in the decision-making process.

Representative democracy: Decision-making which involves various interest groups that represent the balance of individual interests in society.

Representativeness: The degree to which a visualization or set of visualizations represents important and typical views of a scene and viewing conditions.

Residential/wildland interface: The transition zone between residential areas and wildlands or vegetated fuels (cf. Urban, Urban/Wildland Interface, Wildland, Wildland Fire, Rural Urban Interface).

Resilience: Ability to return to original conditions following a disturbance.

Resin acid: Diterpenoid extractives from wood, a component of rosin or tall oil.

***Resin canal*:** Typically, resin canals arise as schizogenous intercellular spaces by separation of parenchyma cells from each other in certain gymnosperms.

Resource inventory: The planning and collection of data for description and analysis of the status, condition, production, or quantity of resources for planning and implementing protection and management activities.

Resource management: Management of a valued reserve or supply of an element that can be drawn upon when needed.

Resources: The elements of supply inherent to an area, including lands, water, minerals, soils, flora, fauna, and cultural values.

Respiration: Within the context of pollen viability testing, this is a technique that relates viability with oxygen uptake in an aqueous solution.

Response equivalence: Response equivalence means that a person's reaction to one stimulus is the same as their reaction to another stimulus. In the landscape visualization context, response equivalence means that a person's response to the landscape visualization they are viewing is the same as their response would be to the same landscape in the real world.

Response function: Multiple regression technique to estimate, e.g., the climatic influence on tree growth.

Restoration: Re-establishment of the presumed structure, productivity, and species diversity originally present at a site. The ecological processes and functions of the restored forest will closely match those of the original forest. Restoration includes rehabilitation measures after fire, or prescribed burning where certain fire effects are desired (cf. rehabilitation, reclamation burning).

Restriction fragment length polymorphisms (RFLP): Variations in the length of DNA fragments caused by digesting DNA with a restriction endonuclease. Restriction endonucleases are enzymes derived from bacteria which cleave DNA molecules at specific recognition sites. Mutations at these recognition sites allow or prevent cleavage and hence cause variation in the length of DNA fragments. RFLPs reflect particular DNA base sequences that are not universally present in the subject population, which provide codominant genetic markers.

Retranslocation: Movement of nutrients from one site of use to another, i.e., usually from old leaves to young leaves.

Rheology: Rheology is the science dealing with the flow and deformation of matter.

Rhizobium: A genus of rod-shaped nitrogen-fixing bacteria that form symbiotic associations with some leguminous plants, usually in root nodules.

Rhizomorphs: Specialized root-like and often melanized structures produced by some fungi, enabling them to spread through the soil.

Ring fire: A fire started by igniting the full perimeter of the intended burn area so that the ensuing fire fronts converge toward the center of the burn.

Ripewood: In ripewood trees the heartwood exhibits a lower moisture content than the sapwood, but not a significant amount of extractives, e.g., spruce, fir, beech, lime, and pear.

Ripping: Decompaction of soil (or soil-forming material) using tines pulled by a crawler tractor. The tines are often winged to increase soil uplift and consequent fissuring.

Riverine: Along river banks.

RMP: Refiner mechanical pulp.

Roguing: Systematic removal of undesired individuals from a population to prevent their reproduction, particularly in progeny tested seed orchards.

Root cortex cells: Parenchyma cells forming the primary tissue of roots between the epidermis and vascular tissue.

Root grafts: Root grafts occur when two individuals of the same tree species grow close together; when the roots of the individuals come into contact, they can fuse.

ROS: Reactive oxygen species, i.e., free oxygen radicals (O^-).

Rotogravure printing: An intaglio printing process for rotary web presses, which is used by newspapers and magazines, for printing catalogs, and also for much specialty printing and paper converting.

Roundwood: See Timbers, round.

Routing: Pertaining to the planning or prescription of routes for off-road extraction and road transportation of timber and by-products, to minimize site and road damage, and for safe and cost-effective delivery of wood and by-products of forest harvesting.

RPA: Resource Planning Act.

Rubisco: Ribulose-bisphosphate carboxylase-oxygenase. The key enzyme for the carboxylation of CO_2 in most green plants.

Ruminate endosperm: A type of endosperm in which the seed coat is folded into it.

Running bamboo: Monopodial bamboo; the culms are spaced out since they arise along the running rhizome such that the plant looks like a patch of individual plants.

Rural development: Strategies and activities to improve the living conditions of rural people by either stimulating rural production processes, ensuring better distribution of resources and products, and/or stimulating emancipation and self-reliance.

Rural fire protection: Fire protection and firefighting problems that are outside of areas covered by municipal Fire and Rescue Services and its Fire Ordinance; these areas are usually remote from public water supplies and require all-terrain vehicles to reach.

Rural livelihood: The combination of capabilities, material and social assets and activities which characterize a person's means of living.

Rust diseases: Diseases caused by obligate basidiomycete pathogens belonging to the Uredinales and often having complex life cycles.

Sacred grove: A patch of forest protected in recognition of a certain deity, god, or goddess.

Salt glands: Glands on the surface of plant tissues that are used for the excretion of salt.

Samaroid: Resembling a samara (a winged fruit).

Sample: A subset of a population used to obtain estimates of one or more of its parameters. In this book we focus on probabilistic samples. For example, a sample can be the diameters (dbh) of all trees on a sample of plots or the amount of time spent picnicking by users of a recreation area on given days.

Sample plot: an area of a stand of trees selected and measured to represent the characteristics of the stand as a whole.

Sample surveys: The design and execution of surveys to provide estimates of characteristics (parameters) of well-defined finite populations.

Sample unit: A unit from a population, i.e., a tree or all trees located within a plot (i.e., fixed-area, strip or point sample).

Sampling design: A formalized method of selecting a sample from the population, for example simple random sampling.

Sampling frame: A list of all sample units used to represent a population.

Sampling strategy: Comprises both the sampling design and the estimator(s) used, for example simple random sampling with the estimator of the population mean, say the sample mean.

Saprophyte: Organism that uses dead or organic material as a food source.

Sapwood: Physiologically active outer rim of wood in a tree stem or log; usually lighter in color than the heartwood; contains living cells that serve to conduct water upward in a tree stem.

Savanna: Tropical or subtropical grassland.

Sawlogs: Larger logs, suited for the production of sawn wood (planks, beams), measuring approximately 3–4 m in length.

Scaling ladder: A ladder used to scale fortified walls.

Scatterhoarding: The collection, movement, and storage in dispersed location of resources, usually fruit and seed, by animals.

Schutzwald: A forest (often also referred as 'protective forest') expected to protect continuously settlements, infrastructure, or traffic lines against natural hazards (snow avalanches, landslides, erosion, debris flows, or rock fall).

Scion: A piece of a plant used for grafting.

Sclerophyllous: Having hard, thick and stiff leaves.

Scorch: A foliage disease with symptoms resembling the action of a flame. Scorch symptoms include extensive necrosis, browning and curling of leaves.

Screening: Process of removal of undesired materials and plastics from pulp.

Scrub: Bushwood or waste areas covered by bushes.

Secondary forest: An area of previously forested land that was subsequently degraded or deforested through human or natural action, but which now supports regenerating or mature natural forest.

Secondary species: In bark beetles, species that attack trees weakened or killed by another cause.

Security of tenure: Tenure held without risk.

Sediment delivery ratio: Ratio of sediment yield at a point (weight/area/time) to total erosion within the watershed above that point (weight/area/time).

Seed: Site of a partial development of the sporophyte (embryo) and the linkage between successive generations. The propagule that is distributed naturally or sown artifically to produce seedlings.

Seed orchard: A plantation consisting of clones or seedlings from selected trees, isolated to reduce pollination from outside sources, and cultured for early and abundant production of seed for reforestation. The individual trees in the orchard are allowed to freely intermate through open pollination to produce genetically improved seed for operational reforestation. Forest seed orchards are often established while genetic evaluation of the material is under way. When results of these tests are known, the undesirable individuals are rogued.

Seed set: The culmination of all steps of sexual reproduction from pollination to seed maturation. For purposes of evaluating field pollination trials, the number of filled seed per cone is used as the sampling unit for seed set.

Seed source: Usually, the locality where a seed lot was collected. If the stand from which collections were made was from non-native ancestors, the original seed source may be used to designate the original place of collection. See also geographic race, provenance.

Seemingly unrelated regression (SUR): Two or more equations are estimated simultaneously accounting for the correlation between the error terms of the models.

Selection methods: In silviculture these regenerate and maintain a multi-aged structure by removing some trees in all size classes either singly (true selection), in small groups, or in strips.

Selective logging: Extraction of commercial timber restricted to trees of specific characteristics, e.g., of certain species, size or quality, and which usually implies the removal of a relatively small proportion of the total number of stems in a given area.

Selective thinning: See thinning.

Selfing/self-pollination: Pollination of female strobili of a tree with that tree's own pollen.

Self-pruning: The ability of trees to shed their lower branches as tree crowns recede up the stem as a response to lower light conditions brought on by increased stand density.

Semichemical pulp: A pulp produced by a mild chemical treatment of the raw material followed by a mechanical fiberizing operation.

Semievergreen: Partly shedding leaves.

Semiochemical: Chemical emitted by organisms that causes a response in receiving organisms. Includes pheromones and kairomones.

Semitransparent stain: A suspension of pigments in either a drying oil – organic solvent mixture or a water – polymer emulsion, designed to color and protect wood surfaces by penetration without forming a surface film and without hiding wood grain.

Series: A grouping below the level of the genus.

Serotiny: Storage of seeds in closed seed containers in the canopy of shrubs and trees. For instance, serotinous cones of Lodgepole Pine do not open until subjected to temperatures of 45 to 50°C, causing the melting of the resin bond that seals the cone scales.

Shade bearer: Normally trees that have the ability to compete for survival and to grow in the shade, and in competition with other trees; if intolerant of shade, they are termed light demanders.

Shade tolerant: See shade bearer.

Shear: Any change of wind velocity with a change of position. Strong vertical shear exists over a shelterbelt and strong horizontal shear exists at the end of shelterbelts. Shear results in the production of turbulence.

Shelf life: The length of time before an item becomes obsolete or devoid of required quality specifications in the case of live materials.

Shelterwood cutting: Any regeneration cutting in a more or less regular and mature crop, designed to establish a new crop under the protection of the old, as typically in the shelterwood system.

Shelterwood system: An even-aged silvicultural system in which, in order to provide a source of seed and/or protection for regeneration, the old crop (the shelterwood) is removed in two or more successive shelterwood cuttings, the first of which is ordinarily the seeding felling and the last is the final felling, any intervening cuttings being termed secondary or intermediate fellings. This may be carried out over the whole of a (sub-) compartment, or in strips (shelterwood-strip system), groups or wedges.

Shelterwood-strip system: A shelterwood system in which regeneration cuttings are carried out on fairly wide strips, generally against the prevailing wind, and progress rapidly.

Shifting cultivation: Any temporally or spatially cyclical agricultural system that involves the clearing of land followed by cultivation and fallow periods.

Shoot Unit: The shoot is composed of shoot units, the stem node with its lateral appendage, usually a leaf, and structure in the axil of the lateral appendage plus the proximal internode.

Short shoot: Dwarfed foliage shoots or brachyblasts that do not elongate repeatedly.

Shredding: The repeated removal of side branches on a short cycle, leaving just a tuft at the top of the tree.

Shrubs: Woody plants generally less than 7 meters in height.

Siddha: Siddha is an ancient Indian health care system which is largely therapeutic in nature. According to this system the human body is the replica of the universe and so are the food and drugs, irrespective of their origin. The practitioners of this system, popularly known as Siddhars, use minerals and plants often in conjunction with divine powers for treatment of diseases.

Silvicultural operations: One or several silvicultural activities that alter a stand's development pathway.

Silvicultural pathway: The sequence of structures that a stand moves through over time following a series of silvicultural operations (such as thinning, weed control, harvesting, or planting).

Silvicultural system: A process following accepted silvicultural principles, whereby the crops constituting a forest are tended, harvested and replaced, resulting in the production of crops of a distinctive form. The extremes are the clear-cutting and the single tree selection system with many other ones in between.

Silviculture: The art and science of forest tending; the growing and tending of stands to meet management objectives. It may be considered the ultimate *application* of stand dynamics knowledge and its ultimate *test*.

Silvopastoral practice: A form of agroforestry which combines trees and grazed pasture.

Simulation models: Models that show change through time. In contrast to optimization models, usually not goal-driven.

Simultaneous estimation: Two or more equations which are estimated simultaneously.

Single tree (true) selection: Individual trees of all size classes are removed more or less uniformly throughout the stand, to promote growth of the remaining trees and to provide space for regeneration.

Single-level sampling: A sampling design where units are selected directly from the sampling frame of the population.

Sink: A process, activity, or mechanism that removes a greenhouse gas from the atmosphere.

Site class: A relative measure of the yield level or yield class, which are defined by the mean annual volume increment in the certain age.

Site index: A measure of the potential growth or productivity of a given tree species grown on a particular site, as estimated from a measurement taken on a tree or stand. For example, the dominant height achieved by a stand at a certain age (10, 25 or 50 years) might be taken as a site index. Site index is often derived by comparing growth assessments with standard curves or charts representing average patterns of growth for the species on different sites.

Sizing: Starches added either internally or on the surface of printing papers to provide certain ink holdout properties.

Skeleton plot: Evaluation of tree-ring time series based on visual examination, highlighting very narrow or very wide rings and plotting these as a skeleton of the time series.

Skidder: Off-road forestry vehicle designed for dragging trees or logs.

Slab avalanche: Most common form of damage-causing avalanche where the snowpack fractures on a fragile layer in the form of a slab. Typical dimensions are between 10–500 m wide and 50–1000 m, with the initial slab wider than it is long.

Slash: Debris (fuels) resulting from natural events (wind/fire) or human activities like forest harvesting.

Slash logs: Composite residue produced by a harvester that has been compacted and balled in round bundles, hence the term log, typically 3 m long and 60–80 cm in diameter.

Sledge: A sled for carrying loads along the ground.

Sleeper: A transverse support to which railroad rails are secured; see Crosstie and Railroad tie.

Small and medium enterprise: An enterprise with a turn over of less than $1 million to less than $50 million.

Small-scale forestry: Small-scale management of forests, a term to separate the type of forestry from industrial or public large-scale forestry. There is no consistent definition of what constitutes small-scale forestry but the definitions, e.g., the maximum size of a woodlot, vary between countries.

Smog: The mix of tropospheric ozone and other photochemical oxidants such as nitrogen oxides and peroxyacetyl nitrate that occurs on warm days downwind of major metropolitan areas.

Smoke haze: An aggregation (suspension) in the atmosphere of very fine, widely dispersed, solid or liquid particles generated by vegetation fires giving the air an opalescent appearance.

Smoothness: The property of a surface determined by the degree to which it is free of irregularities.

Snow gliding: Slow movement ($0.1–1\ \mathrm{m\ day}^{-1}$) of the entire snowpack at the soil–snow interface exerting strong forces on obstacles and plants, occurring especially on wet or sunny slopes.

Snow metamorphism: Change in shape and size of the snow crystals caused by temperature gradients in the snowpack or by melting and refreezing.

Social carrying capacity: The number and kind of recreationists that an area can stand without the volume and type of use causing a negative impact on the experiences of visitors.

Social class: A social distinction and division resulting from the unequal distribution of rewards and resources such as wealth, power, and prestige.

Social forestry: A development strategy to stimulate community involvement in the management of forest resources in order to improve local livelihoods and/or stimulate forest conservation.

Softness: A perceived tissue quality that is related to the bulk of the tissue, its surface smoothness, and mechanical strength.

Softwood: 1. Tree belonging to the botanical group Gymnospermae, and within it, predominantly to the order Coniferales; 2. evergreen, cone-bearing species of trees, such as the pines, spruces, and hemlocks, in which leaves are needlelike, linear, awl-shaped, or scalelike, and the seed are borne either in cones in the axil of a scale, or naked. Wood that is harvested from softwood coniferous species such as pine, spruce, and hemlocks. The wood typically lacks vessels and in many species it has resin ducts.

Soil aeration: Replenishment of O_2 and removal of CO_2.

Soil horizon: A layer of soil approximately parallel to the land surface and differing from adjacent genetically related layers in physical, chemical, and biological properties or characteristics such as color, structure, texture, consistency, kinds and number of organisms present, degree of acidity or alkalinity.

Soil infiltration capacity: Soil characteristic describing maximum rate at which water can enter the soil under specified conditions.

Soil moisture characteristic curve: Describes the relationship between soil moisture (soil water content) and soil water tension (matric suction). Also called soil moisture release curve or retention curve.

Soil preparation 'Wounding'(cultivating, scarifying, rotovating, tilling) the suboil in order to improve the germination chances (seed-bed) or to ease the planting process.

Soil survey: The systematic examination, description, classification, and mapping of soils in an area.

Soil-forming materials: Materials usually of geological origin (e.g., from selected geological strata or overburden types) selectively stored and then used to establish vegetation in the reclamation of the mine site. Often amended with organic materials (e.g., organic wastes such as sewage sludge and composts) to increase fertility and improve physical nature.

Solar radiation: Variation in solar energy input that plants require for photosynthesis.

Solid-color stain (opaque stains): A suspension of pigments in either a drying oil – organic solvent mixture or a water – polymer emulsion designed to color and protect a wood surface by forming a film. Solid-color stains are similar to paints in application techniques and in performance.

Somatic embryogenesis: The production of new embryos from individual cells of immature seed embryos.

Source: A process, activity, or mechanism that releases a greenhouse gas into the atmosphere.

Spatial correlation: Relationships among observations over space.

Spatial resolution: A measure of the smallest angular or linear separation between two objects usually expressed in meters. Often understood as the ground resolution, which is a measure of the resolving power of a sensor when expressed as cycles per unit length on the ground from a given altitude. For instance, the spatial resolution of the Landsat sensor is 30 by 30 meters.

Spatial scale: Large spatial scales generally indicate large tracts of land, whereas small spatial scales indicate smaller land areas.

Special forest products: Term used by the USDA Forest Service; excludes sawtimber, pulpwood, cull logs, small roundwood, house logs, utility poles, minerals, animal parts, rocks, water, and soil.

Species: Group of closely related, morphologically similar, and interbreeding individuals.

Species diversity: The number, types, and distribution of organisms found in a given area.

Specific leaf area: The surface area of an individual leaf divided by the mass of that leaf.

Spectral resolution: The ability of a sensing system to resolve or differentiate electromagnetic radiations of different frequencies, typically reported as the electromagnetic wavelengths captured with a given sensor.

SPECTRUM: An analytical tool for building natural resource management models.

Spices and condiments: Plant components or parts that are used for imparting flavor, aroma, piquancy, and for seasoning of foods.

Spinescent: Developing into, or terminating in, a spine or thorn.

Spore: A general term for the microscopic propagules of fungi. Spores can be one to several cells and are agents of dispersal and infection in pathogenic fungi. Spores are analogous to seeds and are capable of developing into a mature individual under appropriate growing conditions. See ascomycete, basidiomycete, anamorph.

Sporocarp: A fungal structure in which spores are produced; a fungal fruit body. The sporocarp of basidiomycetes is typically a mushroom or woody conk.

Spot fire: (1) Fire ignited outside the perimeter of the main fire by a firebrand (by flying sparks or embers transported by air currents, gravity, or fire whirls). (2) A very small fire which that requires little time and resources to extinguish that jumped over the fireline, by air currents, gravity, and/or fire whirls (cf. Long-Range Spotting).

SSRs: Simple sequence repeats, typically in non-coding parts of the genome, which can be used to provide 'genetic fingerprints.'

Stain: A discoloration in wood that may be caused by such diverse agencies as microorganisms, metal, or chemicals. The term also applies to materials used to impart color to wood.

Stakeholder analysis: A comprehensive documentation and analysis of the public and specific stakeholders interested in or affected by an issue or plan, with classification according to various criteria relevant to their involvement in decision-making.

Stakeholders: All individuals or groups interested in an issue or opportunity driving the participatory process. They are affected by a development outcome or have an interest in a development outcome. Stakeholders include customers (including internal, intermediate, and ultimate customers) but can include more broadly all those who might be affected adversely, or indirectly, by a specific activity who might be identified as a 'customer' or a stakeholder.

Staminal hood: In the Lecythidaceae, the apex of the male part of the flower that projects from one side of the staminal ring and curves over the top of the ovary and usually bears sterile stamens.

Staminal ring: In the Lecythidaceae, the base of the male part of the flower, in the form of a ring, that bears the fertile stamens.

Staminate: Pertaining to a flower or inflorescence of flowers that produces stamens and pollen only. Synonymous with the male gender.

Stand: A contiguous group of trees sufficiently uniform in age class distribution, composition, and structure, and growing on a site of sufficiently uniform quality, to be a distinguishable unit.

Stand boundary: Stand edge.

Stand development: Changes in stand structure over time.

Stand dynamics: The development of forest stands over time. This is typically considered in terms of decades or even centuries.

Stand height: Different indicators of stand height may be derived from a model of individual tree height versus diameter at breast height or directly from sample values. Commonly used indicators include arithmetic mean height, H, height corresponding to mean basal area, H_g, mean height weighted by basal area, H_L, top height or average height of 100 thickest trees per ha, H_{100}, and dominant height or average height of sociologically dominant trees, H_{dom}. While H, H_g and H_L are mostly useful for volume calculations, H_{100} and H_{dom} are better suited for classification of site and stand productivity.

Stand initiation: The first phase of forest development occurring after a disturbance kills some or all of the existing stand, growing space is released, and seedlings establish.

Stand structure: The physical and temporal distribution of trees (living and dead) and other plants in a stand: species, spatial patterns (both vertical and horizontal), size (including crown volume, leaf area, stem volume or cross section), and age or age class distributions. Some possible discriptions of structure include open, dense, understory, savanna, and complex.

Standard deviation: The square root of the variance.

Statistical survey: The design and execution of surveys to provide estimates of characteristics of well-defined finite populations.

Stellate: Star-shaped, referring to shape of individual hairs that make up the pubescence.

Stem density: Relation between the number of tree stems and the area they occupy, generally measured as the number of individuals per hectare.

Stem number: In a forestry context, stem number frequently replaces the number of live trees. Generally, stem number is expressed in count per unit area. Sometimes, stem number refers only to trees above a certain size.

Stem taper: Assuming circular cross sections the cubic volume of the stem or any segment of the tree can be calculated based on the general taper equation $y = k\sqrt{x^r}$, where y is the radius at any point along the length axis x, and k and r defines the rate of taper and the shape of the solid, respectively.

Stem volume: The volume, usually expressed in m^3, of the stem; this may be calculated either from direct measurement of diameters and lengths on the stem, or measurements may be taken on standing trees using an optical instrument.

Steppe: A vast plain dominated by grasses.

Sterm exclusion: The phase of forest development characterized by density-dependent mortality as trees compete with each other for limited site resources.

Stigma: The receptive surface on the female reproductive organs on which pollen is deposited.

Stipules: Paired structures that are found at the point where the leaf stalk joins the stem.

Stock: Wet pulp of any type at any stage in the manufacturing process.

Stockplant: The plant from which cuttings are harvested.

Stomata: Specialized cells located on the leaf epidermis that open and close to regulate carbon dioxide diffusion into, and water loss out of, the leaf.

Stomatal conductance: A measure of the degree of opening of the stomata. It is linearly related to stomatal pore size.

Stool: A living stump (capable of) producing coppice shoots.

Storey: Layer or stratum of forest.

Strain: A group of similar isolates.

Stratum: Horizontal vegetation layer, part of the vertical forest structure (e.g., understory, subcanopy, canopy).

Stream drainage density: Total length of streams per unit area in a watershed.

Stress concentration: The focus of mechanical stress on a very small location or point within a material, as in the case of crack tip in a solid. Stress concentration often leads to catastrophic mechanical failure.

Strip systems: See shelterwood system.

Strobilus: The reproductive structure in gymnosperms, consisting of a number of sporophylls, grouped on a central axis, e.g., a cone.

Stroma (pl stromata): See ascoma.

Structural lumber: Lumber that is intended for use where allowable properties are required. The grading of structural lumber is based on the strength or stiffness of the piece as related to anticipated uses.

Structure: 1. Physical features of the forest ecosystem (e.g., height, diversity, percentage cover, etc.). 2. The combination or arrangement of primary soil particles into secondary units or peds.

Stud: One of a series of slender wood structural members used as supporting elements in walls and partitions.

Subalpine: The altitudinal belt just below the upper forest line, separating the montane from the above-situated alpine belt, and which in the tropics is generally situated between 3000 and 3500 m elevation.

Subcanopy: Below the top canopy.

Sub-compartment: A portion of a compartment, usually contiguous and composed of a single forest stand type, defined for purposes of management.

Subdominant (crown class): See crown class.

Subfamily: Classificatory group below the level of the family but above that of the genus.

Subgenera: Classificatory group below the level of the genus but above that of the tribe.

Substrate: In papermaking the media to be coated or printed, i.e., paper, board, film.

Subsurface flow (also subsurface stormflow, interflow, or throughflow): Lateral water flow in soil or bedrock which results in a delayed runoff generation that is very common in forest soils.

Succession: Natural dynamics in plant societies beginning with the colonization of bare land by stress-tolerant, light-demanding species and shifting towards communities with more shade-tolerant, more competive but less stress-tolerant species.

Succulence: The tendency of a plant organ to store water.

Sucker: A shoot arising from below ground level either from a rhizome (e.g., bamboos) or from a root (e.g., *Populus* sp.).

Suffructex: A plant that is woody at the base but with herbaceous branches.

Supercalendered paper: Paper that has received a gloss finish by being passed between the rolls of a supercalender under pressure; supercalenders are usually composed of alternate chilled cast-iron and cotton rolls.

Supplemental pollination (SP): (sometimes called supplemental mass pollination–SMP) The broadcast spraying of large amounts of pollen (liters) used to both increase orchard yields and/or genetic efficiency.

Suppressed (crown class): See Crown class.

Surface deactivation: A reduction in solid surface energy which can lead to poor (unfavorable) wetting and poor adhesion. In the case of wood, extreme heat and extended exposure to sun light will promote wood surface deactivation, and poor adhesion.

Surface energy: The state of electrical charges which exist on the surfaces of all molecules, and in this case particularly the molecules located on the extreme surfaces of liquids and solids. Surface energy critically impacts adhesion through the interaction of complementary charges when a liquid adhesive contacts a solid substrate.

Surface hoar frost: Condensation of atmospheric vapor on the snow surface in the form of fragile crystals, between 5–30 mm deep and later buried by new snow, creating a preferred layer for slab avalanche formation.

Surfactants: Surface active molecules used as emulsifier or wetting agent, often with pesticides or as detergents and/or defoamers.

Sustainability: The state of providing resources and other benefits in perpetuity without threatening future supplies.

Sustainable forest management: 1. Management that maintains and enhances the long-term health of forest ecosystems for the benefit of all living things while providing environmental economic, social and cultural opportunities for present and future generations. 2. The application of the concept of sustainable development in forestry. Incorporating the concept of sustainable development is achieved through the integration and balanced optimization of social, economic and environmental goals of development over time. 3. Interventionist: any individual or group the undertakes to facilitate change to an ongoing management system. To be successful in introducing collaborative forest management, the interventionist must establish credibility as the honest broker among the stakeholders of the management system.

Sustainable use: The use of components of biological diversity in a way and at a rate that does not lead to the long-term decline of biological diversity, thereby maintaining its potential to meet the needs and aspirations of present and future generations.

Sustained supply: Regular supply generally referred to industrial raw materials to maintain the operation of the assembly lines.

Swamp forests: Inundated forests growing in peat-poor soil.

Syconium: The enclosed inflorescence of a fig.

Symbiosis: Association of two different organisms each of which contributes to the nutrition of the other.

Sympathetic nervous system: The part of the autonomic nervous system that inhibits or opposes the physiological effects of the parasympathetic nervous system, as in tending to reduce digestive secretions, speeding up the heart, and contracting blood vessels.

Sympatry: The situation in which species grow within the same territory or region, often specialized to different environments.

Sympodial bamboo: Bamboo with rhizomes whose tips grow into culms; rhizomes form from bases of older rhizomes.

***Symptom*:** A visible abnormality arising from a disease or a disorder.

Symptom: A visible or otherwise detectable abnormality that is the result of disease.

Syncarp: An aggregate fruit with multiple carpels united.

Systematic thinning: See Thinning.

TAD(through air drying): A process for drying a sheet of paper by blowing warm air through the sheet to remove most or all of the moisture.

Taiga: A Russian term meaning northern, boreal, or coniferous forest.

TAMM: Timber Assessment Market Model.

Taper: The rate of diameter decrease in stems with increasing height.

Taungya: An agroforestry system under which food crops and forest trees are cultivated together during the plantation establishment phase. See also shifting cultivation.

Taxon: Any taxonomic group or rank (e.g., family, genus, species); the ranking being described is determined from context.

Taxonomic surveys: Studies undertaken to locate and document occurrences of particular species.

Taylor series expansion: The linearization of function f near point x_0 based on derivatives

$$f(x) = \sum_{m=0}^{\infty} \frac{f^{(m)}x_0}{m!}(x - x_0)^m.$$

Tear resistance: The force required to tear a specimen of paper of specified dimensions under standardized conditions.

Telemetrics: On-board electronic systems that are used for machine and harvesting process control, including optimization of stem cutting, communication equipment (voice and data), visual display screens, audio and visual warning systems, fault diagnostic systems, weighing scales for determination of payloads, and navigation and route optimization functions.

Telocentric: A chromosome with a terminal centromere.

Temperate: Relating to regions in which the average temperature is about 10°C for 2–4 months of the year.

Temporal correlation: Relationships among observations over time.

Temporal scale: Large temporal scales are long time periods, whereas small spatial scales are small time periods.

Tending: Any treatment or tending designed to enhance growth, quality, vigor and composition of the stand after establishment or regeneration and prior to final harvest.

Tensile strength: Resistance to forces that tend to pull the wood or paper apart. Measured as the force parallel with the plane of the wood or paper required to produce failure in a specimen of specified dimensions under specified conditions of loading.

Termites: Primitive social insects of the order Isoptera which can cause extensive degradation to wood. Termites are classified as either subterranean, which must be in ground contact and construct shelter tubes to reach aboveground wood, or drywood termites which do not need to be in ground contact.

Terpene: Volatile, isoprene-based extractive from wood, a component of turpentine.

Terra firme: Upland terraces with forests that are not flooded.

Tetrad: A dispersal unit comprising four pollen grains.

Tetraploid: A polyploid with four sets of chromosomes.

Texture: The relative proportions of sand, silt, and clay in a soil as described by the classes of soil texture in the textural triangle.

Theory of island Biogeography: Derived by R MacArthur and E Wilson, this theory postulated that the number of species on an island was a dynamic equilibrium reached via a balance between colonization and extinction.

Thermocline: Zone of rapid temperature change.

Thermomechanical (TMP) pulp: A mechanical pulp produced from wood chips, where the wood particles are softened by preheating in a pressurized vessel at temperatures not exceeding the glass transition point of the lignin, before a pressurized primary refining stage.

Thinning: A cultural treatment made to reduce stand density of trees primarily to improve growth, enhance forest health, or recover potential mortality. Types of thinning include the following: **crown thinning:** the removal of trees from the dominant and codominant crown classes in order to favour the best trees of those same crown classes; **low thinning:** the removal of trees from the lower crown classes to favour those in the upper crown classes; **selective**

thinning: the thinning of trees in even- or uneven-aged stands, involving the subjective selection by the forester of the trees to be removed, usually involving low or crown thinning; **systematic thinning:** (or mechanical thinning) the thinning of trees in even- or uneven-aged stands, involving removal of trees in rows, strips, or by using fixed spacing intervals. The felled trees are known as thinnings, and may or may not have economic value. Sometimes thinning operations are carried out exclusively to achieve economic out-turn of produce.

Thinning from below: Alternative name for low thinning or, for example, where the death of suppressed and unhealthy trees follows defoliation during insect outbreaks.

Threatened: Facing the threat of extinction. See Rare, endangered and threatened species.

Three-stage least squares (3SLS): Combination of the two-stage least squares and seemingly unrelated regression.

Timber: Solid-sawn lumber 127 mm (5 in.) or more in nominal thickness.

Timbers, round: Timbers used in the original round form, such as poles, piling, posts, and mine timbers.

Tissue filler: An anhydrous form of either natural or calcined calcium sulfate ($CaSO_4$), derived from ground gypsums, and used as a filler for tissue-type papers.

Tissue paper: Thin, low-weight (10–50 $gm\,m^{-1}$), gauze-like types of paper made from virgin and/or reclaimed pulp, used to manufacture such items as sanitary products, wrapping material, protective packing paper, and stock for waxing and twisting. The product is usually creped or treated in another manner to increase the apparent density.

TLF: Tropical lowland forest.

TLMF: Tropical lower montane forest.

TMCF: Tropical montane cloud forests.

TMF: Tropical montane forests.

TMP: Thermomechanical pulp.

TNAA: TAMM/NAPAP/ATLAS/AREACHANGE. Timber and forest models.

Tomentum: Another word for the collective pubescence or hair, in this case used for plant hairs.

Top or dominant height: The average, total height of the dominant trees in a stand. Top or dominant height is often used in determination of site index.

Topography: Land details like elevation, contour, etc.

Total genetic diversity: An estimate of the genetic variation that exists within species.

Total seed per cone: The total number of fully developed seed coats (from fully developed ovules) and rudimentary seed (from immature ovules).

TPMF: Tropical premontane forest.

Tracheid: An elongate, spindle-shaped wood cell that loses protoplasm at maturity when becoming conductive. Tracheids account for 90–95% of softwood volume, much less in hardwoods.

***Tracheid*:** Tracheids are xylem cells and the principal strengthening and water-conducting cells in gymnosperms.

Trait: A specified characteristic (i.e., growth) which is the criterion used to compare performance of clones or offspring of selected parents.

Transect: A sample area (as of vegetation), usually in the form of a long continuous strip.

Transect intercept: A point or perpendicular line that crosses a central transect.

Transgenic: Of an individual plant that contains a foreign gene introduced by genetic modification as opposed to traditional breeding techniques.

Transgressive segregant: An individual offspring of the F_2 generation whose value for a metric trait lies outside the range defined by the F_1 parent.

Transpiration: The evaporation of water from plants. It occurs mainly through the stomata on leaf surfaces. The rate of plant transpiration depends on the stomatal conductance and the dryness of the air relative to the leaf pore space, as expressed by the difference between the vapor pressure inside and outside the leaf.

Tree: Woody plant, not branching at ground level, with an average adult height of exceeding 5 m when healthy; perennial with branches forming a distinct elevated crown.

Tree improvement: Cumulative genetic improvement of a tree species for a few key traits through the activities of selection, breeding, genetic testing and deployment. Most tree improvement programs employ recurrent selection for general combining ability.

Tree tenure: The terms on which a tree or its products are held; the rights and obligations of the holder of the tree.

Tribe: Classificatory group below the level of the subgenus but above that of the species.

Trifoliate: Having a leaf comprising three leaflets.

Triploid: A polyploid with three sets of chromosomes.

TRMP: Thermorefiner mechanical pulp.

Trophic level: The functional position of an organism within an ecosystem according to its feeding relationships. Folivore populations may be influenced by natural enemies in the trophic level above them (top–down) and/or by the trophic level beneath them, the plants on which they feed (bottom–up). Tri-trophic interactions incorporate the herbivore, its natural enemies, and its host plants.

Tropophilous: Plants adopted to seasonal changes in water availability.

TSF: Tropical subalpine forest.

TSM: Timber Supply Model.

Tuber: Fat part of an underground stem or root which holds nutrients and which has buds from which shoots develop.

TUMF: Tropical upper montane forest.

Turbidity: Property of water that causes light to be scattered or absorbed.

Turbulence: Random motions in the air. Turbulence encourages exchange of gases between the atmosphere and plants. High turbulence can lead to lodging and abrasion.

Two-stage least squares (2SLS): Two or more equations are estimated simultaneously taking into account that an independent variable of any one equation may be the dependent variable of another (endogenous variables). The model is estimated in two stages so that, first, the parameter values are estimated with OLS and, second, the endogenous variables are surrogated with their estimated values and the estimation is done again.

Tyloses: Balloon-like outgrowths from adjacent parenchyma that block the vascular tissues of trees infected by wilt pathogens.

Type species: That corresponding to the individual specimen plant from which a given genus was first described.

Ultisols: Weathered, leached soils of low fertility, and containing few weatherable minerals, and a B-horizon with a marked accumulation of clay. Found in warmer regions where rainfall is considerably in excess of evapotranspiration, characteristically under forests in the humid tropics.

Ultrabasic rocks: Rocks rich in bases such as iron and magnesium and low silica content.

Ultramafic rock: Rock formed directly from magma from the earth's mantle (which is low in silica compared to crustal rocks). The rock has low silica and a very large amount of magnesium and iron. The "ma" and "f" in "mafic" are derived from magnesium and Fe for iron.

Umbel: The term often used to describe the inflorescence of many of the eucalypts where flowers are in clusters extending from a single peduncle. Such inflorescences are effectively a reduced dichasial cyme. There may be a single cluster of buds or they may occur in compound, branched inflorescences.

Umbo: The terminal structure of the cone scale.

Unani: Unani system of medicine (Unanipathy) originated in Greece. This system believes in the humoral theory which presupposes the presence of four humours–Dam (blood), Balgham (phlegm), Safra(Yellow bile) and Sauda (black bile) in the body. According to this system, if these four main humours are in a state of mutual equilibrium, one is considered healthy.

Uncinate hairs: Hooked hairs.

Underburning: Prescribed burning with a low intensity fire in activity-created or natural fuels under a timber canopy.

Understory re-initiation: The phase of forest development characterized by the periodic death of large trees and the establishment of a new cohort beneath the existing overstory. Analogous to gap phase dynamics.

Understory: Plants growing under the canopy of other trees and dominated by them.

Underwood: All forest vegetation growing under an overstory.

Unequal probability sampling: Sampling designs where units are selected with different probabilities. These probabilities need to be known for unbiased estimation.

Unifoliate: Having a leaf comprising one leaflet.

Unilocular, inferior ovary: Ovary with one chamber occurring below the other floral parts.

Uniseriate: Formed of a single row of cells.

Unit: The basic sample unit used, e.g., that used in the last stage of multistage sampling for say trees insects on trees.

Unstocked: Forests on which tree crown cover has been reduced below the minimum threshold defined for forest.

Upper tree line: Altitudinal limit of temperature-dependent tree growth, which separates forest on mountains from shrub and herb-dominated formations or ecosystems.

Urban forest: All trees and forest resources in and near urban areas; includes trees and tree stands in parks, private gardens, streets, cemeteries, on squares, on industrial, commercial and agricultural land, around hospitals and schools, on wasteland, and in existing woodlands.

Urban forestry: The art, science, and technology of managing trees and forest resources in and around urban community ecosystems for the physiological, sociological, economic, and aesthetic benefits trees provide society.

Urban greenspace: Vegetated open space in an urban area.

Urban woodland: A forested ecosystem in and near an urban area; although trees are the dominant element, it can contain other elements such as water and open space.

Urban/wildland interface: The transition zone (1) between cities and wildland (cf. urban, wildland, wildland fire), (2) where structures and other human development meets undeveloped wildland or vegetative fuels (syn. residential/wildland interface, wildland/urban interface, rural urban interface).

USDA: United States Department of Agriculture.

User need: A psychological and/or physiological requirement for the well-being of an individual.

User preference: Desired conditions and favored situations that recreationists expect will facilitate or satisfy unmet needs.

Usufructuary right: The right to use something.

Utricaceous stamens: Anther filaments held inflexed in the bud; at anthesis, they snap outward, propelling pollen into the air.

Validation: Accuracy test of model using data set independent from that used in model development.

Value addition: Process by way of which the economic and/or use value of the product is increased without affecting its intrinsic quality.

Values-at-risk: Natural resources, developments, or other values that may be jeopardized if a fire occurs.

Variable: A characteristic that varies from unit to unit, for example the age of a tree.

Variance: The average of the squares of the deviations between the values of the variables and the overall mean in the case of a population or between the values of the variables and the sample mean in the case of a sample; in the first case it is a population parameter, in the second a sample statistic.

Varnish: A liquid composition of a resin or drying oil dissolved in a suitable solvent which is converted to a transparent solid film by a chemical reaction after application to a surface as a thin layer.

Vascular cambium: Dividing, reproductive cells found in a ring situated between the inner bark (phloem) and wood (xylem) of a tree; responsible for formation of xylem and phloem and diameter expansion, remains active throughout the life of a tree. See also Meristem.

Vector: One method of data type, used to store spatial data. Vector data are comprised of lines or arcs, defined by beginning and end points, which meet at nodes. The locations of these nodes and the topological structure are usually stored explicitly. Features are defined by their boundaries only and curved lines are represented as a series of connecting arcs.

Vegetable tannin: Astringent vegetable extract which has the ability to combine with animal hide and convert it into leather.

Vegetation period: In regions with seasonal climate, the period in which plants grow, flower, and seed.

Vegetative reproduction: Nonsexual reproduction. See Propagule.

Vegetative: Nonsexual.

Vehicle routing functions: Aims to maximize capacity utilization of the transport fleet within the constraints imposed by destination.

Verifiable indications: The factors asserting any logic.

Verification: Check of internal logic of model.

Vessel: The principal vascular or water-conducting component in hardwoods. Composed of vessel elements which are conductive cells with perforated ends; found in the wood of angiosperms but rarely gymnosperms and are of indeterminate length; form axial columns centimetrs to meteres long in the tree and function to conduct water and nutrients throughout the tree stem and branches.

Viability: The ability of a pollen grain or pollen lot to set seed as determined by its assay performance in laboratory tests (viability assays). Various assays are used including staining, respiration, conductivity and germination. Correlation analyses are used to determine the strength of the relationship between laboratory assay response and field fertility (seed set).

Viability selection: Natural selection occurring at the whole organism level.

Viewer sensitivity: The degree of concern that viewers have for visual qualities; used interchangeably with 'visual sensitivity.'

Viewshed: A specific term describing the mappable visible area as seen by an observer from a given location or locations.

Virgin pulp: Pulp that has not previously been used in the papermaking process.

Virtual reality: Virtual reality involves the immersion of a user in a virtual world. This usually involves two main aspects: first, the user is generally presented with an immersive display, either through the use of a head-mounted display or through the use of display screens arranged to surround the user; second, the user has interactive control, such that they can explore the virtual environment, and effect change upon that environment.

Virulence: Degree of pathogenicity of an organism, its ability to cause disease. A more virulent strain of a pathogen causes more damage to its host than does a less virulent strain.

Visitor counting: Method to measure the volume of recreational use of an area in terms of number of visits; observations are often made with the help of electronic equipment.

Visitor survey: Method used to collect visitor information in recreation areas. Data collection is made by questionnaire or interview techniques.

Visual absorption capability: The relative capacity of the landscape to absorb visual alterations and still maintain its visual integrity or landscape character.

Visual impact assessment: An assessment of the type, magnitude, and importance of predicted or existing visual effects of an activity on the landscape.

Visual quality: The part of aesthetic quality that is due to visual characteristics of the landscape; it is often used interchangeably with the term scenic quality, referring to the degree of attractiveness or scenic value in the landscape.

Visual quality objective: A description of the acceptable degree of change to a landscape expressed in terms of the amount and nature of any alteration created through logging practices or other forestry activity. An integral part of VRM systems.

Visual resource management (VRM): A system of classifying, assessing sensitivity and applying visual quality objectives to areas of forest landscape.

Visual resource management: A planning and management system for visual values and resources.

Visual symptoms: Color changes or growth defects resulting from an inadequate supply of a particular nutrient.

Visualization: A visual depiction of landscape conditions, which displays terrain and other recognizable geographic features in perspective view, with varying degrees of realism.

Vivipary: Premature germination of seeds on the maternal plant before they are released.

Volume: Volume is the most widely used measure of wood quantity. The wood volume of a tree includes stem, branches, stump and roots. For standing trees, above-ground volume production is generally calculated as stem wood volume for conifers, but may include branch volume for broad-leaved tree species. Measurements or predictions of wood cubic volume may refer to, for example, total stem volume, v, total tree volume (stem and branches), v_b, or volume above a certain merchantable limit ($d>a$), v_a. Volume estimates may exclude or include bark and, for above-ground estimates, exclude or include stump. Wood cubic volume may be determined by direct or indirect measurement. Direct methods are based on the principle of water displacement or pycnometry (see xylometer), while indirect methods are based on geometry. Indirect methods prevail because these are often more practical. Indirect volume measurement relies on geometrical models of stem, branches, stump and roots and may be carried out for felled as well as for standing trees. In practice, the cubic volume of each segment of a sample tree is calculated from the product of its cross sectional area and length.

Vulnerable: Facing high risk of extinction. See Rare, Endangered and Threatened species.

Wake Zone: The main area of shelter behind a shelterbelt. This is the region in which faster moving air displaced above the trees begins to mix back towards the ground.

Wall-to-wall coverage: Complete spatial mapping of a land area by satellite data.

Washing: Process of removal of dissolved organic and inorganic substances with the use of water.

Watermarks: A localized modification of the formation and opacity of sheet of paper while it is still quite wet, so that a pattern, design, or work groups can be seen in the dried sheet when held up to the light.

Water potential: A measure of the energy that causes water to enter plant cells. There is a net movement of water from a region of high water potential to one of low water potential.

Water repellent: A liquid that penetrates wood which, after drying, materially retards changes in moisture content and in dimensions without adversely altering the desirable properties of wood.

Water-repellent preservative: A water repellent that contains a preservative which, after application to wood and drying, accomplishes the dual purpose of imparting resistance to attack by fungi or insects and also retards changes in moisture content.

Wattle daub: Woven work of sticks intertwined with twigs or branches or bark and covered with plaster, used as sealing between wood members.

Weathering: The mechanical or chemical disintegration and discoloration of the surface of wood caused by exposure to sunlight (ultraviolet light), the action of dust and sand carried by winds, and the alternate shrinking and swelling of the surface fibers with the continual variation in moisture content brought by changes in the weather. Weathering does not include decay.

Wedge system: A modification of the shelterwood-strip system in which cuttings begin as narrow, interior, wedge-shaped strips with the apex into the prevailing wind, and are then successively enlarged and advanced. See Shelterwood system.

Weibull distribution: A probability distribution with density function

$$f(x) = \frac{c}{b^c}(x-a)^{c-1}\exp\left[-\left(\frac{x-a}{b}\right)^c\right]$$

and where a, b, and c are parameters.

Wet deposition: The transfer of atmospheric pollutants from the air to terrestrial ecosystems by rain, fog or snowfall.

Wet end: Part of a paper machine system where fibers are suspended in water.

Wet strength: The ability of paper to retain part of its strength after rewetting.

Wet strength resin: A synthetic material which is incorporated in paper and board to improve its strength when wet.

Wetting: The achievement of intimate molecular level contact when a liquid is deposited on solid surface. Wetting is favorable when liquid/solid adhesive forces are greater than the cohesive forces within the liquid.

Wetting agents: Surface active molecules which are commonly added to aqueous adhesives and which improve wetting (lower the contact angle) by reducing the surface energy of the liquid adhesive. Wetting agents are also known as surfactants or surface active agents because they tend to concentrate at the liquid/air and liquid/solid interfaces.

Wheatfield regeneration: Simultaneous germination of large quantities of seed resulting in a wheatfield-like appearance.

Wildfire: (1) Any unplanned and uncontrolled wildland fire which regardless of ignition source may require suppression response, or other action according to agency policy. (2) Any free burning wildland fire unaffected by fire suppression measures which meets management objectives (cf. wildland, wildland fire, prescribed natural fire, prescribed fire).

Wildland fire: Any fire occurring on wildland regardless of ignition sources, damages or benefits (cf. wildland, wildfire, residential/wildland interface).

Windthrow: Uprooting and blowing down of trees by the wind.

Wireframe: A wireframe model is a 3D computer model that does not have a solid surface, but rather a transparent wire grid is stretched over the surface to indicate its shape. The wire grid shows where the edges of the model are, but the model is not represented as a solid or textured form; linear forms such as trees or towers may be represented as single lines or simple geometric symbols. Modern versions of geometric models may represent solid surfaces with a grid pattern which has a similar abstract, wireframe appearance.

Wood flour: Wood pulverized to finely divided particles, approximately the same as those of cereal flours in size, appearance, and texture and passing a 40 to 100 mesh screen.

Wood gasification: The process of heating wood in an oxygen-starved chamber until volatile pyrolysis gases (e.g., carbon monoxide, hydrogen, and oxygen) are released from the wood. The gases emitted are lower- or medium-energy gases that can be combusted in various ways that include the operation of internal combustion engines.

Wood I-joist: An I-shaped structural member consisting of dimension lumber or laminated veneer lumber flanges and plywood, oriented strand board, or dimension lumber webs.

***Wood nematodes*:** Parasitic nematodes normally survive in roots; however, wood nematodes are unique in surviving in woods and in being mycophagous.

Wood preservation: The treatment of wood, or products made from wood, with biocide-containing systems, or other processes such as heat treatment, to prevent degradation by living organisms or fire.

Wood preservative: The combination of a biocide(s), other inert ingredients, and carrier in a commercial system used to treat wood.

Wood rat middens: Assemblages of plant material collected and amassed by wood rats or other rodents within caves or rocky burrows of arid regions of the American Southwest; these plant materials can generally be dated and identified to provide a record of plants growing in an area with records dating back 40,000 years or more.

Wood ray: See Ray.

Wood-free pulp: A pulp containing no more 5% mechanical woodpulp.

Woodland: Scattered tree formation or simply a small area of forest <25 ha'.

Writing paper: Any grade of paper that is specially sized so that it can be satisfactorily used for pen and ink writing purposes.

***x*:** The basic chromosome number, i.e., the number of different chromosomes that make up a single complete set. For a diploid, x is equal to the number of chromosomes in a gamete.

Xeric: dry.

Xeromorphic: Possessing morphological adaptations for a dry environment.

Xerophilous: Adapted to water deficiency.

Xylem cavitation: Breaks in the water column of the xylem are caused by tension and freezing in the column and are filled with water vapor or air at atmospheric pressure.

Xylometer: Direct volume measurement of irregularly shaped objects, particularly wood samples, is carried out using a xylometer, which is essentially a water tank in which the wood is submerged. The principle of water displacement requires that the xylometer is equipped or used with a suitably graduated volume scale. The cubic volume of wood equals the volume of water and wood minus the volume of water. Pycnometry requires that the wood is weighed before and during submersion, for example on a scale beam or in a sieve bucket. The cubic volume of wood equals the apparent difference in mass.

Yankee dryer: A large diameter, steam-heated pressurized dryer used on a paper machine to produce a glazed finish on one side of the sheet of paper.

Yield table: Table showing timber volume by age for a given species and size index.

Zygomorphic: Bilaterally symmetrical. Capable of being divided into only two equal parts by a line drawn through the middle that results in a mirror image of the part on one side of the line to the part on the other side, e.g., the flower of species of *Lecythis*.

Zygote: The fertilized egg cell that has fused with a pollen nucleus to become the diploid cell from which the seed embryo and ultimately the free-living tree develops.

INDEX

Abbreviations

EFPs – edible forest products
FAO – Food and Agriculture Organization
NWFPs – non-wood forest products
UNCED – United Nations Conference on the Environment (UNCED) (Rio 1992)

Notes

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references – not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of heading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by T and F refer to Tables and Figures respectively. *vs.* indicates a comparison.

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. Prefixes and terms in parentheses are excluded from the initial alphabetization.
